- However, detection of urine crystals is not synonymous with uroliths and clinical signs associated with them, nor is detection of urine crystals irrefutable evidence of a stone-forming tendency.
- Certain crystal types such as cystine, urate, or 2,8-dihydroxyadenine may indicate an underlying disease. Proper identification and interpretation of urine crystals is important in formulation of medical protocols to dissolve uroliths. Evaluation of urine crystals may aid in (1) detection of disorders predisposing animals to urolith formation, (2) estimation of the mineral composition of uroliths, and (3) evaluation of the effectiveness of medical protocols initiated to dissolve or prevent uroliths.
- Crystalluria in individuals with anatomically and functionally normal urinary tracts is usually harmless because the crystals are eliminated before they grow large enough to interfere with normal urinary function.
- However, they represent a risk factor for urolithiasis.
- Crystals that form following elimination or removal of urine from the patient often are of little clinical importance. Identification of crystals that have formed in vitro does not justify therapy. In recent studies following time and temperature changes, crystals formed in 28% of dog and cat samples that were initially free of crystals.
- Detection of some types of crystals (e.g., cystine and ammonium urate) in clinically asymptomatic patients, frequent detection of large aggregates of crystals (e.g., calcium oxalate or magnesium ammonium phosphate) in apparently normal individuals, or detection of any form of crystals in fresh urine collected from patients with confirmed urolithiasis may have diagnostic, prognostic, or therapeutic importance.
- Drug crystals detected in patients being administered high doses of medications such as allopurinol, sulfadiazines, or fluoroquinolones may prompt a change in therapy as they are a risk factor for formation of drug-containing uroliths.

SYSTEMS AFFECTED

Renal/Urologic

SIGNALMENT

- Calcium oxalate in miniature schnauzer, Yorkshire terrier, Lhasa apso, and miniature poodle dogs, and Burmese, Himalayan, and Persian cats.
- Cystine in dachshunds, English bulldogs, Newfoundlands, and others.

- Ammonium urate in Dalmatians and English bulldogs.
- Struvite in any breed of dog with a concomitant urinary tract infection.
- Struvite in cats and ferrets is not typically associated with urinary tract infections.
- Xanthine in Cavalier King Charles spaniels.
- 2,8-dihydroxyadenine in Native American Indian dogs and wolves.

SIGNS

None, or those caused by concomitant urolithiasis.

CAUSES

In Vivo Variables

- Concentration of crystalloidal substances in urine (which in turn is influenced by their rate of excretion and urine concentration of water).
- Urine pH (struvite and calcium phosphate are most common in neutral-to-alkaline urine; ammonium urate, sodium urate, calcium oxalate, cystine, and xanthine crystals are most common in acid-to-neutral urine).
- Solubility of crystalloidal substances in urine.
- Excretion of diagnostic agents (e.g., radiopaque contrast agents) and medications (e.g., sulfonamides).
- Dietary influence—hospital diet may differ from home diet; timing of sample collection (fasting vs. post-prandial) may influence evidence of crystalluria.

In Vitro Variables

- Temperature.
- Evaporation.
- pH changes following sample collection.
- Technique of specimen preparation—centrifugation versus non-centrifugation, volume of urine examined.
- Important in vitro changes that occur following urine collection may enhance formation or dissolution of crystals. When knowledge of in vivo urine crystal type and quantity is especially important, examine fresh specimens, ideally at body temperature. If this is not possible, they should be at room temperature, not refrigeration temperature.
- Collection container—spurious crystals may be contaminants from unclean collection containers.

RISK FACTORS

See preceding discussion about in vivo and in vitro variables in crystalluria.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Ammonium Urate, Sodium Urate, and Amorphous Urate Crystalluria

- Uncommonly observed in apparently healthy dogs and cats.
- Frequently observed in dogs and occasionally observed in cats with portal vascular anomalies, with or without concomitant ammonium urate uroliths.
- Observed in some dogs and cats with urate uroliths caused by disorders other than portal vascular anomalies such as canine breeds

identified as carriers of the hyperuricosuria gene.

Bilirubin Crystalluria

- Observed in highly concentrated urine from some healthy dogs.
- Large numbers in serial samples should arouse suspicion of an abnormality in bilirubin metabolism.
- Usually associated with underlying diseases in cats.

Calcium Oxalate Monohydrate and Calcium Oxalate Dihydrate Crystalluria

- May be observed in apparently healthy dogs and cats and in dogs and cats with uroliths primarily composed of calcium oxalate.
- Calcium oxalate monohydrate crystals are most commonly associated with ethylene glycol toxicity, but calcium oxalate dihydrate may be observed, or ethylene glycol toxicity may also occur without crystalluria.

Calcium Phosphate Crystalluria

- Large numbers of crystals presumed to be composed of calcium phosphate have been observed in apparently healthy dogs, dogs with persistently alkaline urine, dogs with calcium phosphate uroliths, and dogs with uroliths composed of a mixture of calcium phosphate and calcium oxalate.
- Small numbers of calcium phosphate crystals may occur in association with infection-induced struvite crystalluria.
- May be observed in dogs and cats with primary hyperparathyroidism, and renal tubular acidosis.

Cystine Crystalluria

Observed in dogs and cats with inborn errors of metabolism characterized by abnormal transport of cystine and other dibasic aminoacids.

Struvite Crystalluria

- Observed in dogs and cats that are apparently healthy.
- Observed in dogs and cats with infection-induced struvite uroliths, sterile struvite uroliths, non-struvite uroliths, and uroliths of mixed composition (e.g., a nucleus composed of calcium oxalate and a shell composed of struvite).
- Observed in dogs and cats with urinary tract disease without uroliths.

Uric Acid Crystalluria

- Uncommon in dogs and cats.
- Importance as described for ammonium and amorphous urates.

Xanthine Crystalluria

- Suggests administration of excessive dosages of allopurinol in conjunction with consumption of relatively high amounts of dietary purine precursors.
- Primary xanthinuria has been observed in Cavalier King Charles spaniels.
- Primary xanthinuria and xanthine uroliths occur in cats.

Miscellaneous Crystalluria

- Cholesterol crystals—observed in humans with excessive tissue destruction, nephrotic

(CONTINUED)

CRYSTALLURIA

C

- syndrome, and chyluria; observed in apparently healthy dogs. • Hippuric acid crystals—apparently rare in dogs and cats; importance unknown. • Leucine crystals in dogs—importance not determined; may occur in association with cystinuria. • Tyrosine crystals—occur in association with severe liver disease in humans; uncommonly observed in dogs and cats with liver disorders. Sodium urate needle-like appearance commonly misinterpreted as tyrosine needles. • 2,8-dihydroxyadenine- is a genetic disorder, the result of a metabolic abnormality due to the deficiency of the enzyme, adenine phosphoribosyl transferase (APRT).

Drug-Induced Crystalluria

- May be observed following administration of radiopaque contrast agents. • May be observed following treatment with sulfadiazine, fluoroquinolones, primidone, xanthine oxidase inhibitors, and tetracycline.

LABORATORY FINDINGS**Drugs That May Alter Laboratory Results**

- Urinary acidifiers (e.g., *d,l*-methionine and ammonium chloride). • Urinary alkalinizers (e.g., sodium bicarbonate and potassium citrate). • Phenothiazines and phenazopyridine may cause red or orange urine.

Disorders That May Alter Laboratory Results

N/A

Valid if Run in Human Laboratory?

Yes

CBC/BIOCHEMISTRY/URINALYSIS

- Bilirubin crystals may be associated with bilirubinemia and other laboratory abnormalities of hepatic disorders. • Most dogs and cats with calcium oxalate and calcium phosphate crystalluria are normocalcemic; some are hypercalcemic.
- Some dogs and cats with calcium oxalate crystalluria may be acidemic. • Serially examine fresh specimens when knowledge of in vivo urine crystal type is especially important; evaluate the number, size, and structure of crystals and their tendency to aggregate. • Microscopic evaluation of the appearance of urine crystals gives only a tentative indication of their composition; variable conditions associated with their formation, growth, and dissolution may alter their appearance. Definitive identification of crystal composition depends on one or more of these techniques: optical crystallography, infrared spectroscopy, X-ray diffraction, and electron microprobe analysis.

OTHER LABORATORY TESTS

- Cystine crystalluria is usually associated with a positive urine cyanide-nitroprusside reaction. • Sulfonamide crystalluria may be associated with a positive lignin test.
- Ammonium urate and amorphous urate crystals are insoluble in acetic acid; addition of 10% acetic acid to urine sediment containing these crystals often yields uric acid and sometimes sodium urate crystals. • Most dogs and a few cats with struvite crystalluria have urinary tract infections caused by urease-producing bacteria (especially staphylococci and sometimes *Proteus* spp.).
- Dogs and cats with ammonium urate crystalluria and portosystemic shunts often have high serum bile acid levels and hyperammonemia. • Dogs and cats with calcium oxalate crystalluria secondary to ethylene glycol poisoning have detectable levels of ethylene glycol in serum and urine up to 48 hours after ingestion. • Cystine crystals may be confused with struvite crystals. Cystine crystals are insoluble in acetic acid while struvite crystals are soluble. A urine nitroprusside test is positive for cystine.

IMAGING

Crystalluria may be associated with radiographically or ultrasonographically detectable uroliths.

DIAGNOSTIC PROCEDURES

Voiding urohydropropulsion or aspiration through a transurethral catheter to retrieve small urocystoliths.

**TREATMENT**

- Manage clinically important in vivo crystalluria by eliminating or controlling the underlying cause(s) or associated risk factors.
- Minimize clinically important crystalluria by increasing urine volume, encouraging complete and frequent voiding, modifying the diet, by appropriate drug therapy, and in some instances by modifying pH.

**MEDICATIONS****DRUG(S) OF CHOICE**

N/A

PRECAUTIONS

N/A

ALTERNATIVE DRUG(S)

N/A

**FOLLOW-UP****PATIENT MONITORING**

- Recheck urinalysis to determine if crystalluria is persistent. • See chapters on specific urolith types for monitoring urolithiasis.

POSSIBLE COMPLICATIONS

- Persistent crystalluria may contribute to formation and growth of uroliths.
- Crystalluria may solidify crystalline-matrix plugs, resulting in urethral obstruction.

CUTANEOUS DRUG ERUPTIONS

BASICS

OVERVIEW

- A wide spectrum of diseases and clinical signs that vary markedly in clinical appearance.
- Many mild drug eruptions may go unnoticed or unreported; incidence rates for specific drugs are unknown.

SIGNALMENT

- Dogs and cats.
- Age, breed, and sex predispositions—largely unknown.
- Some types of drug eruptions appear to have a familial basis (e.g., rabies vaccine reactions in canine littermates).

SIGNS

- Pruritus—can be activated by a wide variety of compounds.
- Macular and papular rashes—commonly accompany pruritus as a non-specific sign of inflammation.
- Exfoliative erythroderma—a diffuse erythematous response caused by vasodilation; often leads to exfoliation (diffuse scaling).
- Urticaria/angioedema—results from an immediate (type I) hypersensitivity; requires prior sensitization; increased vascular permeability leads to fluid leakage into the interstitium.
- Hypersensitivity vasculitis— inflammation of cutaneous vasculature; results in poor blood flow and anoxic injury to recipient tissue; in most cases, thought to represent a type III hypersensitivity response.
- Eosinophilic dermatitis with edema (Wells'-like syndrome) of dogs—deeply erythematous plaques or macules (may be targetoid) that may be accompanied by marked edema; localized, regional, or generalized distribution; clinical appearance of lesions may be indistinguishable from vasculitis and erythema multiforme.
- Erythema multiforme—erythematous macules or plaques expand peripherally and may clear in the center (targetoid); multiple shapes/forms noted.
- Stevens-Johnson syndrome—similar to toxic epidermal necrolysis with less extensive epidermal detachment (< 30%) and often involvement of the oral mucosa.
- TEN—extensive (> 30%) necrosis and sloughing of the epidermis in sheets; results in a moist and intensely inflamed skin surface.
- Drug-induced pemphigus/pemphigoid—least common drug reaction in animals; can closely mimic the auto-immune (spontaneous) forms of these diseases; symptoms may persist after drug withdrawal.

CAUSES & RISK FACTORS

- Drugs of any type.
- Can occur after the first dose or after weeks to months of administration of the same drug.
- Exfoliative erythroderma—most often associated with shampoos and dips; also commonly seen with reactions to topical ear medications (in ear

canals and on concave pinnae).

- Eosinophilic dermatitis with edema—strong association with concurrent acute gastrointestinal disease and use of antidiarrheal and/or antiemetic drugs.
- Temporal association in dogs between application of metaflumizone (Promeris) and onset of pemphigus foliaceus.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Pruritus, macular/papular rashes, and urticaria/angioedema—allergic and parasitic diseases (e.g., atopy, adverse reactions to foods, contact hypersensitivity, flea bite hypersensitivity, scabies, stinging insects).
- Exfoliative erythroderma—epitheliotropic lymphoma in old dogs and cats.
- Vasculitis—once confirmed by biopsy: rule out infectious, neoplastic, and auto-immune diseases for cause; many cases of vasculitis are idiopathic.
- EM/SJS/TEN—rule out respiratory infections, herpes virus, parvovirus, bacterial infection (non-cutaneous) and internal neoplasia; an idiopathic/chronic form of EM occurs in older adult dogs.
- Pemphigus/pemphigoid—consider drug reaction whenever these diseases are diagnosed; however, spontaneously occurring auto-immune disease is much more common.

CBC/BIOCHEMISTRY/URINALYSIS

Potential for concurrent hepatic, renal, and gastrointestinal disease with concurrent vasculitis.

OTHER LABORATORY TESTS

- Dogs with vasculitis—rickettsial serology.
- Cats with vasculitis—FIV and FeLV serology, and tests to rule out FIP.
- Both dogs and cats—bacterial and fungal cultures when vasculitis with pyogranulomatous inflammation is diagnosed.

DIAGNOSTIC PROCEDURES

Skin biopsy for histopathology—mandatory for diagnosis of most drug-induced diseases (vasculitis, EM, TEN, eosinophilic dermatitis, pemphigus/pemphigoid).

PATHOLOGIC FINDINGS

Determined by specific disease process

TREATMENT

- Discontinue use of the offending or suspect drug.
- SJS/TEN—intensive supportive care and fluid/nutritional support because of fluid and protein exudation and risk of sepsis.
- Pain relief when indicated; however, minimal drug use recommended when drug eruption is suspected.
- For chronic/persistent idiopathic EM, azathioprine or cyclosporine may be effective.

MEDICATIONS

DRUG(S)

Most conditions respond to immunosuppressive therapy if withdrawal of the offending drug alone is insufficient (controversial in the case of SJS/TEN due to risk for sepsis).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Avoid the offending drug or any other drug in the same class or family.

FOLLOW-UP

PATIENT MONITORING

- Inpatient—if debilitated.
- Outpatient—regular rechecks, depending on physical condition.

PREVENTION/AVOIDANCE

See "Contraindications/Possible Interactions"

POSSIBLE COMPLICATIONS

- Secondary infections
- Electrolyte and plasma protein depletion (SJS/TEN)

EXPECTED COURSE AND PROGNOSIS

- Some reactions appear to activate self-perpetuating immune responses.
- Some drug metabolites may persist for days to weeks and provoke a continued response.
- TEN—prognosis poor.
- Vasculitis—prognosis guarded when there are systemic complications.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Cutaneous vasculitis—arthropathy, hepatitis, glomerulonephritis, and neuromuscular disorders, among others.

SEE ALSO

- Pemphigus
- Vasculitis, Cutaneous

BASICS

OVERVIEW

- Flies of the genus *Cuterebra* are found in the Americas, where they are obligatory parasites of rodents and lagomorphs. Adult flies lay eggs on blades of grass or in nests, and they hatch and crawl onto the skin of the passing host. The small maggots enter a body orifice, migrate through various internal tissues, and, ultimately, make their way to the skin, where they establish a warble. The mature maggots, which may be an inch long, then drop out of the rodent or rabbit host and then pupate in the soil.
- Dogs and cats become infected when they walk past a blade of grass with an egg containing an infective maggot that is stimulated to hatch and to jump onto the passing animal. The maggots then crawl around on the cat or dog until they find an orifice in which to enter.
- Dogs and cats can develop maggots in warbles or can develop signs associated with the larvae migrating within their tissues.
- Dogs and cats can present with respiratory signs, neurologic signs, ophthalmic lesions, or maggots in their skin.

SIGNALMENT

- Dogs and cats—all ages.
- In northern United States, most cases occur in late summer and early autumn based on the time of emergence of the adult egg-laying females in spring and early summer.

SIGNS

- Dermatologic—warble containing bot with protruding spiracles.
- Neurologic—ataxia, circling, paralysis, blindness, recumbency.
- Ophthalmic lesions—larva in conjunctiva.
- Respiratory—eosinophilic respiratory disease.

CAUSES & RISK FACTORS

- Dogs and cats with access to outdoors, where they contact the eggs and larvae.
- Neonatal cats have been infected, presumably with larvae being brought home on the queen's fur.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Respiratory—allergies, lungworms, migrating ascarids, or hookworms.
- Neurologic—rabies, distemper, angiostrongylosis.
- Ophthalmic lesions—larval *Hypoderma* or *Oestrus*.
- Dermatologic—mature warble unmistakable, young warble may present as a pustule or papule.

CBC/BIOCHEMISTRY/URINALYSIS

May have elevated eosinophils

OTHER LABORATORY TESTS

N/A

IMAGING

CT scan has shown lesions in cranial images of cats

DIAGNOSTIC PROCEDURES

N/A

TREATMENT

- Can remove maggots from subcutaneous lesions, eyes, or nares.
- Manifestations of lung migration may be alleviated by corticosteroids.
- Neurologic disease may have a poor prognosis; euthanasia is an option.

MEDICATIONS

DRUG(S)

Ivermectin 0.2 mg/kg SC should kill migrating maggots; may want to begin corticosteroid treatment before administering the ivermectin. The ivermectin can be administered either to alleviate the signs caused by maggots suspected of migrating in the lungs or to kill larvae in other tissues, including the CNS.

FOLLOW-UP

Good return of function following ivermectin treatment possible

MISCELLANEOUS

- In northern United States, disease is very seasonal, with most cases occurring in late summer and early fall when the adult flies are active. Seasonality is less demarcated in areas where warmer temperatures and active flies occur through longer periods of the year.
- Does not seem to be any prolonged immunity; the same cat can develop skin lesions several years in a row.
- Application of monthly heartworm preventatives (ivermectin-containing products), flea development control products (lufenuron-containing products), or topical flea and tick treatments may prevent the maggots from either developing in the dog or cat, or may kill them before they have time to gain access to an orifice for entry. However, based on anecdotal information, some cats and dogs on these products still develop warbles with maggots.

ZOONOTIC POTENTIAL

The maggots in the dog or cat pose no zoonotic threat.

ABBREVIATIONS

- CNS = central nervous system
- CT = computed tomography

CYANOSIS

BASICS

DEFINITION

A bluish discoloration of the skin and mucous membranes owing to an increase in the amount of reduced, or deoxygenated, hemoglobin within the blood.

PATHOPHYSIOLOGY

- Concentration of deoxygenated hemoglobin—must be > 5 g/dL to detect condition; thus anemia (PCV < 15%) may obscure recognition of cyanosis.
- Central—associated with systemic arterial hypoxemia or hemoglobin abnormalities.
- Peripheral—limited to one or more extremities of the body; associated with diminished peripheral blood flow; arterial oxygen tension and saturation typically normal.

Arterial Hypoxemia

- Decreased fraction of inspired oxygen—high altitude. • Hypoventilation—upper airway obstructive disorders; restrictive or obstructive lung diseases; pleural space disorders; neuromuscular failure.
- Ventilation-perfusion mismatching—pulmonary parenchymal or thromboembolic diseases. • Diffusion impairment—thickening of the alveolar barrier through which oxygen must pass to reach the RBCs. • Addition of venous blood to the arterial circulation—congenital right-to-left shunting cardiac defects (e.g., tetralogy of Fallot, transposition of the great vessels); reversed shunting cardiac defects caused by high pulmonary vascular resistance (e.g., right-to-left shunting PDA, ASD, VSD). • Anatomic shunts—distinguished from other causes of hypoxemia by the failure to respond to supplemental oxygen.

Abnormal Hemoglobin

- Methemoglobin—most common abnormal heme pigment; unable to bind oxygen; normally formed at a low rate in erythrocytes.
- NADH-MR—intracellular reductive enzyme; maintains the methemoglobin: hemoglobin ratio at $< 2\%$; deficiency and/or exposure to oxidizing agents causes methemoglobinemia. • Hypoxia—when $> 20\text{--}40\%$ of hemoglobin has been oxidized to methemoglobin.

Other

- Peripheral cyanosis—results from increased oxygen extraction from the arterial supply to an area (e.g., a limb); caused by severe vasoconstriction, poor peripheral blood flow, obstruction to flow associated with arterial thromboembolism, or stagnation or obstruction of venous blood flow.
- Differential cyanosis—with reverse shunting PDA, the head and neck receive oxygenated blood via the brachiocephalic trunk and left subclavian artery, which arise from the aortic

arch; the rest of the body receives desaturated blood through the ductus located in the descending aorta.

SYSTEMS AFFECTED

- Central—all systems affected.
- Peripheral—may diminish or abolish neuromuscular function of the affected limb(s).

SIGNALMENT

- Right-to-left cardiac shunts in association with high pulmonary vascular resistance and pulmonary hypertension (Eisenmenger physiology)—dogs: Keeshonden, English bulldogs, and beagles; some cats; generally young animals. • Tracheal collapse—usually young or middle-aged small-breed dogs (e.g., Pomeranians, Yorkshire terriers, poodles).
- Congenital laryngeal paralysis—young animals; reported in Dalmatians, Bouvier des Flandres, and Siberian huskies. • Acquired laryngeal paralysis—most common in old large-breed dogs (e.g., retrievers).
- Hypoplastic trachea—identified in young English bulldogs; occasionally other breeds.
- Brachycephalic airway syndrome—dogs: English and French bulldogs, Pekinese, Pugs; cats: Himalayan, Persian. • Asthma (cats)—higher incidence reported in Siamese.

SIGNS

Historical Findings

- Central—stridor; respiratory distress; cough; voice change; episodic weakness; syncope; exposure to oxidizing substances or drugs causing methemoglobinemia.
- Peripheral—limb paresis or paralysis.

Physical Examination Findings

- Heart murmur or splitting of the second heart sound—with cardiac disease or pulmonary hypertension. • Pulmonary crackles or wheezes—with pulmonary edema or respiratory disease. • Muffled heart sounds—owing to pleural space or pericardial disease. • Upper airway stridor with laryngeal paralysis. • Honking cough—typical of tracheal collapse; often induced by tracheal palpation. • Dyspnea—may be inspiratory, expiratory, or a combination (see “Differential Diagnosis”). • Limbs—may be cyanotic, cool, pale, painful, and edematous; can lack a pulse in conditions causing peripheral cyanosis.
- Weakness—can be generalized and persistent with severe cardiac diseases; can be episodic and especially noticeable with exercise or excitement. • Posterior paresis or paralysis—can be seen with distal aorta arterial thromboembolism; differentiated from primary neuromuscular disease by absence (or near absence) of pulses.

CAUSES

Respiratory System

- Larynx—paralysis (acquired or congenital); collapse; spasm; edema; trauma; neoplasia; granulomatous disease. • Trachea—collapse; neoplasia; foreign body; trauma; hypoplasia.

- Lower airway and parenchyma—pneumonia (viral, bacterial, fungal, eosinophilic, mycobacteria, aspiration); chronic bronchitis; hypersensitivity bronchial disease or asthma; bronchiectasis; neoplasia; foreign body; parasites (*Filaroides*, *Paragonimus*, *Pneumocystis jiroveci*, toxoplasmosis, *Aelurostrongylus* spp.); pulmonary contusion or hemorrhage; non-cardiogenic edema (inhalation, snake bite, electric shock); near drowning. • Pleural space—pneumothorax; infectious (bacterial, fungal, FIP); chylothorax; hemothorax; neoplasia; trauma.
- Thoracic wall or diaphragm—congenital (pericardial, diaphragmatic hernia); trauma (diaphragmatic hernia, fractured ribs, flail chest); neuromuscular disease (tick bite paralysis, coonhound paralysis).

Cardiovascular System

- Congenital defects—Eisenmenger physiology (right-to-left shunting PDA, VSD, ASD); tetralogy of Fallot; truncus arteriosus; double outlet right ventricle; anomalous pulmonary venous return; atresia of aortic or tricuspid or pulmonary valves. • Acquired disease—mitral valve disease; cardiomyopathy.
- Pericardial effusion—idiopathic disease; neoplasia. • Pulmonary thromboembolic disease—hyperadrenocorticism; immune-mediated hemolytic anemia; protein-losing nephropathy; dirofilariasis.
- Pulmonary hypertension—idiopathic; right-to-left cardiac shunts. • Peripheral vascular disease—arterial thromboembolism (feline cardiomyopathies); venous obstruction; reduced cardiac output; shock, arteriolar constriction.

Neuromusculoskeletal System

- Brainstem dysfunction—encephalitis; trauma; hemorrhage; neoplasia; drug-induced depression of respiratory center (morphine, barbiturates). • Spinal cord dysfunction—edema; trauma; vertebral fractures; disk prolapse. • Neuromuscular dysfunction—overdose of paralytic agents (succinylcholine, pancuronium); tick bite paralysis; botulism; acute polyradiculoneuritis (coonhound paralysis); dysautonomia; myasthenia gravis.

Methemoglobinemia

- Congenital—NADH-MR deficiency (dogs). • Ingestion of oxidant chemicals—acetaminophen; nitrates; nitrites; phenacetin; sulfonamides; benzocaine; aniline dyes; dapsone.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Generalized—systemic hypoxemia or heme abnormality. • Peripheral only—reduced blood flow to extremities. • Caudal

(CONTINUED)

CYANOSIS

C

- body—right-to-left shunting PDA. • Cardiac versus respiratory causes—differentiation can be difficult; cardiac murmur may suggest cardiac disease but murmurs are often heard in older patients with primary respiratory disease; thoracic radiography and echocardiography useful for differentiation.
- Central or peripheral neurologic signs—should prompt concern of arterial hypoxemia owing to primary neuromuscular disease.

Breathing Pattern

- May help define cause. • Inspiratory effort—often associated with obstructive upper airway or pleural space disease; stridor frequently localizes problem to the larynx or cervical trachea. • Expiratory effort—generally seen with obstructive lower airway disease. • Rapid shallow (restrictive)—may be associated with pleural space disease or neuromuscular abnormalities of the thoracic wall.

CBC/BIOCHEMISTRY/URINALYSIS

- Color of blood—may be darkened; chocolate brown with methemoglobinemia.
- Polycythemia—often accompanies congenital heart disease; may occur with chronic hypoxemia owing to severe respiratory disease. • Proteinuria—accompanies protein-losing nephropathies, which may result in secondary pulmonary thromboembolism. • Panhypoproteinemia—accompanies protein-losing enteropathies, which may lead to pulmonary thromboembolism.

OTHER LABORATORY TESTS

- Methemoglobin concentrations—measure through a laboratory; alternatively, shake a blood sample in air 15 minutes: red, reduced hemoglobin with cardiac or respiratory disease; chocolate brown, methemoglobin.
- Arterial blood gas analysis. • Urine protein:creatinine ratio—with suspected pulmonary thromboembolism secondary to a protein-losing nephropathy.

IMAGING

- Radiography—essential for determining cause. • Echocardiography with Doppler—aids in diagnosis of congenital or acquired cardiac disease, pulmonary hypertension, and pulmonary thromboembolism. • Computed tomography—can further define obstructive nasal, pulmonary or pleural space disease.

DIAGNOSTIC PROCEDURES

- Pulse oximetry—determine oxygen saturation. • Laryngoscopic examination—evaluate laryngeal structure and arytenoid function. • Bronchoscopy—often useful in the diagnosis of airway and pulmonary diseases. • Transtracheal wash, bronchoalveolar lavage, or fine-needle lung aspirate—often required to characterize bronchopulmonary diseases.

- Thoracocentesis—required for diagnosis and treatment of pleural space disorders.
- Electrocardiography—may reveal heart enlargement changes; unreliable; echocardiography better. • Lung biopsy—can be necessary for diagnosis of interstitial lung disease.

**TREATMENT**

- Inpatient—immediate diagnostic testing and treatment. • Stabilization therapy (e.g., oxygen, thoracocentesis, tracheostomy)—usually instituted before aggressive diagnostics. • Specific therapy—depends on the ultimate diagnosis; usually exercise restriction and dietary modification required.
- Surgical treatment—depends on primary disease process and the extent of cardiac or respiratory involvement. • Warn client when admitting the patient that diseases associated with cyanosis can have dire outcomes.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Oxygen therapy—provide as soon as possible.
- Additional drug therapy depends on final diagnosis.
- Furosemide—aggressive use indicated with suspected cardiogenic pulmonary edema.
- Methemoglobinemia as a result of ingestion of oxidizing substances (acetaminophen)—give acetylcysteine as soon as possible (140 mg/kg PO or IV; then 70 mg/kg q4h for five treatments); cimetidine (10 mg/kg PO; then 5 mg/kg PO q6h for 48 hours) is a useful adjunct to acetylcysteine; ascorbic acid (30 mg/kg PO q6h for seven treatments) may be of some value but do not use as the sole agent.
- Sildenafil citrate—phosphodiesterase type 5 inhibitor used to treat pulmonary arterial hypertension at 1–3 mg/kg PO q8–12h.

CONTRAINDICATIONS

Avoid using paralytic agents (succinylcholine, pancuronium) and agents that cause profound depression of the respiratory center (morphine, barbiturates).

**FOLLOW-UP****PATIENT MONITORING**

- Patients in an oxygen cage should be disturbed as infrequently as possible for monitoring. • Assess efficacy of therapy—changes in depth and rate of respiration; color of mucous membranes (should return to a

normal pink color if the cause is not an anatomic shunt and patient has adequate reserves); pulse oximetry or arterial blood analysis. • Instruct client to monitor mucous membrane color and respiratory effort and advise immediate veterinary care if cyanotic condition returns.

POSSIBLE COMPLICATIONS

Advanced pulmonary or airway disease and severe cardiac disease—poor long-term prognosis.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- Obesity—can complicate or exacerbate underlying respiratory or cardiac diseases.
- Ascites—can complicate or exacerbate respiratory effort and reduce lung capacity due to cranial displacement of diaphragm.

AGE-RELATED FACTORS

Congenital cardiac abnormalities—usually the cause in young patients.

PREGNANCY/FERTILITY/BREEDING

- Advanced pregnancy may exacerbate signs because of pressure on the diaphragm and reduced lung expansion. • Fetuses are likely to be harmed or aborted by hypoxemia associated with cyanosis.

SEE ALSO

- Dyspnea and Respiratory Distress • Panting and Tachypnea • Stertor and Stridor

ABBREVIATIONS

CYCIC HEMATOPOIESIS

BASICS

OVERVIEW

- Cyclic hematopoiesis in color-dilute gray collie pups is characterized by frequent episodes of infection with failure to thrive and early death. Systems affected are hematopoietic, respiratory, gastrointestinal, and skin. Clinically, the pups may appear normal for the first 4–6 weeks and then develop diarrhea, conjunctivitis, gingivitis, pneumonia, skin infections, carpal joint pain, and fever. A frequent cause of death is intussusception of the small intestine.
- Episodes of illness, varying from inactivity accompanied by fever to life-threatening infection, repeat at 11- to 14-day intervals.
- The gray pups are usually smaller than their litter mates at birth, weak, and often pushed aside by the bitch.
- Cyclic hematopoiesis has been observed in many collie bloodlines in the United States and in other countries.
- Cyclic hematopoiesis has also been reported in two cats with FeLV infection.

SIGNALMENT

- Cyclic hematopoiesis in the collie breed is present only in the color-dilute pups. The color dilution and bone marrow disorder are inherited as an autosomal recessive trait (presumably the same gene). The bone marrow disorder and color dilution have been present in crossbred collie/beagle pups.
- Clinical signs occur as early as 1–2 weeks of age and are always apparent by 4–6 weeks of age.
- An apparently similar disease was reported in normal-colored pups in two border collie litters in the UK. Single cases of cyclic hematopoiesis have been reported in Pomeranians and cocker spaniels; the disease is not well characterized in these breeds.
- Cyclic hematopoiesis observed in the two cats appears to be another possible non-neoplastic manifestation of FeLV infection.

SIGNS

Historical Findings

- Weakness
- Failure to thrive
- Conjunctivitis
- Gingivitis
- Diarrhea
- Pneumonia
- Skin infections
- Carpal joint pain

Physical Examination Findings

- Dilute coat color with color dilution of nasal epithelium.
- Smaller and weaker than normal-colored littermates.
- Fever.
- Watery eyes, reddened gums, tonsillitis, and diarrhea nearly always present during the phase of the hematopoietic cycle when clinical signs are evident; other signs vary depending on the site of sepsis.
- Painful carpal joints observed during the initial recovery phase of the disease cycle.
- Signs and symptoms of FeLV in cats.

CAUSES & RISK FACTORS

- Inherited disease in purebred or crossbred collie dogs.
- FeLV infection, cats.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Coat color dilution pathognomonic for the disease in collies or collie mixed breeds.
- Color dilution not associated with cyclic hematopoiesis also observed in collie pups. However, the pups are normal size, do not develop frequent episodes of infection, may attain normal coat color intensity by 6 months of age, normal color intensity on the nose.
- Collie pups with cyclic hematopoiesis always have nasal epithelial color dilution.
- Cats will present with signs and symptoms consistent with FeLV infection.

CBC/BIOCHEMISTRY/URINALYSIS

- Severe neutropenia, lasting 2–5 days and occurring at 11- to 14-day intervals with marginal normocytic to microcytic anemia in dogs; slight to moderate normocytic or macrocytic anemia in cats.
- Important to recognize that signs of infection are often minimal during the neutropenic episodes.
- Local swelling, redness, and systemic signs of infection usually occur during the first days of the neutrophilic phase of the disease cycle; therefore, on initial CBC examination, neutrophilia with moderate monocytosis is observed.
- CBC should be repeated at 1- to 2-day intervals to confirm the diagnosis.

TREATMENT

- Advise clients not to attempt to raise the pup(s).
- Antibiotics and supportive therapy may extend the life of the pups for several years but at considerable cost.

MEDICATIONS

DRUG(S)

Antibiotics and fluids as required for infections.

FOLLOW-UP

PATIENT MONITORING

Owner advised to watch for signs of infection.

PREVENTION/AVOIDANCE

Dogs should not be boarded.

POSSIBLE COMPLICATIONS

Respiratory infection can be life threatening if untreated.

EXPECTED COURSE AND PROGNOSIS

Intermittent infections are expected. Prognosis is guarded.

MISCELLANEOUS

PREGNANCY/FERTILITY/BREEDING

Carriers or affected collies should not be bred.

SEE ALSO

Neutropenia

ABBREVIATION

FeLV = feline leukemia virus

Acknowledgment The author and editors acknowledge the prior contribution of Drs. John E. Lund and Peter MacWilliams.

CYLINDRURIA

BASICS

OVERVIEW

- Abnormally high number of casts ($> 2-3$ casts/lpf) in urine sediment. May develop in dogs or cats with primary kidney disease or systemic disorders that secondarily affect the kidneys.
- High numbers of casts indicate accelerated renal cellular degeneration, glomerular leakage of protein, hemorrhage, or exudation into renal tubular lumens.

SYSTEMS AFFECTED

Renal/Urologic

SIGNALMENT

Dog and cat

CAUSES & RISK FACTORS

Nephrotoxicosis

- Toxins—ethylene glycol, grape/raisin ingestion (dogs), lily ingestion (cats), hypercalcemia
- Nephrotoxic drugs—aminoglycosides, intravenously administered tetracycline, amphotericin B, cisplatin, nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors
- Diagnostic agents—intravenously administered radiocontrast agents

Renal Ischemia (Anoxia)

- Dehydration
- Low cardiac output—congestive heart failure, cardiac arrhythmia, or pericardial disease
- Renal vessel thrombosis—emboli from bacterial endocarditis or DIC
- Hemoglobinuria—intravascular hemolysis
- Myoglobinuria—rhabdomyolysis

Renal Inflammation

Infectious diseases (e.g., pyelonephritis, leptospirosis, feline infectious peritonitis, Rocky Mountain spotted fever, or ehrlichiosis)

Glomerular Disease

- Glomerulonephritis
- Amyloidosis

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- History of potential exposure to toxins or nephrotoxic drugs—rule out acute tubular necrosis.
- Recent onset of vomiting or diarrhea—rule out renal ischemia caused by dehydration.
- Recent inhalational anesthesia—rule out tubular necrosis caused by ischemia.
- Potential for exposure to infectious diseases—rule out nephritis.
- Fever—rule out infectious, inflammatory, and neoplastic disease.
- Cardiac murmur, especially if diastolic and of recent onset—rule out bacterial endocarditis.
- Petechiae and ecchymoses—rule out systemic thrombosis.
- Cylindruria plus azotemia and adequately concentrated urine (specific gravity 1.030 in dogs and 1.040 in

cats)—consider prerenal disorders such as dehydration.

- Cylindruria plus azotemia and inadequately concentrated urine (specific gravity < 1.030 in dogs and < 1.040 in cats)—consider kidney failure.
- Cylindruria plus leukocytosis—consider infectious and inflammatory disorders.
- Cylindruria plus thrombocytopenia—consider DIC.
- Cylindruria plus glucosuria and proteinuria—consider renal tubular necrosis.

LABORATORY FINDINGS

Disorders That May Alter Laboratory Results

- Waiting longer than 2 hours to perform urinalysis may result in disappearance of casts.
- Alkaline urine causes dissolution of casts.
- Dilute urine (specific gravity < 1.003) causes dissolution of casts; interpret numbers of casts in light of urine specific gravity.

Valid if Run in Human Laboratory?

Yes

CBC/BIOCHEMISTRY/URINALYSIS

- Epithelial, granular, and/or waxy casts indicate diseases that cause degeneration and necrosis of renal tubular epithelial cells.
- RBC casts indicate severe glomerular disease or hemorrhage into renal tubules.
- WBC casts indicate renal inflammation, most often caused by pyelonephritis; however, most patients with pyelonephritis do not have WBC casts.
- Hyaline casts—associated with disorders that cause proteinuria; also may be observed during diuresis and after dehydration.
- Anemia, hemoconcentration, leukocytosis, or thrombocytopenia in some patients.
- High serum concentrations of urea nitrogen, creatinine, and phosphorus in patients with dehydration or kidney disease.

OTHER LABORATORY TESTS

- If the patient has thrombocytopenia or RBC casts, perform coagulation studies (e.g., PTT, PT, FDP, D-dimers) to rule out consumptive coagulopathy such as DIC.
- If the patient has proteinuria, determine urine protein:creatinine ratio to evaluate magnitude of proteinuria.
- If the patient has pyuria or WBC casts, perform urine culture to rule out urinary tract infection.
- If systemic infectious diseases are suspected, submit serum for appropriate titers.

DIAGNOSTIC PROCEDURES

Consider renal biopsy if kidney disease persists or progresses and the cause cannot be determined from routine diagnostic tests.

TREATMENT

- Manage as an outpatient unless the patient is dehydrated or has decompensated kidney failure.
- If the patient is healthy otherwise, feed normal food and allow normal exercise.
- If there is chronic kidney disease and creatinine remains > 2 mg/dL, recommend a

therapeutic renal diet to improve survival time and quality of life.

- If the patient cannot maintain hydration, administer lactated Ringer's solution or a maintenance fluid either intravenously or subcutaneously.
- If the patient has dehydration or continuing fluid losses such as vomiting or diarrhea, administer fluids intravenously to correct hydration deficits, maintain daily fluid requirements, and replace ongoing losses.

MEDICATIONS

CONTRAINDICATIONS

Avoid nephrotoxic drugs.

FOLLOW-UP

PATIENT MONITORING

Physical examination including patient's weight to assess hydration status.

PREVENTION/AVOIDANCE

Avoid or correct risk factors that predispose to development of exposure of kidneys to toxins and/or renal anoxia.

POSSIBLE COMPLICATIONS

Permanent kidney disease depending on underlying cause of cylindruria.

MISCELLANEOUS

ZOONOTIC POTENTIAL

Possible in patients with leptospirosis. Avoid direct contact with infected urine in these

CYSTICERCOSIS

BASICS

OVERVIEW

- Rare disease of dogs caused by the larvae of *Taenia crassiceps*, the adults of which are found in foxes, coyotes, and sometimes domestic dogs, and *Taenia solium*, the adults of which are found in humans.
- In the case of *T. crassiceps*, eggs shed by foxes are consumed by rabbits or other rodents, where they develop into a cysticercal stage in the abdominal and subcutaneous tissues. The cysticercus of *T. crassiceps* is capable of undergoing asexual multiplication, so very large numbers of cysticerci can develop in the tissues of the intermediate hosts. Dogs have been infected with the cysticercal stage and have developed large masses of cysticerci in the abdominal cavity, lungs, muscles, and subcutaneous tissues. Rare cases reported from Europe and the United States.
- In the case of *T. solium*, eggs shed by people are consumed by pigs, where they develop into a solitary cysticercal stage in muscles and neural tissues. Most common in countries where the infection is endemic, but rare cases of neurologic disease have been reported in the United States, most often in dogs that have traveled to endemic areas such as parts of Latin America.

SIGNALMENT

Dogs, older dogs, and young immunocompromised animals

SIGNS

- T. crassiceps*: Subcutaneous masses. Signs associated with masses in other organs—respiratory insufficiency (lungs), pericardial effusion and circulatory collapse (pericardium), icterus (abdominal cavity) pale mucous membranes (anemia) and anorexia.
- T. solium*: Neurologic signs.

CAUSES & RISK FACTORS

- T. crassiceps*: Mode of infection not clear, but three hypothesized: (1) Ingestion of parasite eggs (probably in feces of infected fox); (2) Autoinfection with eggs from an intestinal infection with the adult stages; (3) Ingestion of cysticercal stage.
- T. solium*: Ingestion of eggs (from feces of infected human).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Larval *Mesocestoides* spp. infection
- Neoplasia, especially in older animals

CBC/BIOCHEMISTRY/URINALYSIS

Anemia of chronic disease

OTHER LABORATORY TESTS

N/A

IMAGING

- Radiographs—determine degree of spread to internal organs; *T. solium* typically diagnosed as cyst-like lesions in the brain seen on radiographs.
- Ultrasound—delineates cystic nature of mass (in cutaneous or abdominal cavity) as opposed to solid mass of a neoplasm.
- Ultrasound and computed tomography have identified cysticerci of *T. solium* in dogs.

DIAGNOSTIC PROCEDURES

- Aspirate cytology
- Surgical biopsy

TREATMENT

- Inpatient if debilitated.
- Treat signs as needed.
- Surgically remove, through biopsy or laparotomy, as many organisms as possible.

MEDICATIONS

DRUG(S)

- Praziquantel 5 mg/kg PO, initially, then progressively increase dose over several weeks to 50 mg/kg if appears tolerated. Concern is that dog may react to dying cysticerci.
- Albendazole 50 mg/kg PO q24h for 10–20 days after the termination of praziquantel therapy may aid in preventing recurrence. NOTE: Albendazole may be myelosuppressive at this dose—monitor CBC.
- Fenbendazole 50 mg/kg PO q24h for 30 days may be used also with some hope of success for long-term prevention of recurrence.

FOLLOW-UP

- Lesions of *T. crassiceps* very often recur. Thus, necessary to carefully monitor the dog with abdominal ultrasound for the potential spread of lesions and the development of new lesions in different sites.
- Removal of *T. solium* cysticerci will be curative.

MISCELLANEOUS

ZOONOTIC POTENTIAL

Stages causing clinical signs in dogs pose no zoonotic threat.

Suggested Reading

- Buback JL, Schulz KS, Walker MA, et al. Magnetic resonance imaging of the brain for diagnosis of neurocysticercosis in a dog. J Am Vet Med Assoc 1996, 208:1846–1848.
Hoberg EP, Ebinger W, Render JA. Fatal cysticercosis by *Taenia crassiceps* (Cyclophyllidae: Taeniidae) in a presumed immunocompromised canine host. J Parasitol 2000, 85:1174–1180.

Author Dwight D. Bowman

Consulting Editor Stephen C. Barr

BASICS

OVERVIEW

- Infection with the protozoan *Cytauxzoon felis*.
- Affects vascular system of lungs, liver, spleen, kidneys, and brain; bone marrow; developmental stages of RBCs.
- Uncommon in most regions, but common during the spring and summer in endemic regions.
- Affects feral and domestic cats in south-central, southeastern, and mid-Atlantic United States. Range appears to be expanding towards the eastern and northeastern United States.

SIGNALMENT

- Feral and domestic cats of all ages
- No breed or sex predilection

SIGNS

- Most cats have severe illness at presentation.
- Pale mucous membranes.
- Depression.
- Anorexia.
- Dehydration.
- High fever.
- Icterus.
- Splenomegaly.
- Hepatomegaly.
- Some cats may be infected but asymptomatic.

CAUSES & RISK FACTORS

- Bite of infected tick (*Amblyomma americanum* or *Dermacentor variabilis*).
- Roaming in areas shared by reservoir hosts (bobcat, Florida panther).
- Living in the same household as a cat diagnosed with cytauxzoonosis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of pancytopenia such as sepsis and panleukopenia.
- Other causes of fever and jaundice such as pancreatitis, hepatitis, and cholangitis.

CBC/BIOCHEMISTRY/URINALYSIS

- Bi-cytopenia or pancytopenia are the most common findings. Thrombocytopenia is almost always present.
- Moderate hyperbilirubinemia and bilirubinuria.

- Normal to mildly increased ALT.
- Mild hyperglycemia.
- Reflect changes associated with the severe anemia, caused by combination of hemolysis and hemorrhage.

OTHER LABORATORY TESTS

- Fresh blood smear—*Cytauxzoon* erythrocytic form; 1–3 µm in diameter; shape of a signet ring or safety pin.
- Splenic, lymph node, liver, or bone marrow aspirate—best suited to demonstrate extra-erythrocytic form.
- A PCR assay is commercially available.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

Organisms inside myeloid cells in bone marrow aspirate and in dramatically enlarged myeloid cells in vessels of multiple organs including lung, liver, spleen, kidney, and brain.

TREATMENT

- Inpatient with aggressive supportive therapy
- Blood transfusion
- Feeding tube for medication and nutritional support

MEDICATIONS

DRUG(S)

- Combination of atovaquone (15 mg/kg PO q8h with a fatty meal) and azithromycin (10 mg/kg PO q24h) and supportive care is associated with survival rates of 60%.
- Imidocarb dipropionate 5 mg IM two injections 14 days apart has been recommended but is associated with survival rates of approximately 27%.
- Heparin (100–300 U/kg SC q8h or 300–900 U/kg/day as a CRI) until time of discharge (longer if develop significant coagulation problems such as pulmonary thromboembolism).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

- With aggressive supportive care and treatment expect 3–7 days of hospitalization with severe illness.
- Some cats develop pleural effusion (presumably secondary to pulmonary hypertension) and require thoracocentesis.
- However, cats that survive will return to normal within 2–4 weeks of discharge and appear immune to re-infection.
- Some cats remain persistently infected with the intra-erythrocytic form without overt signs.
- Without treatment, most infected cats have died within 5 days of presentation.

MISCELLANEOUS

ZOONOTIC POTENTIAL

- No known risk to humans.
- Cannot be directly transmitted to another cat except by blood or tissue inoculation

ABBREVIATIONS

- PCR = polymerase chain reaction
- RBC = red blood cell

Consulting Editor Stephen C. Barr

Acknowledgment The author and editors acknowledge the prior contribution of Johnny D. Hoskins.

DEAFNESS

BASICS

DEFINITION

- Partial or complete hearing loss.
- Two forms:
 - Sensorineural deafness—caused by damage to receptors in cochlea, cochlear nerve, or auditory pathways in central nervous system.
 - Conduction deafness—caused by inability to conduct sound vibration through external-to-inner-ear structures.

PATHOPHYSIOLOGY

Sensorineural Deafness

- Hereditary—breed-related cochlear degeneration of neonatal dogs and cats; closely associated with merle and piebald pigmentation genes. Recessive alleles of these genes alter the ability of neural crest melanocytes to populate regions of the body including skin, hair, iris, ocular tapetum, and portions of the cochlea. The absence of melanocytes in the stria vascularis of cochlea is associated with early post-natal degeneration of this structure. Can also be non-pigment associated such as in Doberman pinchers.
- Acquired—cochlear degeneration due to chronic infection, ototoxicity, neoplasia, chronic exposure to loud noises, anesthesia-associated or age-related loss of hair cells and ganglion nerves (presbycusis).

Conduction Deafness

- Congenital defects in external ear canal, tympanic membrane, or ossicles that transmit vibration in middle ear are rare. Hereditary predisposition in primary secretory otitis media in the CKCS.
- Acquired defects resulting in stenosis/obstruction of external ear canal, rupture of tympanic membrane or fusion of bony ossicles; most commonly associated with chronic otitis or middle ear polyps.

SYSTEMS AFFECTED

Nervous—inner ear

GENETICS

Genetics of congenital deafness unknown although strong association with the piebald and the merle genes (pigment-associated genes related to coat color).

INCIDENCE/PREVALENCE

- Dogs with a single merle allele—3.5%.
- Dogs with double merle allele—25%; no genetic test for the piebald gene.
- Prevalence of congenital deafness in one or both ears available for the following breeds—Catahoula leopard dog—63%, dappled dachshund—55%, Dalmatian—30% in USA, 18% in UK, Jack Russell terrier—4.07%, Australian cattle dog—15%, bull terrier—11% (20% if

white), English setter—8%, English cocker spaniel—7% border collie—2.4%, whippet—1.3%, purebred white cats—20.2%.

GEOGRAPHIC DISTRIBUTION

Prevalence for different breeds varies between countries.

SIGNALMENT

- Breed-related congenital cochlear degeneration described in > 90 breeds of dogs. Most breeds have a large amount of white pigmentation associated with merle or piebald genes except for Doberman pinscher, Puli, Shropshire terrier. Congenital sensorineural deafness present by 6 weeks of age.
- No association with gender or coat pigmentation genes unrelated to merle or piebald. Dogs with blue iris color have a higher incidence of congenital deafness.
- Mixed-breed cats with white hair coat and blue irises—high incidence of deafness. Purebred white cats that carry the Siamese gene for blue eyes have a lower incidence of congenital deafness.
- Acquired deafness may occur in any breed or age dog.

SIGNS

- Unilateral deafness often goes unnoticed. Rarely dogs have difficulty localizing sound.
- With bilateral disease, animals do not respond to auditory cues such as calling its name or rattling food dish. Often they are easily startled. Commonly have heightened response to vibration and visual cues.

CAUSES

Sensorineural Deafness

- Genetic etiology likely in neonates.
- Acquired cochlea and cochlear nerve damage—*infectious, neoplasia of bony labyrinth or nerve, trauma, systemic, or topically applied drugs or toxins (antibiotics—aminoglycosides, polymyxin, erythromycin, vancomycin, chloramphenicol; antiseptics—ethanol, chlorhexidine, cetrimide; antineoplastics—cisplatin; diuretics—furosemide; heavy metals—arsenic, lead, mercury; miscellaneous—ceruminolytic agents, propylene glycol, salicylates); middle-ear polyps.*

Conduction Deafness

- Otitis externa and other external ear canal disease (e.g., stenosis of canal, neoplasia, or ruptured tympanum).
- Otitis media.

RISK FACTORS

- Merle, piebald gene, or white coat color
- Chronic otitis externa, media, or interna
- Use of ototoxic drugs.
- General anesthesia

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Early age onset—suggests congenital causes in predisposed breeds.
- Use of ototoxic drugs, recent anesthesia or chronic ear disease—suggests acquired causes.
- Evaluate for brain disease.

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal

OTHER LABORATORY TESTS

- Bacterial culture and sensitivity of ear canal if otitis externa.
- Myringotomy with culture of aspirates if otitis media.

IMAGING

- Tympanic bullae and skull radiographs—not sensitive for otitis media or otitis interna.
- CT/MRI—sensitive for middle-inner-ear disease.

DIAGNOSTIC PROCEDURES

- Brainstem auditory evoked response (BAER)—measure electrical response of cochlea and auditory pathways in the brain to an auditory stimulus; reliable to identify dogs with unilateral disease or partial hearing loss. Bone conduction stimulation can be useful to distinguish sensorineural from conduction deafness. Can be used to determine the hearing threshold.
- Otoacoustic emissions (OAEs)—low-level sounds produced by inner ear as part of the normal hearing process that can be measured by placing a probe containing a microphone in the external ear canal. Two forms have been used in dogs for assessment of sensorineural deafness: transient-evoked OAEs (TEOAEs) and distortion-product OAEs (DPOAEs). OAE is best suited for cases with congenital deafness as it tests outer hair cell function and is not affected by inner hair cell, synapse or cochlear nerve deficiencies.

PATHOLOGIC FINDINGS

- Congenital deafness—degeneration of the stria vascularis with subsequent collapse of membranous labyrinth structures. Bony labyrinth remains intact.
- Acquired deafness—related to primary disease such as otitis or neoplasia.
- Ototoxicity—degeneration of otic hair cells, ganglion cell loss, and loss of stria vascularis.

TREATMENT

CLIENT EDUCATION

Deaf animals may be functional pets but require patience, specialized training, and extra protection from traffic.

(CONTINUED)

DEAFNESS

D

SURGICAL CONSIDERATIONS

- Directed toward acquired causes; congenital deafness irreversible.
- Otitis externa, media, or interna—medical or surgical approaches depend on culture and sensitivity test results, response to antibiotics, and imaging findings.
- Conduction—may improve as otitis externa or media resolve.
- Cochlear implants can be used in dogs with moderate to profound deafness but only preliminary data available and very expensive.

**MEDICATIONS****DRUG(S) OF CHOICE**

- None for congenital deafness.
- Treat otitis based on culture and sensitivity results.

PRECAUTIONS

- Aminoglycosides or other ototoxic drugs—use with caution.

- Topical treatment of external ear canal—avoid if tympanic membrane is ruptured.

**FOLLOW-UP****PATIENT MONITORING**

As needed for management of otitis

POSSIBLE COMPLICATIONS

Deaf dogs need protected environments and training to be functional pets.

**MISCELLANEOUS****PREGNANCY/FERTILITY/BREEDING**

Dogs homozygous for recessive merle gene can be blind and sterile.

ABBREVIATIONS

- BAER = brainstem auditory evoked responses
- CKCS = Cavalier King Charles spaniel
- CT = computed tomography
- DPOAE = distortion product OAE
- MRI = magnetic resonance imaging
- OAE = otoacoustic emission
- TEOAE = transient evoked OAE

DECIDUOUS TEETH, PERSISTENT

BASICS

OVERVIEW

- A persistent (retained) deciduous tooth is one that is still present when the permanent tooth begins to erupt or has erupted.
- Numerous factors influence the exfoliation of deciduous teeth: lack of a permanent successor; ankylosis of the deciduous crown or root to the alveolus; and failure of the developing permanent crown to contact the deciduous root preventing resorption of the deciduous root.

SIGNALMENT

- More common in dogs than cats. • More common in small-breed dogs (e.g., Maltese, poodle, Yorkshire terrier, etc). • Occurs during permanent tooth eruption phase—beginning at 3 months of age for the incisors and 6–7 months of age for the canine teeth and molars. • Persistent deciduous teeth may go undetected and therefore undiagnosed until adulthood. • No sex predilection.

SIGNS

General Comments

- Persistent deciduous teeth can cause the permanent teeth to erupt in an abnormal positions resulting in a malocclusion. Early recognition and intervention is essential.
- Maxillary canine teeth erupt mesial (rostral) to the persistent deciduous canine teeth. This can narrow the space (diastema) between the maxillary canine tooth and the third incisor, leaving no room for the mandibular canine tooth to occupy. • Mandibular canine teeth erupt lingual (medial) to the persistent deciduous teeth. This can result in a narrow space between the lower canines (base narrow), resulting in impingement on the soft tissue of the hard palate. • All permanent incisors erupt lingual to the persistent deciduous incisors. This can result in a rostral (anterior) crossbite.

Physical Examination Findings

- Presence of a deciduous tooth with the permanent tooth either partially or fully erupted. • Abnormal position of the permanent tooth due to persistence of the deciduous tooth. • Oral malodor from accumulation of debris and plaque due to crowding of the permanent tooth and the persistent deciduous teeth. • Local gingivitis and early-onset periodontal disease due to plaque accumulation from crowding.
- Oronasal fistula from base-narrow mandibular permanent canine teeth (linguoversion). • Deciduous tooth present with no permanent successor. • Deciduous tooth is usually smaller than the permanent tooth. • Without underlying permanent tooth, deciduous tooth will often remain intact and viable, though can eventually exfoliate.

CAUSES & RISK FACTORS

- Cause is unknown but is suspected to have a genetic basis. • Small-breed dogs are predisposed.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Supernumerary teeth • Gemination of the crown

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

Intraoral Radiography

- Distinguish between permanent teeth and deciduous teeth. • Provide evidence or extent of root resorption of the deciduous tooth.
- Identify dental abnormalities prior to extraction, including persistent deciduous tooth with no permanent successor, retained root with crown missing, and unerupted permanent tooth. • Identify relationship of deciduous root and permanent crown prior to extraction.

DIAGNOSTIC PROCEDURES

- Complete oral examination—charting of oral cavity to indicate presence of deciduous teeth, malpositioned teeth, missing teeth, soft tissue trauma, and other abnormalities.
- Appropriate preoperative diagnostics when indicated prior to procedure.

PATHOLOGIC FINDINGS

N/A

TREATMENT

CLIENT EDUCATION

- Persistent deciduous teeth may be prevalent in certain breeds. • Start looking at teeth from the first puppy or kitten visit. • Inform owners that you will be evaluating for exfoliation of deciduous teeth as well as proper eruption of permanent teeth.

SURGICAL CONSIDERATIONS

- Ideally, extract the deciduous tooth as soon as the permanent tooth has erupted through the gingiva. • General anesthesia with endotracheal tube in place and cuff inflated. • Intraoral radiographs.

Extraction

- Careful, gentle elevation is critical. Excessive force or pressure can damage the developing permanent tooth. • If a permanent tooth has erupted in an abnormal position, full root extraction of the deciduous tooth is essential.
- A fractured or retained root may need to be removed with a gingival flap. • In some cases, the root may have already undergone

resorption and the remaining crown needs to be extracted.

MEDICATIONS

DRUG(S)

- Topical oral antimicrobial rinse prior to extraction.
- Pain management prior to, during and following extraction.

CONTRAINdications/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

PATIENT MONITORING AND HOMECARE

- After surgery, restrict activity for the rest of the day. • Soft diet for 24 hours—canned food or moistened dry kibble. • Analgesia (NSAIDs) for 24–36 hours post-op. • No chew toys for 24 hours. • Oral rinse (chlorhexidine) for 3–5 days if indicated.
- Continue daily tooth brushing after 24 hours.

PREVENTION/AVOIDANCE

May be prevalent in certain breeds and lines—avoid similar breeding.

POSSIBLE COMPLICATIONS

- Malocclusion of permanent teeth may need to be treated. • Base narrow (linguoversion) of the mandibular canine teeth. • Rostral crossbite. • Rostrally deviated maxillary canine teeth.

EXPECTED COURSE AND PROGNOSIS

- Once extracted, there should be no further problems. • Gingiva generally heals uneventfully. • Prognosis depends on occlusion after eruption of permanent teeth is complete.

DEGENERATIVE MYELOPATHY

BASICS

DEFINITION

Canine progressive adult-onset fatal neurodegenerative disease that has recently been shown in many breeds to be a result of a mutation in the superoxide dismutase 1 gene (*SOD1*). Mutations in *SOD1* are known to cause some forms of amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig's disease. Initial signs of progressive upper motor neuron spastic paresis and general proprioceptive ataxia in the pelvic limbs occur in older dogs. If euthanasia is delayed, clinical signs progress to flaccid tetraparesis/plegia and other lower motor neuron signs.

PATHOPHYSIOLOGY

- A *c.118 G > A* transition in Exon 2 of *SOD1* that predicts an E40K missense mutation underlies most DM. A second *SOD1* missense mutation (*c.52 A > T*) has been seen only in Bernese mountain dogs.
- Lesions may represent a multisystem central-peripheral axonopathy.
- Predilection for lesion severity in mid-thoracic spinal cord may be a result of lower percentages of radicular artery contributions and small diameter vessels when compared to other spinal cord regions.
- Paucity of vascular supply in thoracic spinal cord may predispose it to damage from oxidative and metabolic disturbances.

SYSTEMS AFFECTED

- Central and peripheral nervous systems.
- Thoracolumbar spinal cord in early stage.
- Progresses to involve the cervical and lumbar spinal cord and the peripheral nervous system later in the course of the disease.
- Neurons in brainstem also may be affected.
- Disease also involves the sensory nerve roots and dorsal root ganglia.

GENETICS

- Most commonly autosomal recessive inheritance.
- Due to preponderance of purebred dogs affected, a familial inheritance is currently suspected.
- Mutations in *SOD1* are causative for degenerative myelopathy but are incompletely penetrant.
- Dogs that are homozygous for the mutant allele are at highest risk for developing degenerative myelopathy. Not all dogs that test homozygous for the mutation will develop DM. Dogs that test normal (clear) are highly unlikely to develop DM. Dogs that test carrier are less likely to develop DM.

INCIDENCE/PREVALENCE

Prevalence rate of DM reported for all dogs collected from the Veterinary Medical Database (1990–1999) was 0.19%.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Breed Predilections

So far the DM-associated *SOD1:c.118A* allele in 124 different dog breeds or varieties; a second *SOD1* mutation (*c.52 A > T*) was found only in Bernese mountain dogs. DM has been histopathologically confirmed in over 25 purebred and mixed-breed dogs.

Mean Age and Range

- Mean—9 years of age in large dogs. Mean age at onset is 11 years in Pembroke Welsh Corgi.
- Range—between 8 and 14 years.

Predominant Sex

No known sex predilection

SIGNS

- Early:
 - Upper motor neuron paraparesis.
 - Insidious, progressive, asymmetric general proprioceptive ataxia. Gait shows long-strided spastic paraparesis.
 - Paw replacement deficits.
 - Spinal reflexes usually present or exaggerated (patellar reflex may be reduced).
 - Presence of crossed-extensor reflex is variable.
 - Lack of paraspinal hyperesthesia is a key clinical feature.
- Later:
 - Pelvic limb paresis leading to plegia, eventually progressing to tetraparesis/plegia.
 - Mild to moderate loss of muscle mass in pelvic limbs due to neurogenic atrophy.
 - Reduced spinal reflexes in pelvic limbs.
 - ± urinary and fecal incontinence.
- End stage:
 - Flaccid tetraplegia.
 - Difficulty with swallowing and tongue movements.
 - Absence of spinal reflexes in all limbs.
 - Reduced to absent cutaneous trunci reflex.
 - Profound generalized muscle wasting.
 - Urinary and fecal incontinence.
 - Nociception remains unaffected.

CAUSES

- Hereditary disease and genetic predisposition.
- Other hypothesized causes include: immune-mediated, metabolic deficiencies, toxic and oxidative stress.

RISK FACTORS

- Dogs homozygous for the mutant allele(s) are at highest risk.
- There may be other environmental factors and modifying genes; studies underway.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Type II intervertebral disc herniation
- Intramedullary spinal cord neoplasia
- Degenerative lumbosacral stenosis
- Hip dysplasia
- Other coexisting orthopedic disease

CBC/BIOCHEMISTRY/URINALYSIS

- Usually normal
- Performed to rule out other underlying metabolic disease
- Urinalysis may identify secondary urinary tract infection

OTHER LABORATORY TESTS

- Urine culture and sensitivity testing
- Thyroid function testing
- Electrodiagnostic testing results are normal in the early diagnosis of DM
- Genetic testing—test result of at-risk can support a presumptive diagnosis of DM in light of typical clinical signs and normal findings on neuroimaging and CSF analysis.

IMAGING

- Survey spinal radiography.
- Myelography evaluates for compressive spinal cord disease.
- Myelography combined with CT—more sensitive technique to evaluate suspicious lesions.
- MRI—preferred technique to evaluate for extramedullary compressive and intramedullary lesions.

DIAGNOSTIC PROCEDURES

- Cerebrospinal fluid analysis evaluates for inflammatory disease.
- Definitive diagnosis is determined by post-mortem histopathology of the spinal cord.

PATHOLOGIC FINDINGS

- Spinal cord axons and myelin affected most severely in the dorsal, and dorsal portion of the lateral funiculi.
- Vacuolated axon cylinders/myelin sheaths most extensive in the mid-thoracic spinal cord.
- Astroglial proliferation is prominent in severely affected areas of lesion distribution.
- Usually, lesion distribution is described as asymmetric and discontinuous. However, more recent evidence describes lesion distribution as symmetric and continuous in dogs that survive for long periods with DM.
- Neuronal cell body loss in the ventral horn is evident at terminal or end-stage disease.
- Nerve specimens show nerve fiber loss resulting from axonal degeneration and secondary demyelination.
- Muscle specimens show large and small groups of atrophic fibers typical of denervation.

DEGENERATIVE MYELOPATHY

(CONTINUED)

D

TREATMENT

APPROPRIATE HEALTH CARE

- Supportive care.
- Breeds of small size may survive longer with DM because the pet owner is able to more easily give the appropriate care.

NURSING CARE

- When dog becomes non-ambulatory, keep on a well-padded surface to prevent decubitus ulceration over bony prominences.
- Keep hair trimmed, and skin clean and dry to prevent urine scald secondary to incontinence.
- The urine should be monitored for odor and color change, which may indicate a urinary tract infection.
- Physical therapy using range-of-motion and active exercises may help maintaining limb mobility and muscle strength.

ACTIVITY

- Exercise is encouraged to slow disuse atrophy of pelvic limbs but fatigue should be monitored and exercise intensity adjusted.
- Hydrotherapy can involve use of an underwater treadmill setup.
- A wheel cart may assist with patient mobility.

DIET

- Maintain balanced diet.
- Prevent weight gain.

CLIENT EDUCATION

- Long-term prognosis is poor.
- Meticulous nursing care is crucial to preventing secondary complications in a recumbent patient.

SURGICAL CONSIDERATIONS

None

MEDICATIONS

DRUG(S) OF CHOICE

No drug has been proven to be effective in slowing or halting disease progression.

CONTRAINdicATIONS

N/A

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

PATIENT MONITORING

- Repeat neurologic examinations
- Urinary retention
- Urinalysis and urine culture to monitor for urinary tract infection

PREVENTION/AVOIDANCE

- Decubitus ulceration
- Urine retention
- Dermatitis from urine scald
- Weight gain

POSSIBLE COMPLICATIONS

- Urine retention may predispose to urinary tract infections.
- Local skin infections from decubitus ulceration.

EXPECTED COURSE AND PROGNOSIS

- Paraplegia occurs within 9–12 months from time of onset of signs.
- Tetraparesis may be evident within 3 years from time of onset of signs.
- Long-term prognosis is poor.

DEMODICOSIS

BASICS

DEFINITION

- An inflammatory parasitic disease of dogs and rarely cats that is characterized by an increased number of mites in the hair follicles and on the epidermis. • Often leads to furunculosis and secondary bacterial infection. • May be localized or generalized.

PATOPHYSIOLOGY

Dogs

- Three species of mites identified in the dog:
 - *Demodex canis*—follicular mite; part of the normal fauna of the skin; typically present in small numbers; resides in the hair follicles and sebaceous glands of the skin, transmitted from the mother to the neonate in 2–3 days of nursing.
 - *Demodex injai*—large, long-bodied mite found in the pilosebaceous unit, mode of transmission unknown; only associated with adult-onset disease with highest incidence noted in the terrier breeds often along the dorsal midline (West Highland white terrier and wirehaired fox terrier).
 - *Demodex cornei*—lives in the stratum corneum of the epidermis; mode of transmission unknown; most likely a morphologic variant of *D. canis*.
- Pathology develops when numbers exceed those tolerated by the immune system, causing immunologic exhaustion. • The initial proliferation of mites may be the result of a genetic or immunologic disorder.

Cats

- Poorly understood disorder. • Mites have been identified on the skin and within the external ear canal.
- Two species of mites identified in the cat (a third, unnamed mite has been reported):
 - *Demodex gatoi* is considered to be potentially contagious and associated with pruritic dermatitis.
 - *Demodex cati* infections are often associated with immunosuppressive and metabolic disease.

SYSTEMS AFFECTED

Skin/Exocrine

GENETICS

Initial proliferation of mites may be the result of a genetic disorder

INCIDENCE/PREVALENCE

- Dogs—common
- Cats—rare

SIGNALMENT

Species

Dogs and cats

Breed Predilections

- *D. canis*: American Staffordshire terrier, Shar-Pei, Boston terrier, English bulldog, and West Highland white terrier.
- *D. injai*: West Highland white and wirehaired fox terriers, Shih Tzu.
- Potential increased incidence in Siamese and Burmese cat.

Mean Age and Range

- Localized—usually in dogs < 1 year of age; median 3–6 months.
- Generalized—both young and old animals.
- No data collected for the cat.

SIGNS

Dogs

Localized, Juvenile-Onset

- Lesions—usually mild; consist of erythema and a light scale.
- Patches—several may be noted; most common site is the face, especially around the perioral and periocular areas and forelegs; may also be seen on the trunk and rear legs.

Generalized, Juvenile-Onset or Adult-Onset

- Can be widespread from the onset, with multiple poorly circumscribed patches of erythema, alopecia, and scale. • As hair follicles become distended with large numbers of mites, secondary bacterial infections are common, often with resultant rupturing of the follicle (furunculosis). • With progression, the skin can become severely inflamed, exudative, and granulomatous.
- *D. injai* may be associated with a greasy seborrheic dermatitis of the dorsal trunk, comedones, erythema, alopecia, and hyperpigmentation.

Pododemodicosis

- Can present without generalized lesions
- Secondary and deep pyoderma common
- Lesions often painful and edematous

Cats

- Often characterized by partial to complete multifocal alopecia of the eyelids, periocular region, head, neck, flank, and ventrum.
- Lesions—variably pruritic with erythema, scale, and crust; those caused by *D. gatoi* are often quite pruritic and may be contagious.
- Ceruminous otitis externa has been reported.
- *D. cati* often associated with immunosuppressive disease.

CAUSES

- Dog—*Demodex canis*, *Demodex injai*, and *Demodex cornei*.
- Cat—*Demodex cati* and *Demodex gatoi*.

RISK FACTORS

Dogs

- Exact immunopathologic mechanism unknown.
- Studies indicate that dogs with generalized demodicosis may have abnormal numbers of IL-2 receptors on lymphocytes and subnormal IL-2 production by lymphocytes, abnormal T_H1 versus T_H2 responses, and depressed T-cell function.
- Genetic factors (especially localized, juvenile-onset), immunosuppression, and/or metabolic diseases may predispose animal.

Cats

- *D. cati*—often associated with metabolic diseases (e.g., FIV, systemic lupus erythematosus, diabetes mellitus).
- *D. gatoi*—short and blunted; rarely a marker for metabolic disease; may be transferable from cat to cat within the same household.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Dogs

- Bacterial folliculitis/furunculosis
- Dermatophytosis
- Contact dermatitis
- Pemphigus complex
- Dermatomyositis
- Systemic lupus erythematosus

Cats

- Allergic dermatitis
- Notoedres
- Dermatophytosis
- Psychogenic dermatitis

CBC/BIOCHEMISTRY/URINALYSIS

Normal unless there is an underlying process

OTHER LABORATORY TESTS

- FeLV and FIV serology, toxoplasmosis titers
- Fecal samples: rare finding of mites in feces

DIAGNOSTIC PROCEDURES

- Skin scrapings—diagnostic for finding mites in the majority of cases.
- Trichograms may be an effective technique for mite identification.
- Skin biopsy—may be needed when lesions are chronic, granulomatous, and fibrotic (especially on the foot).

TREATMENT

APPROPRIATE HEALTH CARE

- Outpatient.
- Localized—conservative; most cases (90%) resolve spontaneously with no treatment.
- Evaluate the general health status of dogs with either the localized or the generalized form.

CLIENT EDUCATION

- Localized—most cases resolve spontaneously.
- Generalized—frequent management problem; expense and frustration with the chronicity of the problem; juvenile-onset cases may resolve with treatment; adult-onset cases are usually medically controlled but not cured; juvenile-onset considered an inheritable predisposition therefore breeding of affected animals is not recommended.

MEDICATIONS

DRUG(S) OF CHOICE

Amitraz

- A formamidine, which inhibits monoamine oxidase and prostaglandin synthesis; an α₂-adrenergic agonist: use weekly to every other week until resolution of clinical signs and negative skin scrapings; do not rinse off; let air-dry.
- Treat for 1 month following negative skin scrape.
- Clipping the hair coat and applying a benzoyl peroxide shampoo before application

DEMODICOSIS

(CONTINUED)

of the rinse as bactericidal therapy and to increase exposure of the mites by removal of debris from the skin and follicles.

- Efficacy is proportional to the frequency of administration and the concentration of the rinse.
- Rarely used in cats—0.015%–0.025% applied to the entire body every 1–2 weeks (do not use on diabetic cats).
- Dogs—0.03–0.05% applied weekly to every other week; total body/additional topical treatments for focal areas (pododermatitis) may be used every 1–3 days with 0.125% solution.
- Preventic collar—anecdotal reports of success; change collar every 2–4 weeks; non-FDA-approved usage.
- Between 11% and 30% of cases will not be cured; may need to try an alternative therapy or control with maintenance rinse every 2–8 weeks.

Ivermectin

- A macrocyclic lactone with GABA agonist activity.
- Dog: daily oral administration of 0.3–0.6 mg/kg very effective, even when amitraz fails; initiate therapy with a test dose of 0.12 mg/kg q24h for the first week to observe for any signs of toxicity/side effects.
- Treat for 30–60 days beyond negative skin scrapings (average 3–8 months).
- Reported as a treatment option in the cat; exact dose is unknown (often dosed at 300 µg/kg).
- Non-FDA-approved usage.

Milbemycin

- A macrocyclic lactone with GABA agonist activity.
- Dosage of 1–2 mg/kg PO q24h cures 50% of cases; 2 mg/kg PO q24h cures 85% of cases.
- Treat for 30–60 days beyond multiple negative skin scrapings.
- Very expensive/not commercially available in the US.
- Non-FDA-approved usage.

Moxidectin and Doramectin

- Anecdotal reports in the dog when used topically once weekly or orally (0.2–0.3 mg/kg q24h moxidectin; 0.2–0.6 mg/kg weekly doramectin).
- Do not use orally in ivermectin sensitive breeds.
- Non-FDA-approved usage.

Cats

- Exact protocols are not defined.
- Topical lime-sulfur dips every 3–7 days for four to eight treatments often lead to good resolution of clinical signs; recommended therapy in cats.
- Studies with milbemycin and ivermectin are lacking, although there are numerous anecdotal reports of efficacy.
- Doramectin has also been reported to be effective at 0.6 mg/kg SC once weekly.

CONTRAINDICATIONS

- Ivermectin—contraindicated in collies, Shetland sheepdogs, Old English sheepdogs, Australian shepherds, other herding breeds, and crosses with these breeds; sensitive breeds appear to tolerate the acaricidal dosages of milbemycin (see above).
- Sensitive breeds may lack a gene (*MDR1/ABCB1* mutation) that codes for a p-glycoprotein (drug-efflux pump) that predisposes to toxicity.

PRECAUTIONS

Amitraz

- Side effects—somnolence, lethargy, depression, anorexia seen in 30% of patients for 12–36 hours after treatment.
- Rare side effects—vomiting, diarrhea, pruritus, polyuria, mydriasis, bradycardia, hypoventilation, hypotension, hypothermia, ataxia, ileus, bloat, hyperglycemia, convulsions, death.
- Incidence and severity of side effects do not appear to be proportional to the dose or frequency of use.
- Human beings can develop dermatitis, headaches, and respiratory difficulty after exposure.
- Yohimbine at 0.11 mg/kg IV is an antidote.

Ivermectin and Milbemycin

- Signs of toxicity—salivation, vomiting, mydriasis, confusion, ataxia, hypersensitivity to sound, weakness, recumbency, coma, and death.
- Ivermectin—contraindicated in collies, Shetland sheepdogs, Old English sheepdogs, Australian shepherds, other herding breeds, and crosses with these breeds; sensitive breeds appear to tolerate the acaricidal dosages of milbemycin (see above).
- Sensitive breeds may lack a gene (*MDR1/ABCB1* mutation) that codes for a p-glycoprotein (drug-efflux pump) that predisposes to toxicity.

POSSIBLE INTERACTIONS

- Amitraz—may interact with heterocyclic antidepressants, xylazine, benzodiazepines, and macrocyclic lactones.
- Ivermectin and milbemycin—cause elevated levels of monoamine neurotransmitter metabolites, which could result in adverse drug interactions with amitraz and benzodiazepines.
- Spinosad (flea control) usage contraindicated with ivermectin therapy.

FOLLOW-UP

PATIENT MONITORING

Repeat skin scrapings (trichograms) and evidence of clinical resolution are used to monitor progress.

PREVENTION/AVOIDANCE

Do not breed animals with generalized form.

POSSIBLE COMPLICATIONS

Secondary bacterial folliculitis and furunculosis

EXPECTED COURSE AND PROGNOSIS

- Prognosis (dogs)—depends heavily on genetic, immunologic, and underlying diseases.
- Localized—most cases (90%) resolve spontaneously with no treatment; < 10% progress to the generalized form.
- Adult-onset (dogs)—often severe and refractory to treatment.
- Feline cases with *D. cati* may have a poor prognosis associated with underlying disease.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Adult-onset—sudden occurrence is associated with internal disease, malignant neoplasia, and/or immunosuppressive disease; approximately 25% of cases are idiopathic over a follow-up period of 1–2 years.
- *D. cati* associated with FeLV, FIV, toxoplasmosis, and SLE.

AGE-RELATED FACTORS

Young dogs are often predisposed to a localized form.

ZOONOTIC POTENTIAL

None

PREGNANCY/FERTILITY/BREEDING

Do not breed animals with the generalized form.

SYNONYMS

- Mange • Red Mange

SEE ALSO

- Amitraz Toxicosis • Ivermectin and Other Macrocylic Lactones Toxicosis

ABBREVIATIONS

- FeLV = feline leukemia virus
- FIV = feline immunodeficiency virus
- GABA = gamma-aminobutyric acid

BASICS

OVERVIEW

- Caries is the decay of the dental hard tissues (enamel, cementum, and dentin) due to the effects of oral bacteria on fermentable carbohydrates on the tooth surface.
- The word "caries" is Latin for rottenness and is both the singular and plural form.
- Oral bacteria ferment carbohydrates on the tooth surface, resulting in the production of acids leading to demineralization of the hard tissues, thus allowing bacterial and leukocytic digestion of the organic matrix of the tooth.
- Caries has been very common in humans in "westernized" society, where diets rich in highly refined carbohydrates are the norm. Aggressive public education and preventive measures have resulted in a decline in the incidence over the past several decades.
- In humans, *Streptococcus mutans* is particularly implicated in the development of caries.
- For various reasons (e.g., diet lower in refined carbohydrates, higher salivary pH, lower salivary amylase, conical crown shape, wider interdental spacing, different indigenous oral flora), caries is not common in the domestic dog, but it does occur and should be looked for.
- A study published in the *Journal of Veterinary Dentistry* in 1998 (see "Suggested Reading") reported that 5.3% of dogs 1 year of age or older had one or more caries lesions, with 52% having bilaterally symmetrical lesions.
- Caries can affect the crown or roots of the teeth and is classified as pit-and-fissure, smooth-surface, or root caries.

SIGNALMENT

- Caries occurs in dogs.
- Reported in cats; tooth resorption (feline odontoclastic resorptive lesions) have sometimes been misnamed feline caries. To the author's knowledge, there are no published reports of true dental caries occurring in the domestic cat, though it is theoretically possible.
- There is no reported breed, age, or gender predilection.

- Anecdotally, the author has observed a higher incidence of pit-and-fissure lesions in the occlusal tables of the maxillary first molar teeth in large-breed dogs such as Labrador retrievers and German shepherds.

SIGNS

- Incipient smooth-surface caries—appears as an area of dull, frosty-white enamel.
- Clinical caries—appears as a structural defect on the surface of the crown or root.
- The defect is frequently filled with or lined by dark, soft necrotic dentin. The defect may also trap and hold food debris.
- Affected dentin will yield to a dental explorer and can be removed with a dental excavator or curette.

CAUSES & RISK FACTORS

- Caries is caused by oral bacteria fermenting carbohydrates on the tooth surface, leading to the production of acids (acetic, lactic, propionic) that demineralize the enamel, cementum, and dentin, followed by digestion of the organic matrix of the tooth by oral bacteria and/or leukocytes.
- There is a constant exchange of minerals between the tooth surfaces (enamel, any exposed dentin or root cementum) and the oral fluids; if there is a net loss of mineral, caries develops.
- Early (incipient) caries may be reversible through remineralization.
- Once the protein matrix collapses, the lesion is irreversible.
- Any factors that allow prolonged retention of fermentable carbohydrates and bacterial plaque on the tooth surface predispose to the development of caries.
- A deep occlusal pit on the maxillary first molar is the most common place for caries to develop.
- Dental surfaces in close contact with an established caries are at risk of developing a lesion by extension.
- Deep occlusal pits and developmental grooves on the crown surface predispose to pit-and-fissure caries.
- Tight interdental contacts predispose to smooth-surface caries.
- Deep periodontal pockets predispose to root caries.
- Animals with poorly mineralized enamel, lower salivary pH, diets high in fermentable

carbohydrates, and poor oral hygiene are at risk of developing caries.

- Loss of enamel through any means (hypocalcification at the developmental stage, abrasive wear or attrition, traumatic fracture) that exposes the softer, underlying dentin may increase the risk for the development of caries.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Crown fracture, abrasive wear or attrition with exposed tertiary dentin, or extrinsic staining.
- Enamel hypocalcification with exposed and stained dentin.
- Tooth resorption (TR; feline odontoclastic resorptive lesions [FORL]) has been misnamed feline caries in the past.
- Tooth resorption can also occur in dogs and may be mistaken for caries.
- Sound dentin is hard and will not yield to a dental explorer, whereas carious dentin is soft and will yield to a sharp instrument.
- Root caries may be confused with external root resorption, though the distinction would often be academic, as either usually indicates the need for extraction.
- The lesion should be staged as to the depth of the pathology.
- Table 1 below is adapted from the American Veterinary Dental College approved nomenclature for tooth resorption as published on their website.

CBC/BIOCHEMISTRY/URINALYSIS N/A

OTHER LABORATORY TESTS N/A

IMAGING

Intraoral dental radiography:

- Areas of demineralization and tissue loss will appear as lucent areas contrasted against radiodense normal dental tissues.
- If the lesion has penetrated into the pulp chamber, there will be endodontic disease and there may be periapical disease evident if the lesion is sufficiently long-standing.
- Small lesions may be difficult to demonstrate due to superimposition of normal, radiodense tissues (dental and skeletal).

Table 1

Stage	Description
Stage 1	Defect involves enamel or cementum only.
Stage 2	Defect extends into dentin but not into pulp chamber.
Stage 3	Deep dental hard tissue loss (cementum and/or enamel with loss of dentin that extends to the pulp cavity); most of the tooth retains its integrity.
Stage 4	Extensive dental hard tissue loss (cementum and/or enamel with loss of dentin that extends to the pulp cavity); most of the tooth has lost its integrity.
Stage 5	Majority of crown lost; root remnants remaining.

DENTAL CARIES

(CONTINUED)

DIAGNOSTIC PROCEDURES

- Visual examination of the clean, dry tooth surface under good light and with the aid of magnification.
- Exploration with a sharp dental explorer—the explorer will sink into carious dentin and stick, providing the sensation of “tug-back” upon withdrawal.
- Subgingival exploration—reveals irregularities in the root surface.
- Caries detection dyes have been used by human and veterinary dentists to aid in the differentiation between sound and carious dentinal tissue. However, their use may lead to false-positive results and overtreatment through the removal of excess tissue. Reliance on visual, tactile, and radiographic findings is preferable.

TREATMENT

- Focus on prevention—examine the adult dentition of adolescent dogs (6–8 months of age) to identify anatomically compromised areas at risk for the development of caries. Deep pits in the occlusal surface of the maxillary first molar (for example) can be filled with a pit-and-fissure sealant or fluoride-releasing dental bonding agent to prevent caries development if identified prior to the development of any decay.
- Incipient caries—can be arrested and possibly reversed by application of a fluoride varnish or fluoride-releasing dental bonding agent and modification of the risk factors.
- Lesions that result in mild to moderate coronal tissue loss (stage 1 or 2)—remove carious dentin and unsupported enamel using hand instruments and power rotary dental instruments, then restore the coronal anatomy with a bonded, composite restoration or prosthetic restoration.
- Lesions that extend into pulp tissue (stage 3)—endodontic treatment must precede restorative treatment. Alternatively, extraction may be indicated. As the pulp tissue in the roots will be contaminated, complete removal of all root remnants is essential if extraction is performed.
- Lesions that result in extensive coronal tissue loss (stage 4 or 5)—extraction is typically the only treatment option. As the pulp tissue in the roots will be contaminated, complete removal of all root remnants is essential.

- Root caries—if the periodontal disease can be managed and the restoration placed supragingivally, restoration may be possible; however, for most teeth with root caries, extraction will be the treatment of choice.
- If only one root of a multirooted tooth is carious—extraction of the affected root with endodontic treatment of the remaining root(s) is also an option.
- For high-risk patients—application of a pit-and-fissure sealant and/or fluoride-releasing dental bonding agent on remaining teeth with occlusal surfaces may be considered.

MEDICATIONS

DRUG(S)

- Postoperative broad-spectrum antibiotics—may be indicated if there is pulp involvement necessitating endodontic treatment or extraction.
- Postoperative analgesia with non-steroidal anti-inflammatory drugs and/or narcotics is indicated following endodontic or exodontic treatment or extensive restorative work of vital teeth.

CONTRAINdications/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

PATIENT MONITORING

- Examine and radiograph treated teeth 6 months postoperatively, then annually or as the opportunity presents.
- Evaluate the integrity of the restorations, assess for further decay at the margins or under the restorations, assess for the development of endodontic disease.
- As affected individuals frequently have more than one caries, examine all teeth carefully (clinically and radiographically) at any opportunity to monitor for the development of new lesions.

PREVENTION/AVOIDANCE

Avoidance of diet and treats high in refined carbohydrates may reduce the risk of the development of further caries.

EXPECTED COURSE AND PROGNOSIS

If a lesion has been properly debrided and restored it should have an excellent prognosis. Appropriate staging and case selection, thorough removal of all carious tissues, and adherence to restorative principles are essential.

MISCELLANEOUS

SYNONYMS

- Cavities
- Dental decay

ABBREVIATIONS

- FORL = feline odontoclastic resorptive lesions
- TR = tooth resorption

Consulting Editor Heidi B. Lobprise

BASICS

OVERVIEW

Cyst formation originating from tissue surrounding the crown of an unerupted tooth.

SIGNALMENT

- Any breed that is at an increased risk for impaired eruption.
- Boxers, bulldogs—mandibular first premolars, often bilateral.
- Unerupted teeth at 6–7 months of age, but cystic development may not occur until much later, if at all.

SIGNS

- Cystic changes may be initially unapparent without diagnostic imaging.
- “Missing” tooth.
- Formation of a soft swelling at the site of a missing tooth, often fluctuant with fluid.
- Patient may present, with no previous indication of a problem, for a pathologic fracture of the mandible due to cystic destruction of the surrounding bone.

CAUSES & RISK FACTORS

Unerupted teeth

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Odontogenic keratocyst—cysts of the jaw demonstrating aggressive expansion that may, or may not, be associated with unerupted teeth.
- Primordial cyst—cystic degeneration of a tooth bud before enamel/dentin formation (cyst without a tooth).
- Oral mass—odontoma. Tooth structures (complex or compound) sometimes contained within cystic structure, but with different levels of organization.
- Transformation to ameloblastomas has been reported in humans; histologic evaluation of the cyst lining is highly recommended.

CBC/BIOCHEMISTRY/URINALYSIS

- No abnormalities typically found.
- Preoperative diagnostics where appropriate.

OTHER LABORATORY TESTS

N/A

IMAGING

- Definitive diagnosis from radiography.
- Radiographs are essential in any instance of missing or unerupted teeth.
- Radiographically—radiolucent cyst originating from the remnant enamel organ at the neck of the tooth and encompassing the crown (a halo).

DIAGNOSTIC PROCEDURES

Histopathologic assessment if atypical.

TREATMENT

- Appropriate preoperative antimicrobial and pain management therapy when indicated.
- Appropriate patient monitoring and support during anesthetic procedure.
- If cystic formation is present—surgical extraction, complete debridement of cyst lining, and histologic evaluation.
- If an embedded tooth has been present in a mature animal—assess for any cystic structure or other pathologic changes involving the tooth; continued monitoring may be reasonable if surgical extraction would damage large amounts of bone.
- If a non-strategic tooth can be easily extracted, it would be best to do so, even if cystic changes are not present.

MEDICATIONS

DRUG(S)

Postoperative analgesics, as necessary.

CONTRAINdications/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

POSSIBLE COMPLICATIONS

- Pathologic fracture may occur if dentigerous cyst is not diagnosed and treated.
- Fracture of mandible at time of extraction, if compromised.

EXPECTED COURSE AND PROGNOSIS

- Good with early detection and extraction.
- Fair to guarded with extensive bone destruction or pathologic fracture.

DERMATOMYOSITIS

BASICS

DEFINITION

An inheritable inflammatory disease of the skin, muscles, and vasculature that develops in young collies, Shetland sheepdogs, and their crossbreeds.

PATHOPHYSIOLOGY

- The exact pathogenesis of dermatomyositis is unknown.
- A familial predisposition has been reported in collies and Shetland sheepdogs; however, possible triggers for the disease include infectious agents (especially viral), vaccines, drugs, malignancy, toxins, infection—as seen with ischemic dermatopathy in other breeds.
- Based on the clinical and histopathologic evidence, an immune-mediated or auto-immune process may be involved.

SYSTEMS AFFECTED

- Skin/Exocrine
- Musculoskeletal

GENETICS

Autosomal dominant inheritance, with variable expression in collies and Shetland sheepdogs.

INCIDENCE/PREVALENCE

Exact prevalence is unknown

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Dogs

Breed Predilections

- Inheritable disease of collies, Shetland sheepdogs, and their crossbreeds, Beauceron shepherds, Belgian Tervurens, and Portuguese water dog.
- Similar symptoms reported in the mongrel, Welsh corgi, Lakeland terrier, chow chow, German shepherd dog, schipperke, and Kuvasz.
- Some animals in other breeds with similar signs are now classified as ischemic dermatopathy (dermatomyositis-like), and not dermatomyositis as previously reported.

Mean Age and Range

- Cutaneous lesions typically develop before 6 months, and may develop as early as 7 weeks of age.
- The full extent of lesions is usually present by 1 year of age, and may lessen thereafter.
- Adult-onset dermatomyositis can occur, but is rare, and is usually less severe.

Predominant Sex

None reported

SIGNS

General Comments

- The clinical signs vary from subtle skin lesions and subclinical myositis to severe skin

lesions with generalized muscle atrophy, abnormal gait and megaesophagus.

- Several littermates may be affected, but the severity of the disease often varies significantly among affected dogs.

Physical Examination Findings

- Waxing and waning lesions around the eyes, lips, face, inner ear pinnae, tip of the tail, and bony prominences—usually seen in affected dogs before they are 6 months old.
- Scarring—often a sequela to the initial skin lesions.
- Atrophy of the masseter and temporal muscles.
- Severe cases may have difficulty eating, drinking, and swallowing.
- Stiff or high-stepping gait.
- Skin lesions—characterized by variable degrees of crusted erosions, ulcers, and alopecia, with erythema, scaling, and scarring on the face, around the lips and eyes, in the inner ear pinnae, on the tip of the tail; the entire face may be involved.
- Pressure points over bony prominences, especially the carpal and tarsal regions.
- Foot pad and oral ulcers, as well as nail abnormality or loss may occur.
- Myositis—signs may be absent or vary from subtle decrease in the mass of the temporalis muscles to generalized symmetric muscle atrophy and stiff high-stepping gait.
- Dogs with megaesophagus may present with aspiration pneumonia.

CAUSES

- Hereditary in collies, Shetland sheepdogs, and their crosses.
- Infectious agents, toxins, malignancy, vaccines or drugs may be a triggering event.
- Immune-mediated disease in other breeds.

RISK FACTORS

Mechanical pressure and trauma, and ultraviolet light exposure may worsen cutaneous lesions.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Demodicosis
- Dermatophytosis
- Bacterial folliculitis
- Juvenile cellulitis
- Discoid lupus erythematosus
- Systemic lupus erythematosus
- Polymyositis
- Ischemic dermatopathy
- Epidermolysis bullosa simplex

CBC/BIOCHEMISTRY/URINALYSIS

Serum creatine kinase may be elevated due to muscle damage.

OTHER LABORATORY TESTS

- Antinuclear antibody titers—rule out systemic lupus erythematosus.

- Elevated levels of immunoglobulin G and circulating immune complex correlated with disease severity.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Skin biopsy—may be diagnostic for dermatomyositis, although this disease can be difficult to definitively diagnose; avoid infected and scarred lesions.
- Muscle biopsy—proper muscle selection can be difficult because pathologic changes may be mild consisting of muscle necrosis and atrophy.
- EMG—ideally, is used to select affected muscles for biopsy; if EMG is not available, atrophied muscles should be biopsied.

PATHOLOGIC FINDINGS

Skin Biopsy

- Scattered apoptosis or vacuolation of individual and follicular basal cells; may lead to intrabasal or subepidermal clefting.
- Mild pigmentary incontinence.
- Superficial, mild, diffuse dermal and perivascular cellular infiltrates—composed of lymphocytes, plasma cells, and histiocytes.
- Follicular atrophy and perifollicular fibrosis in chronic cases.
- Secondary epidermal ulceration and dermal scarring—may be present.
- Histopathologic features may be subtle and consist mostly of atrophic changes; however, the combination of epidermal and follicular basal cell degeneration, perivascular inflammation, and follicular atrophy with fibrosis is highly suggestive of dermatomyositis.

Muscle Biopsy

- Variable multifocal accumulations of inflammatory cells, including lymphocytes, plasma cells, macrophages, and neutrophils.
- Myofibril degeneration—characterized by fragmentation, vacuolation, atrophy, fibrosis, and regeneration.

Electromyography

EMG abnormalities are present especially in the muscles of the head and distal limbs; findings include fibrillation potentials (rapid, irregular, and unsynchronized contraction of muscle fibers), and positive sharp waves.

TREATMENT

APPROPRIATE HEALTH CARE

- Most dogs can be treated as outpatients.
- Dogs with severe myositis and megaesophagus may need to be hospitalized for supportive care.
- Severe cases may warrant euthanasia.
- Assist to eat if muscles of mastication are affected; feed at an elevated position if megasophagus develops.

(CONTINUED)

- Nonspecific supportive therapy includes gentle bathing and soaking to remove crusts, and treatment of secondary bacterial folliculitis (if present).

ACTIVITY

- Avoid activities that may traumatize the skin.
- Keep indoors during the day to avoid solar radiation.

DIET

N/A

CLIENT EDUCATION

- Discuss the hereditary nature of the disease.
- Note that affected dogs should not be bred.
- Inform the owner that the disease is not curable, although spontaneous resolution or waxing and waning of symptoms may occur.
- Discuss prognosis and possible complications, especially in severely affected dogs.
- Therapeutic efficacy of medical treatment can be difficult to assess because the disease tends to be cyclic in nature and is often self-limiting.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Vitamin E 200–800 IU PO q12–24h.
- Essential fatty acid supplements.
- Prednisone 1–2 mg/kg PO q12–24h until remission, then alternate day to twice weekly administration using the lowest dosage possible for long-term control.
- Nonsteroidal anti-inflammatory medication.
- Pentoxifylline 10–25 mg/kg q12h.
- Tetracycline (250 mg > 10 kg, 500 mg < 10 kg q8–12h), doxycycline (10 mg/kg q24h), minocycline (5 mg/kg q12h), with niacinamide (250 mg > 10 kg, 500 mg < 10 kg q8–12h).
- Tacrolimus 0.1% applied q12h.

CONTRAINDICATIONS

Pentoxifylline should not be used in dogs that are sensitive to methylxanthine derivatives.

PRECAUTIONS

- Pentoxifylline—rarely causes gastric irritation; can affect clotting times (PT/PTT prolongation and thrombocytopenia) and dogs receiving anticoagulant therapy should be monitored carefully when treated with this drug; possible rare seizure or reduction of seizure threshold in epileptics.

- Glucocorticoids—discuss possible side effects with the owner.
- Tacrolimus can cause local irritation.

POSSIBLE INTERACTIONS

Glucocorticoids and nonsteroidal anti-inflammatory medications can cause GI bleeding if used concurrently.

ALTERNATIVE DRUG(S)

N/A

**FOLLOW-UP****PATIENT MONITORING**

N/A

PREVENTION/AVOIDANCE

- Do not breed affected animals.
- Neuter intact animals to reduce hormonal influence on symptoms.
- Minimize trauma and exposure to sunlight.

POSSIBLE COMPLICATIONS

- Secondary bacterial folliculitis.
- Mildly to moderately affected dogs may have residual scarring.
- Severely affected dogs may have trouble chewing, drinking, and swallowing due to scarring of the masticatory and esophageal muscles.
- Megaesophagus may develop, predisposing the dog to aspiration pneumonia.
- Dogs may be lame due to damage of the muscles of the extremities.

EXPECTED COURSE AND PROGNOSIS

- Long-term prognosis—variable, depending on severity of disease.
- Minimal disease—prognosis good; tends to spontaneously resolve with no evidence of scarring.
- Mild-to-moderate disease—tends to resolve spontaneously, but residual scarring is common.
- Severe disease—prognosis for long-term survival is poor as damage to the skin and muscle may be life-long.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

None

DERMATOMYOSITIS**AGE-RELATED FACTORS**

- Initial clinical signs usually occur in dogs younger than 6 months.
- Adult-onset—rare; more commonly seen in dogs that had subtle lesions as puppies.

ZOONOTIC POTENTIAL

None

PREGNANCY/FERTILITY/BREEDING

- Do not breed affected dogs.
- Pregnancy may exacerbate clinical symptoms.
- Oestrus may exacerbate clinical symptoms.

SYNONYMS

- Familial canine dermatomyositis
- Canine familial dermatomyositis
- Ischemic dermatopathy in collies and Shetland sheepdogs

SEE ALSO

- Lupus Erythematosus, Cutaneous (Discoid)
- Lupus Erythematosus, Systemic

ABBREVIATIONS

- EMG = electromyography, electromyographic
- GI = gastrointestinal
- PT = prothrombin time
- PTT = partial thromboplastin time

available online

D

DERMATOPHILOSIS

BASICS

OVERVIEW

- “Mud rash” or “mud fever” a rare crusting dermatitis of dogs and cats.
- A rare nodular subcutaneous and oral disease in cats.
- *Dermatophilus congolensis*—causative agent; Gram-positive, branching filamentous bacterium classified as an actinomycete; very common cause of crusting dermatoses in hoofed animals; persists in the environment within crusts.
- Dogs, cats, humans, and other animals can rarely be secondarily infected.

D

SYSTEMS AFFECTED

Skin/Exocrine

SIGNALMENT

- Dogs and cats
- No age, breed, or sex predilection

SIGNS

Historical Findings

- Association with cattle, sheep, or horses.
- Occasionally free-roaming dogs.
- Cats with subcutaneous disease—episode of trauma; existence of a foreign body; lesions generally chronic; no systemic clinical signs, except when internal organs or large oral lesions develop.

Physical Examination Findings

- Dogs—circular to coalescing, papular, crusted lesions on the head and/or trunk; lesions resemble superficial bacterial pyoderma caused by *Staphylococcus pseudintermedius*; lesions may resemble dermatophilosis in horses (adherent thick, gray-yellow crusts that incorporate hair and leave a circular, glistening, shallow erosion when removed); variable pruritus.
- Cats—subcutaneous, oral, or internal ulcerated and fistulated nodules or abscesses similar to lesions caused by other actinomycetes; superficial pyogenic crusting disease of the face has been reported.

CAUSES & RISK FACTORS

- Dogs, cats, and humans can be exposed directly from lesions on large animals or from environmental exposure.
- Infectious stage—requires wetting for activation; cannot penetrate intact epithelium; minor trauma or mechanical transmission by biting ectoparasites (*Amblyomma variegatum*) may help in establishing infection.
- Deeper infection—require traumatic inoculation of infectious materials.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Dogs

- Staphylococcal folliculitis
- Acute moist dermatitis
- Dermatophytosis
- Pemphigus foliaceus
- Keratinization disorder

Cats

- Actinomycosis and nocardiosis
- Opportunistic mycobacterial granuloma
- Sporotrichosis
- Cryptococcosis
- Foreign body
- Chronic bite/wound abscess
- Bacterial L-form infection
- *Rhodococcus equi* infection
- Cutaneous or mucosal neoplasm, especially squamous cell carcinoma

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal; possible neutrophilic leukocytosis in cats.

DIAGNOSTIC PROCEDURES

Dogs

- Cytologic examination of crusts—most important procedure; differentiates from more typical bacterial pyoderma.
- Organism—distinctive morphology in cytologic and histopathologic preparations; resembles “railroad tracks” as the bacterium forms branching chains of small diplococci.
- Cytologic diagnosis—impression smears of exudate from under crusts or by preparation of macerated crusts; mince crusts finely in a drop of water and allow to macerate several minutes; dry the preparation and stain with Wright-Giemsa.
- Histopathologic specimens—crusts contain organisms; submit with tissue samples.

Cats

- Histopathologic examination—biopsy of nodules; procedure of choice.
- Cytologic examination—exudate obtained from aspiration of nodule or swabbing of a draining tract.
- Culture of biopsy specimens—may yield the organism; facilitated if the laboratory is alerted to the differential diagnosis of *Dermatophilus* (aerobic, relatively slow growing, and easily obscured by contamination).
- Culture from crusts—requires the use of special selective medium; isolation is possible but usually very difficult.

PATHOLOGIC FINDINGS

- Dogs—crusting and superficial pustular dermatitis; palisading of the crusts with orthokeratotic and parakeratotic hyperkeratosis; organism visualized within the crusts.
- Cats—pyogranulomatous inflammation; central necrosis; fistulous tract formation; organism visualized near the necrotic center of granulomas, especially with Gram stain.

TREATMENT

- Dogs—antibacterial shampoo and gentle removal (and disposal) of crusts; shampoo containing benzoyl peroxide, ethyl lactate, chlorhexidine, or selenium disulfide; one or two applications suffice in most cases. Iodine or lime-sulfur may also be used.
- Cats—for pyogranulomas and abscesses: surgical debridement; exploration for foreign body; establishment of drainage for exudate.

MEDICATIONS

DRUG(S)

- Penicillin V 10 mg/kg PO q12h for 10–20 days; drug of choice.
- Tetracycline 22–30 mg/kg, q8h, PO; doxycycline 5–10mg/kg, q12h, PO; or minocycline 5–12 mg/kg, q12h, PO.
- Ampicillin 10–20 mg/kg PO q12h for 10–20 days; some isolates resistant in vitro.
- Amoxicillin 10–20 mg/kg PO q12h for 10–20 days; some isolates resistant in vitro.

CONTRAINdications/POSSIBLE INTERACTIONS

Penicillin and ampicillin hypersensitivity

FOLLOW-UP

PATIENT MONITORING

- Dogs—reexamine after 2 weeks of treatment to ensure complete resolution; give an additional 7 days of systemic therapy if indicated.
- Cats—monitor biweekly for 1 month after apparent resolution of lesions, depending on location.

EXPECTED COURSE AND PROGNOSIS

- Dogs—excellent.
- Cats—varies with the location of lesions; recurrence possible due to persistence of organism in crusts and extent of surgical debridement; complete resolution can be achieved with early diagnosis and medical/surgical therapy.

MISCELLANEOUS

ZOONOTIC POTENTIAL

- Veterinarians and animal care workers—seldom infected, even after traumatic exposure when working with infected farm animals.
- Dogs and cats—unlikely but possible to serve as a source for human infection; caution is warranted for exposure of immunocompromised individuals.

Greene CE. Dermatophilosis. In: Greene CE, ed., *Infectious Diseases of the Dog and Cat*, 3rd ed. St. Louis, MO: Saunders Elsevier, 2006, pp. 488–490.

Author Mitchell D. Song

Consulting Editor Alexander H. Werner

DERMATOPHYTOSIS

D

BASICS

DEFINITION

- A cutaneous fungal infection affecting the cornified regions of hair, nails, and occasionally the superficial layers of the skin.
- *Microsporum* and *Trichophyton* dermatophytes are most commonly isolated: the majority of cases caused by *Microsporum canis*; infection with *Trichophyton mentagrophytes*, *M. gypseum*, or *M. persicolor* also occurs.

PATHOPHYSIOLOGY

- Dermatophytes—grow in the keratinized layers of hair, nail, and skin; do not thrive in living tissue or persist in the presence of severe inflammation.
- Exposure to or contact with a dermatophyte does not necessarily result in an infection.
- Infection may not result in clinical signs.
- Incubation period from exposure to clinical lesions: approximately 2–4 weeks.
- Infective spores must contact the skin surface and defeat host protective mechanisms (innate immunity, normal flora, sebum, grooming), in order for infection to occur.
- Factors that favor the development of disease: stress, trauma, ectoparasite infestations, and immunosuppression.
- An infected animal may remain as an asymptomatic (inapparent) carrier for a prolonged period of time; some animals never become symptomatic.

SYSTEMS AFFECTED

Skin/Exocrine

INCIDENCE/PREVALENCE

- Lesions may mimic many dermatologic conditions; over-diagnosis is likely common.
- Infection rates (inapparent and clinical) vary widely, depending on the population studied.

GEOGRAPHIC DISTRIBUTION

- More common in hot, humid climates.
- Incidence of dermatophyte species may vary seasonally and geographically (e.g., northern vs. southern hemisphere, rural vs. urban environment, indoor vs. outdoor housing).

SIGNALMENT

Species

Dog and cat

Breed Predilections

- Cat—more common in longhaired breeds (i.e., Persian and Himalayan)
- Dog: Yorkshire terrier and Manchester terrier

Mean Age and Range

- *M. canis* is more common in younger animals; other species (associated with rodents or wildlife) seen more often in adults.
- Generalized dermatophytosis in older dogs associated with immunosuppression.

SIGNS

Historical Findings

Previously confirmed infection or exposure to an infected animal or environment (e.g., a cattery) is a useful but not consistent finding.

Physical Examination Findings

- Inapparent carrier state—cats.
- Only consistent finding is extreme variability of clinical signs.
- Classical lesion: slowly expanding circular patch of alopecia with scale.
- Seborrheic or greasy hair coat.
- Papular or pustular eruptions.

CAUSES

Multiple species identified; majority of cases caused by *Microsporum canis*, *Microsporum gypseum*, *Trichophyton mentagrophytes*, and *Microsporum persicolor* (non-follicular).

RISK FACTORS

- Immunocompromise caused by disease (FeLV, FIV) or by medications (glucocorticoids).
- High population density.
- Poor management practices.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Staphylococcal folliculitis
- Demodexis
- Allergic dermatitis
- Pemphigus (especially foliaceus)
- Keratinization defects

DIAGNOSTIC PROCEDURES

Wood's Lamp Examination

- Can be misleading: only 50% of *M. canis* isolates fluoresce; most other pathogenic dermatophytes do not fluoresce.
- True positive reaction consists of apple-green fluorescence of the hair shaft.

Microscopic Examination of Hair

- Choose hairs that fluoresce under Wood's lamp illumination to increase success.
- Hyphae and arthrospores seen invading hair shafts.

Fungal Culture with Identification

- "Gold standard" for diagnosis.
- Choose hairs that fluoresce under Wood's lamp if possible.
- Sampling methods: Pluck hairs from the periphery of an alopecic area. Brush haircoat with a sterile toothbrush or carpet square (especially inapparent or treated patient).
- Dermatophyte test media—dermatophytes change media color to red during the early growing phase of the culture; saprophytes cause color change after significant colony growth; examine inoculated media daily.
- Fungal colonies are non-pigmented.
- Microscopic examination of the growth for microconidia and macroconidia—necessary to confirm pathogenic dermatophyte and to identify

genus and species; helps identify source of infection.

- Positive culture—indicates presence of a dermatophyte; however, organisms may be transient (i.e., geophilic dermatophytes on the feet).

Skin Biopsy

- Not usually required for diagnosis.
- Can be helpful in confirming true invasion and infection, or to diagnose suspicious cases with negative fungal culture.

PATHOLOGIC FINDINGS

- Folliculitis, perifolliculitis, or furunculosis.
- Hyperkeratosis, intraepidermal pustules, and pyogranulomatous reaction pattern may occur.
- Fungal hyphae seen in H&E-stained sections; special stains allow easier visualization of the organism.

TREATMENT

APPROPRIATE HEALTH CARE

- Most animals are treated as outpatients.
- Consider quarantine owing to the infective and zoonotic nature of the disease.

CLIENT EDUCATION

- Many shorthaired cats in a single-cat environment and many dogs will undergo spontaneous remission within 3 months.
- Longhaired animals should be clipped to reduce environmental contamination.
- Decontamination of the environment reduces the risk of false positive fungal cultures which can lead to prolonged treatment and confinement.
- Infective spores are shed into the environment, but do not multiply in the environment; transmission of the disease strictly from a contaminated environment (i.e., no direct contact with an infected animal) is extremely rare.
- Effective disinfectants
 - Sodium hypochlorite (0.5%): potential to react with other chemicals to create toxic gases; can be irritating and result in "bleaching" of colors.
 - Enilconazole: available as a concentrated spray or fogger; 10-minute contact time is recommended.
 - Accelerated hydrogen peroxide: should not be mixed with concentrated sodium hypochlorite products; 10-minute contact time recommended.
 - Potassium peroxyomonosulfate (2% solution): recent studies report antifungal properties against *M. canis* and *Trichophyton* spp.
- Advise that treatment can be both frustrating and expensive, especially in multi-animal households or with recurrent cases; consider referral to a veterinarian with expertise in treatment of dermatophytosis.

DERMATOPHYTOSIS

(CONTINUED)

MEDICATIONS

DRUG(S) OF CHOICE

- Topical therapy and clipping—recommended concurrently with systemic therapy; may help prevent environmental contamination; may be associated with an initial exacerbation of signs
- Rinses: lime sulfur (1:16 dilution or 8 oz. per gallon of water), miconazole/ chlorhexidine (0.2%), or enilconazole (0.2%) applied once to twice weekly; lime sulfur is odoriferous and can stain; enilconazole is not currently approved for use in companion animals in the US. Shampoos containing 1–2% ketoconazole, miconazole, or 0.5% climbazole; a minimum of a 3-minute contact time is recommended; have little to no residual effect.
- Use of an Elizabethan collar, particularly in cats, is recommended to prevent ingestion of these products.
- Griseofulvin—effective but use is declining due to relatively high costs and side effects.
- Ketoconazole—true efficacy unknown; some studies have shown *in vitro* resistance of *M. canis*: dogs, 10 mg/kg PO q24h or divided q12h for 4–8 weeks; anorexia and vomiting are the most common side effects; not recommended in cats.
- Itraconazole—similar to ketoconazole, but more effective; fewer side effects, expensive: dogs, 5–10 mg/kg PO q24h for 4–8 weeks; cats, 10 mg/kg PO q24h for 4–8 weeks or until cured. Alternate dosing—20 mg/kg q48h cats and dogs. In some cats, dosage regimen is altered after 4 weeks of therapy to every other week schedule for a total of 8–10 weeks of therapy; alternative schedule—one-week-on, one-week-off with apparent efficacy to reduce drug cost; manufactured drug preferred over compounded formulations due to absorption/concentration variability.
- Terbinafine—may be helpful in cases resistant to azole drugs; dogs, 20–30 mg/kg q12–24h for 4–8 weeks; cats, 20–40 mg/kg q24–48h for 4–8 weeks; dermatophyte carriers, 8.25 mg/kg q24h for 4–8 weeks; side effects may include gastrointestinal upset, hepatotoxicity, neutropenia, and pancytopenia.

CONTRAINdications

- Corticosteroids: can modulate inflammation and prolong the infection. • Griseofulvin: cats with FeLV or FIV; teratogen.

PRECAUTIONS

Ketoconazole

- Hepatopathy has been reported and can be severe in cats. • Inhibits endogenous production of steroid hormones in dogs.

Itraconazole

- Rare vasculitis and ulcerative skin lesions at doses of 5 mg/kg q12h; not noted in patients receiving 5 mg/kg q24h. • Hepatotoxicity reported infrequently in dogs.

Terbinafine

- Gastrointestinal upset, hepatotoxicity, and bone marrow suppression (pancytopenia, neutropenia). Decrease dosage with renal and/or hepatic insufficiency. Cimetidine increases blood concentration; rifampin decreases blood concentration.

Lime-Sulfur Solution

- Ingestion of lime sulfur may lead to oral erosions.

ALTERNATIVE DRUG(S)

- Lufenuron—a chitin synthesis inhibitor used in flea control; not effective in controlled studies. • Fluconazole—effectiveness not well documented in studies; less expensive than itraconazole.

FOLLOW-UP

PATIENT MONITORING

- Dermatophyte culture is the only appropriate method for monitoring response to therapy; many animals clinically improve but remain culture-positive. • Repeat fungal cultures toward the end of the treatment regimen and continue treatment until at least two subsequent cultures are negative. • In resistant cases, cultures should be repeated weekly using the toothbrush technique.
- Weekly or biweekly CBC if treating with griseofulvin; periodic evaluation of liver enzymes if treating with ketoconazole, itraconazole, or terbinafine.

PREVENTION/AVOIDANCE

- Initiate a quarantine period and obtain dermatophyte cultures of all animals entering the household to prevent reinfection from inapparent carriers. • Consider the possibility of rodents aiding in the spread of the disease.
- Decontaminate the environment. • Avoid infective soil if a geophilic dermatophyte is cultured. • Consider prophylactic treatment of exposed animals.

POSSIBLE COMPLICATIONS

False-negative dermatophyte culture

EXPECTED COURSE AND PROGNOSIS

- Many animals will “self-clear” infection over a period of a few months. • Treatment hastens clinical cure and helps reduce environmental contamination. • Some infections, particularly in longhaired cats or multi animal situations, can be persistent.

MISCELLANEOUS

ZOONOTIC POTENTIAL

- Dermatophytosis is a significant zoonosis. • Considered a low level pathogen; disease is not life-threatening, can be easily treated, but may cause scarring.

PREGNANCY/FERTILITY/BREEDING

- Griseofulvin is teratogenic. • Ketoconazole can affect steroid hormone synthesis, especially testosterone.

SYNONYMS

Ringworm

ABBREVIATIONS

- FeLV = feline leukemia virus • FIV = feline immunodeficiency virus • H&E = hematoxylin and eosin

DERMATOSES, DEPIGMENTING DISORDERS

BASICS

DEFINITION

- Pathologic or cosmetic condition involving loss of pigmentation of the skin and/or hair coat either by lack of pigmentation or by melanocyte damage.
- Leukotrichia—whitening of the hair (nonspecific location).
- Poliosis—whitening of hair on the head/face.
- Leukoderma—whitening of the skin.

PATHOPHYSIOLOGY

- Dependent on cause.
- Melanocytes may be damaged or destroyed by toxins (including toxic melanin precursors), inflammatory mediators, auto-antibodies, and/or inhibitors of melanogenesis.
- Some diseases may be distinguished clinically by depigmentation as the initial symptom versus depigmentation occurring secondary to inflammation.

SYSTEMS AFFECTED

- Skin/Exocrine
- Ophthalmic

GEOGRAPHIC DISTRIBUTION

Discoid lupus erythematosus and pemphigus erythematosus more common in locations with higher exposure to ultraviolet light.

SIGNALMENT

- Mucocutaneous pyoderma—German shepherd dog
- Systemic lupus erythematosus—German shepherd dog
- DLE—collie, Shetland sheepdog, German shepherd dog, Siberian husky; may occur more often in females
- Pemphigus foliaceus—chow chow, Akita, cocker spaniels, dachshunds, Labrador retriever
- Uveodermatologic syndrome—Akita, Samoyed, Siberian husky
- Vitiligo—Dogs: Belgian Tervuren, German shepherd dog, Doberman pinscher, rottweiler, German shorthaired pointer, Old English sheepdog, dachshund; usually less than 3 years of age: Cats: Siamese
- Seasonal nasal hypopigmentation—Siberian husky, Alaskan malamute, yellow Labrador retriever, golden retriever
- Epitheliotropic lymphoma (mycosis fungoïdes)—typically dogs > 10 years old
- Proliferative arteritis of the nasal philtrum—Saint Bernard, giant schnauzer
- Periocular leukotrichia—Siamese cat
- Chediak-Higashi syndrome—Persian cat

SIGNS

- Leukotrichia
- Leukoderma
- Lightening of the pigmentation in the skin (seen as a “graying” or “browning” of previously pigmented areas)

- Erythema
- Erosion and ulcerations

CAUSES

- Mucocutaneous pyoderma
- Discoid lupus erythematosus
- Systemic lupus erythematosus
- Pemphigus foliaceus
- Pemphigus erythematosus
- Uveodermatologic syndrome
- Contact hypersensitivity
- Vitiligo
- Seasonal nasal depigmentation
- Albinism
- Schnauzer gilding syndrome
- Endocrinopathy
- Drug reaction
- Erythema multiforme
- Proliferative arteritis of the nasal philtrum
- Post-inflammatory depigmentation
- Immune-mediated pigmentary incontinence

RISK FACTORS

Sun exposure—DLE, SLE, and PE

Drug triggered—PF, EM

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Mucocutaneous Pyoderma

- Depigmentation is secondary and develops with chronicity.
- Skin lesions—affects the lips, perioral area, and nasal/alar folds.
- Clinically similar to intertrigo (skin-fold bacterial folliculitis).
- Swelling and fissuring leads to erosions and crusts.
- Biopsy—epidermal hyperplasia with superficial pustulation.
- Very antibiotic-responsive.
- Frequent recurrence if due to an underlying cause.

Nasal Solar Dermatitis

- Depigmentation is secondary and develops with chronicity.
- Lesions confined primarily to dorsal muzzle and precipitated by actinic radiation.
- Begins in poorly pigmented skin at the junction of the nasal planum and dorsal muzzle.
- Negative for direct immunofluorescence.
- Solar vasculopathy may appear similar.

Discoid Lupus Erythematosus

- Depigmentation is a primary symptom.
- Primarily affects nasal area, eyelid margins, and lip margins.
- Exacerbated by actinic radiation.
- Positive direct immunofluorescence at basement membrane zone.
- Biopsy—interface dermatitis.

Systemic Lupus Erythematosus

- Depigmentation is a primary symptom.
- Multisystemic disease.

- Skin lesions—often involve nose, face, and mucocutaneous junctions; multifocal or generalized.
- ANA—positive.
- Positive direct immunofluorescence at basement membrane zone.

Pemphigus Foliaceus

- Depigmentation is secondary and develops with chronicity.
- Lesions—usually start on face and ears; commonly involve footpads; eventually generalized.
- Biopsy—subcorneal pustules with acantholysis.
- Positive direct immunofluorescence in intercellular spaces of epidermis.

Pemphigus Erythematosus

- Depigmentation is a primary symptom.
- Lesions—primarily confined to face and ears, nasal planum, and lip margins.
- Depigmentation is more striking than in PF and often precedes significant lesions.
- Exacerbated by actinic radiation.
- Biopsy— intraepidermal pustules with acantholysis and interface dermatitis.
- Positive direct immunofluorescence at basement membrane zone and intercellular spaces.
- ANA—occasionally positive.

Uveodermatologic Syndrome

- Depigmentation is a primary symptom.
- Uveitis—usually (but not always) precedes dermatologic disease.
- Cutaneous macular depigmentation with inflammation on nose, lips, and eyelids.
- Striking poliosis and leukotrichia.
- Biopsy of early lesions—interface dermatitis, pigmentary incontinence.

Others

- Plastic or rubber dish/toy dermatitis (very uncommon)—depigmentation is secondary and develops with chronicity; erythema of the rostral nasal planum and lips; no ulceration and minimal crusting; history of exposure.
- Vitiligo—depigmentation is a primary symptom; cutaneous macular depigmentation without inflammation on nose, lips, eyelids, footpads, and nails; leukotrichia may be present with leukoderma.
- Seasonal nasal hypopigmentation—depigmentation is a primary symptom; normal black coloration of nasal planum fades to light tan or pink; usually seasonal or slowly progressive with age.
- Albinism—hereditary lack of pigment of the skin, hair coat, and irises (not a depigmenting process).
- Schnauzer gilding syndrome—young miniature gray schnauzers may develop idiopathic golden hair coat coloration, primarily of the trunk.
- Endocrinopathy can cause coat color change, mainly from black to reddish-brown.
- Drug reaction—depigmentation is often secondary; resembles many cutaneous

DERMATOSSES, DEPIGMENTING DISORDERS

(CONTINUED)

- disorders such as DLE, SLE, PF, and PE; pruritus is variable; onset of symptoms is usually within 2 weeks of administration.
- Proliferative arteritis of the nasal philtrum—depigmentation is secondary and develops with chronicity; marked focal ulceration of the nasal planum often resulting in acute, severe hemorrhage. No additional skin lesions noted. This may be an idiopathic syndrome associated with allergy.
 - Dermatophytosis—depigmentation is secondary and develops with chronicity; especially develops on the dorsal muzzle and face. Hyperpigmentation may also occur, especially with *Trichophyton mentagrophytes* infection.
 - Epitheliotropic lymphoma—depigmentation is secondary and develops with chronicity; occurs in mucocutaneous areas, nose, and skin.
 - Erythema multiforme in dogs—classic annular lesions with a clear center; depigmentation is secondary and develops with chronicity.
 - Zinc deficiency—depigmentation may be a primary or secondary symptom; zinc is required for normal melanin synthesis.
 - Chediak-Higashi syndrome—depigmentation is a primary symptom; young Persian cats (blue smoke color); ophthalmologic signs, prolonged bleeding.
 - Cyclic neutropenia in young silver-gray collie dogs with light-colored nose.
 - Post-inflammatory depigmentation is a benign loss of pigment and should resolve when the cause of inflammation is treated.
- CBC/BIOCHEMISTRY/URINALYSIS**
- Usually normal.
 - SLE—may see hemolytic anemia, thrombocytopenia, or evidence of glomerulonephritis.
 - Hematologic abnormalities in Persian cats with Chediak-Higashi syndrome.
 - Cyclic neutropenia in collie dogs (cyclic hematopoiesis anomalies).
- OTHER LABORATORY TESTS**
- Fungal culture—dermatophytosis
 - ANA—positive in most cases of SLE
- DIAGNOSTIC PROCEDURES**
- Cytology—acantholytic cells (pemphigus), neoplastic lymphocytes (epitheliotropic lymphoma).
 - Joint tap—evidence of polyarthritis in SLE.
 - Ocular examination—uveitis in uveodermatologic syndrome.
 - Direct immunofluorescence—deposition of immunoglobulin at the basement membrane zone with DLE, SLE, and PE, and in the intercellular spaces of the epidermis with PF and PE.
 - Skin biopsy.

PATHOLOGIC FINDINGS

Histopathologic examination of the skin

- Interface dermatitis—DLE, SLE, uveodermatologic syndrome.
- Pigmentary incontinence—DLE, PE.
- Intraepidermal pustules with acantholysis—PF and PE.
- Hypomelanosis—vitiligo, uveodermatologic syndrome, seasonal nasal hypopigmentation, and schnauzer gilding syndrome.
- Apoptosis (individual cell necrosis of keratinocytes)—drug reaction and erythema multiforme.
- Proliferation of spindle cells of dermal arteries and arterioles—proliferative arteritis.
- Infiltration of neoplastic lymphocytes—epitheliotropic lymphoma.

TREATMENT

- Outpatient, except for SLE, EM, and cutaneous lymphoma with systemic involvement.
- Reduce exposure to sunlight—DLE, SLE, and PE.
- Immunosuppressive therapy—SLE, PF, PE.
- Avoid contact with topical drugs.
- Replace plastic or rubber dishes—particularly if roughened edges cause abrasions.
- Application of water-resistant sunblock ointments or gels with an SPF/UVA and UVB > 30 to depigmented and sun-exposed areas of skin.
- Uveodermatologic syndrome—management by veterinary ophthalmologist recommended.
- Appropriate antibiotics—pyoderma.
- Appropriate antifungals—dermatophytosis.

MEDICATIONS

DRUG(S) OF CHOICE

- SLE—immunosuppressive therapy with prednisolone or dexamethasone and azathioprine (dogs) or chlorambucil (cats).
- Tetracycline and niacinamide (dogs, < 10 kg 250 mg each q8h; > 10 kg, 500 mg each q8h): PE, DLE.
- Topical corticosteroids—PE, DLE.
- Vitiligo and nasal depigmentation—no treatment.
- Epitheliotropic lymphoma—multiple treatment protocols.

CONTRAINDICATIONS

Azathioprine therapy—not recommended in cats; may cause fatal leukopenia or thrombocytopenia.

PRECAUTIONS

Ketoconazole may cause lightening of the hair coat, elevated alkaline phosphatase, and gastrointestinal distress.

ALTERNATIVE DRUG(S)

- Cyclosporine, modified—5 mg/kg/day for auto-immune disorders.
- Tacrolimus—0.1% gel applied daily to lesions in combination with or to replace corticosteroids. May sting. Avoid licking. Wear latex gloves to apply.
- Pimecrolimus—1% cream applied daily to lesions in combination with or to replace corticosteroids. May sting. Avoid licking. Wear latex gloves to apply.

FOLLOW-UP

PATIENT MONITORING

Varies with specific disease and treatment prescribed.

POSSIBLE COMPLICATIONS

- Sunburn in areas of depigmentation.
- Squamous cell carcinoma—in cases of solar damage and actinic keratosis of depigmented areas.
- SLE—associated scarring with ulcerative dermatitis.

MISCELLANEOUS

ZOONOTIC POTENTIAL

Dermatophytosis—can cause infection in humans.

DERMATOSSES, EROSIONS OR ULCERATIVE

BASICS

DEFINITION

A heterogenous group of skin disorders characterized by disruption of the epidermis (erosions) or, if the basement membrane is compromised, the epidermis and dermis (ulcers).

PATOPHYSIOLOGY

Varies widely, depending on the cause; may include congenital or developmental disorders that compromise tissue cohesion; cell-mediated (inflammatory or neoplastic) injury; anoxic injury; antigen-specific auto-immune disorders; and necrosis due to trauma, toxins, contactants (irritants), microbial organisms, or parasitic migration.

SYSTEMS AFFECTED

Skin/Exocrine

GENETICS

Some diseases are likely heritable due to breed predilections; however, there are no genetic screening tests available for any of the diseases listed.

INCIDENCE/PREVALENCE

- Rare to common, depending on the cause.

SIGNALMENT

Species

Dogs and cats

Breed Predilections

Some specific causes (see below) have strong breed predilections, e.g., lupoid disorders, familial dermatomyositis and zinc-responsive dermatosis.

Mean Age and Range

- Highly variable according to etiology.
- Canine juvenile cellulitis and several congenital diseases (see below) are diagnosed in very young animals.

Predominant Sex

Sex predispositions may vary according to the disease in question.

SIGNS

Historical Findings

- Pruritus may result in ulcers or erosions due to self-trauma; especially ectoparasitism, superficial pyoderma, and *Malassezia* dermatitis.
- Exposure to caustic chemicals, burns, cold stress, venomous reptiles and insects, etc.
- Some infectious diseases (e.g., pythiosis, coccidioidomycosis, feline cow pox) have very restricted ranges.
- Previous or concurrent systemic symptoms or illness.

Physical Examination Findings

- Lesions may be heterogenous in gross appearance. Some diseases result in erythematous erosions with minimal crust or scale, while others cause scale or crusting that (when removed) results in erosion.
- Ulcers may be shallow/superficial or deep; deep

ulceration can present as sinuses with draining tracts, cavitated lesions with well-demarcated borders, or exudative crusted lesions.

- Some specific diseases are typically accompanied by fever and malaise; especially auto-immune disorders and infectious etiologies.
- May be associated with extra-cutaneous disease (e.g., superficial necrolytic dermatitis and hypereosinophilic syndrome of cats).

CAUSES

Auto-immune

- Pemphigus foliaceus*: crusting with erosion.
- Pemphigus vulgaris*: superficial ulcerative.
- Bullous pemphigoid* and *epidermolysis bullosa acquisita*: superficial ulcerative.
- Discoid lupus erythematosus*: erosive or superficial ulcerative.
- Exfoliative lupus* (German shorthaired pointers): scaling with erosion.
- Vesicular lupus* (rough collies and Shetland sheepdogs): superficial ulcerative.
- Cold agglutinin disease*: deep ulcerative.

Immune-Mediated

- Erythema multiforme* and toxic epidermal necrolysis (usually drug-induced): erosive to superficial ulcerative.
- Vasculitis*: superficial to deep ulcerative (may be cavitated).
- Idiopathic panniculitis*: deep ulcerative (usually exudative with crusting).
- Canine eosinophilic furunculosis* of the face (may be insect-related): ulcerative and crusting.
- Canine juvenile cellulitis* (puppy strangles): erosive to superficial or deep ulcerative.
- Feline indolent ulcer* (rodent ulcer): erosive to superficial or deep ulcerative.

Infectious

- Surface pyoderma*: acute moist pyotraumatic dermatitis ("hot spots"): erosive.
- Superficial staphylococcal folliculitis*: erosive to superficial ulcerative.
- Bacterial folliculitis/furunculosis*: deep ulcerative (usually crusted, with or without sinuses and draining tracts).
- Superficial fungal* (*Malassezia* dermatitis, dermatophytosis): erosive to superficial ulcerative.
- Deep fungal* (e.g., sporotrichosis, cryptococcosis, histoplasmosis, blastomycosis, coccidioidomycosis): deep ulcerative with or without sinuses and draining tracts.
- Opportunistic mycobacteriosis*: deep ulcerative nodules with sinuses and draining tracts.
- Actinomycetic bacteria* (e.g., *Nocardia* spp., *Actinomyces* spp., *Streptomyces* spp.): deep ulcerative nodules with sinuses and draining tracts.
- Pythiosis/laegenidiosis* and *protothecosis*: ulcerative, proliferative with or without draining tracts.
- Leishmaniasis*: erosive to superficial or deep ulcerative.
- Feline cow pox*: deep ulcerative.
- FIV/FeLV-related*: erosive to superficial ulcerative.
- Feline herpesvirus-associated dermatosis*: ulcerative with crusting.

Parasitic

- Demodicosis*: ulcerative with crusting (especially with secondary bacterial

folliculitis).

- Sarcoptic/notoedric mange*: erosive with crusting.
- Flea bite allergy*: erosive to ulcerative (if secondary infection is present).
- Feline mosquito bite hypersensitivity*: erosive to superficial or deep ulcerative.
- Pelodera* and hookworm migration: deep ulcerative.

Congenital/Hereditary

- Canine familial dermatomyositis* (predominantly in collies and Shetland sheepdogs): erosive.
- Epidermolysis bullosa*: superficial ulcerative.
- Cutaneous asthenia* (Ehlers-Danlos syndrome): skin tears.

Metabolic

- Superficial necrolytic dermatitis* (usually associated with hepatic disease or pancreatic glucagonoma): crusting with erosion.
- Hyperadrenocorticism*: erosive to ulcerative when complicated by secondary infections or calcinosis cutis.
- Uremia* (mucous membranes): superficial ulcerative.

Neoplastic

- Squamous cell carcinoma*: erosive to ulcerative with scale or crust.
- Feline squamous cell carcinoma in situ* (Bowenoid *in situ* carcinoma): erosive with scale or crust.
- Mast cell tumors*: superficial to deep ulcerative.
- Epitheliotropic lymphoma* (mycosis fungoides): erosive to superficial ulcerative.
- Feline thymoma-associated exfoliative dermatosis*: scaling with erosion.
- Feline paraneoplastic alopecia*: erosive.

Nutritional

- Zinc-responsive dermatosis*: crusting with erosion.
- Generic dog food dermatosis*: crusting with erosion.

Physical/Conformational Dermatoses

- Pressure point ulcers*: deep ulcerative.
- Intertrigo* (skin fold pyoderma): erosive.
- Self-trauma* as a result of pruritic dermatoses: highly variable.

Idiopathic

- Feline dorsal neck ulcer*: deep ulcerative with crusting.
- Canine and feline acne*: erosive to ulcerative with crusting (especially with secondary bacterial infection).
- Feline plasma cell pododermatitis*: superficial to deep ulcerative.

Miscellaneous

- Thermal, electrical, solar, or chemical burns*: depth of lesions depends on severity of insult.
- Frost bite*: depth of lesions depends on severity of insult.
- Chemical irritants*: depth of lesions depends on severity of insult.
- Venomous snake and insect bites*: deep ulcerative (usually with necrosis).

RISK FACTORS

Highly variable according to disease (e.g., underlying immunosuppression associated with secondary infectious diseases).

DERMATOSSES, EROSIONS OR ULCERATIONS

(CONTINUED)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

History and physical examination are especially important due to the extensive differential list. Many of these diseases exhibit subtle differences in appearance and distribution of lesions. Careful attention to the character and progression of lesions, and the distribution pattern on the patient, can yield valuable clues.

CBC/BIOCHEMISTRY/URINALYSIS

Most helpful when metabolic disease is suspected or in any patient with signs of systemic disease.

OTHER LABORATORY TESTS

See "Diagnostic Procedures" for routine tests.

IMAGING

- Rarely indicated.
- Thoracic radiographs—for deep/systemic fungal diseases, feline thymoma-associated exfoliative dermatitis, and systemic neoplasia.
- Abdominal ultrasound—superficial necrolytic dermatitis (dogs) or paraneoplastic alopecia (cats) suspected or confirmed by skin biopsy.

DIAGNOSTIC PROCEDURES

- Skin scraping—suspected parasitism.
- Direct impression cytology—identify bacteria, yeast, or acantholytic keratinocytes in pemphigus.
- Fine-needle aspirate with cytology—indurated or nodular lesions.
- Culture: bacterial (aerobic and anaerobic), mycobacterial, and/or fungal—suspected infectious disease (especially in cats with ulcers or draining tracts).
- Fungal serology and serology for pythiosis and lagendiosis may be indicated on a case-by-case basis and depending upon geographic location.
- PCR and immunohistochemistry are adjuncts to the histologic diagnosis of feline herpesvirus-associated dermatitis.

PATHOLOGIC FINDINGS

- Skin biopsy for histopathology—most informative test.
- For cavitated lesions, the leading edge should be harvested with a scalpel blade if the defect is too large to be excised in total.
- Punch biopsy sufficient for diffuse erosive lesions; should take normal skin near a lesion and lesions that are both early and late in their development.

TREATMENT

APPROPRIATE HEALTH CARE

- Outpatient for most diseases
- Varies widely according to the cause

NURSING CARE

- Supportive therapy.
- Pain control may be an important consideration for some animals.

ACTIVITY

No restrictions necessary for most conditions (except zoonotic infections and infestations).

DIET

- Nutritional support may be necessary in debilitated animals, especially those with superficial necrolytic dermatitis.
- Correcting dietary deficiencies is the only treatment for generic dog-food dermatosis.
- Supplementation of zinc is necessary for zinc-responsive dermatosis.

CLIENT EDUCATION

Variable by diagnosis; most important with suspected or diagnosed zoonotic disease.

SURGICAL CONSIDERATIONS

- Indicated as curative treatment for feline thymoma-associated exfoliative dermatitis.
- May be curative for non-metastatic pancreatic or hepatobiliary tumors causing paraneoplastic alopecia.
- Radical surgical excision of nodules and draining tracts may be an adjunct to antimicrobial therapy of infections caused by rapid-growing *Mycobacterium* spp. and *Nocardia* spp. in cats and pythiosis or lagendiosis in dogs.

MEDICATIONS

DRUG(S) OF CHOICE

Vary widely according to cause

CONTRAINDICATIONS

Definitive diagnosis is imperative because some immune-mediated cases that require immunosuppression may mimic infectious diseases that require specific antimicrobial chemotherapy (and for which immunosuppression could prove fatal).

PRECAUTIONS

Side effects—associated with many antimicrobial, immunosuppressive, and antineoplastic drugs.

POSSIBLE INTERACTIONS

Dependent on medications administered

FOLLOW-UP

PATIENT MONITORING

Dependent on the disease process, concurrent systemic disease(s), drugs used, and potential side effects expected.

PREVENTION/AVOIDANCE

- The incidence of many feline infectious diseases can be minimized by restricting outdoor activity.
- Some auto-immune diseases (e.g., discoid lupus erythematosus and pemphigus erythematosus) are aggravated by ultraviolet light exposure; patients should be restricted from sun exposure during peak hours of the day.

POSSIBLE COMPLICATIONS

- Determined by cause.
- Some diseases are potentially life-threatening.
- Some diseases have zoonotic potential.
- Infections and drug side effects are possible in cases requiring immunosuppression.

EXPECTED COURSE AND PROGNOSIS

- Some infectious diseases (nocardiosis, atypical mycobacteriosis) may be controlled with chronic antimicrobial therapy, but are generally not curable if lesion progression is extensive by the time of diagnosis.
- Pythiosis/lagendiosis: prognosis is extremely poor for response to therapy and survival when lesions are extensive.

MISCELLANEOUS

ZOONOTIC POTENTIAL

- Sarcoptic acariasis.
- Dermatophytosis.
- Sporotrichosis.
- Mycelial phase of some fungi (e.g., *Coccidioides immitis*, *Blastomyces dermatitidis*), when grown on culture media, can be infectious to humans through inhalation. In-clinic fungal culturing (other than for dermatophytes) is not advised.

PREGNANCY/FERTILITY/BREEDING

- Due to the potential severity of clinical signs and syndromes, any patient diagnosed with an erosive/ulcerative disease that occurs with moderate to strong breed predilections should not be used for breeding.
- Many drugs used to treat the auto-immune, immune-mediated, and infectious diseases listed may be teratogens.

SYNOMYS

Superficial necrolytic dermatitis = necrolytic migratory erythema, metabolic epidermal necrosis, hepatocutaneous syndrome

SEE ALSO

Specific chapters devoted to diseases listed under "Causes"

ABBREVIATIONS

- FeLV = feline leukemia virus
- FIV = feline immunodeficiency virus
- PCR = polymerase chain reaction

DERMATOSSES, EXFOLIATIVE

D

BASICS

DEFINITION

Excessive or abnormal shedding of epidermal cells resulting in the clinical presentation of cutaneous scaling.

PATHOPHYSIOLOGY

- An increase in the production, an increase in the desquamation, or a decrease in the cohesion of keratinocytes results in abnormal shedding of epidermal cells individually (fine scale) or in sheets (coarse scale).
- Primary exfoliative disorders—keratinization defects, in which the genetic control of epidermal cell proliferation and maturation is abnormal.
- Secondary exfoliative disorders—the effects of a disease alter the normal maturation and proliferation of epidermal cells.
- Anomalies in sebaceous or apocrine gland function may be present.

SYSTEMS AFFECTED

Skin/Exocrine

SIGNALMENT

- Dog and cat.
- Primary—apparent by 2 years of age; characteristic in affected breeds (see “Causes”).
- Secondary—any age; any breed of dog or cat.

SIGNS

Historical Findings

- Excessive scaling
- Malodorous skin
- Pruritus
- Oily skin and hair

Physical Examination Findings

- Dry or greasy collections of fine or coarse scale located diffusely throughout the hair coat or focally in keratinaceous plaques
- “Rancid fat” odor
- Comedones
- Follicular casts (collection of adherent debris around the hair shaft)
- Candle wax–like deposits on hair
- Alopecia
- Pruritus
- Secondary bacterial folliculitis and/or *Malassezia* dermatitis.

CAUSES

Primary

• Primary idiopathic seborrhea (primary keratinization disorder)—primary cellular defect; accelerated epidermopoiesis and hyperproliferation of the epidermis, follicular infundibulum, and sebaceous gland. Breeds at risk: cocker and springer spaniel, West Highland white terrier, basset hound, Doberman pinscher, Irish setter, and Labrador retriever.

• Vitamin A-responsive dermatosis—nutritionally responsive seen mainly in young cocker spaniels; clinically similar to severe idiopathic seborrhea; identified by response to oral vitamin A supplementation.

• Zinc-responsive dermatosis—nutritionally responsive; results in alopecia, dry scaling, crusting, and erythema around the eyes, ears, feet, lips, and external orifices; two syndromes: young adult dogs (mainly Siberian husky and Alaskan

malamute) and rapidly growing large-breed puppies

- Ectodermal defects—follicular dysplasias; seen as color mutant or dilution alopecia; represent anomalies in melanization of the hair shaft and structural hair growth; keratinization defects theorized as causative for several syndromes; breeds commonly affected: blue and fawn Doberman pinscher, Irish setter, dachshund, chow chow, Yorkshire terrier, poodle, Great Dane, whippet, saluki, and Italian greyhound; signs include the failure to regrow blue or fawn hair with normal “point” hair growth, excessive scaliness, comedone formation, and secondary pyoderma
- Idiopathic nasodigital hyperkeratosis—excessive build-up of scale and crusts on the nasal planum and footpad margins; possibly a senile change; generally asymptomatic: seen in spaniels and retrievers. Cracking and secondary bacterial infection can cause pain
- Sebaceous adenitis—*inflammatory disease targeting sebaceous glands and ducts*. Three specific syndromes: (1) middle-aged standard poodle and Samoyed: patchy or diffuse hair loss and excessive scaling; tightly adherent follicular casts; most dogs are healthy and asymptomatic; (2) Akita: similar appearance but frequently develop severe secondary bacterial pyoderma; (3) vizsla: disease appears distinctly different and granulomatous. Other breeds show lower incidence
- Ichthyosis—rare and severe congenital disorder of keratinization; reported in West Highland white terrier, golden retriever, Cavalier King Charles spaniel, and Norfolk terrier; generalized accumulations of scale and crusts at an early age; secondary infections (bacterial and yeast) common
- Primary seborrhea in newborn Persian kittens.

Secondary

- Cutaneous hypersensitivity—atopy, flea allergic dermatitis, food allergy, and contact dermatitis; pruritus, secondary skin trauma, and irritation
- Ectoparasitism—scabies, demodicosis, and cheyletiellosis; inflammation and exfoliation
- Bacterial folliculitis—bacterial enzymatic disadhesion and increased exfoliation of keratinocytes in the attempt to shed pathogenic organisms
- Dermatophytosis—usually exfoliative; increased shedding of affected keratinocytes is a primary skin mechanism in resolving fungal infection
- Endocrinopathy—hypothyroidism: abnormalities in keratinization, failure to regrow hair, and excessive sebum production; hyperadrenocorticism: abnormal keratinization and decreased follicular activity; excessive scaling and secondary pyoderma common in both syndromes; other hormonal abnormalities may also be associated with excessive scaling
- Age—geriatric animals may have a dull, brittle, and scaly hair coat; alterations may be caused by natural changes in epidermal metabolism associated with age;

no specific defect identified

- Nutritional disorders—malnutrition and generic dog food dermatosis; result in scaling from abnormalities in keratinization
- Auto-immune dermatoses—pemphigus complex: may appear exfoliative; vesicles become scaly and crusty; cutaneous and systemic lupus erythematosus: cutaneous signs often appear as areas of alopecia and scaling
- Neoplasia—primary epidermal neoplasia (*epitheliotropic lymphoma*): may produce alopecia and scaling as epidermal structures are damaged by infiltrating lymphocytes; preneoplastic conditions (*actinic keratosis*): initially appear exfoliative
- Miscellaneous—any disease process may result in excessive scale formation due to a metabolic disorder or to cutaneous inflammation
- Exfoliative disorders—rare in cats: tail gland hyperplasia, feline thymoma-associated exfoliative dermatitis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Signalment and history—capital in distinguishing the possible causes of exfoliation
- Presence of pruritus—helps in determining the possibility of a cutaneous hypersensitivity; primary keratinization defects are often non-pruritic, unless secondary bacterial folliculitis or *Malassezia* dermatitis develops
- Concurrent signs (e.g., lethargy, weight gain, polyuria/polydipsia, reproductive failure, change in body conformation, and lack of hair regrowth), with or without inflammation, can aid in differentiation.

CBC/BIOCHEMISTRY/URINALYSIS

- Normal with primary keratinization disorders.
- Mild, nonregenerative anemia and hypercholesterolemia are consistent with hypothyroidism.
- Neutrophilia, monocytosis, eosinopenia, lymphopenia, elevated serum alkaline phosphatase, hypercholesterolemia, and hyposthenuria suggest hyperadrenocorticism.

OTHER LABORATORY TESTS

Thyroid hormone levels and adrenal function tests if an endocrinopathy is suspected; see specific chapters for test recommendations.

IMAGING

Thoracic radiographs—feline thymoma-associated exfoliative dermatitis

DIAGNOSTIC PROCEDURES

- Skin scraping—diagnose ectoparasitism
- Skin biopsy—rule out particular differential diagnoses; strongly recommended for most cases
- Intradermal allergy test—identify allergens for immunotherapy
- Restricted-ingredient food trial—identify food hypersensitivity
- Cytology of skin surface—identify bacteria and/or yeast on the skin

DERMATOSSES, EXFOLIATIVE

(CONTINUED)

- Examination of plucked hairs—macromelanosomes and structural anomalies in follicular dysplasia and color dilution alopecia.

D

TREATMENT

- Frequent and adequate topical therapy—cornerstone of proper treatment.
- Underbathing, rather than overbathing, is a common error. • Diagnose and control all treatable primary and secondary diseases.
- Recurrence of secondary infections may require repeated therapy and further diagnostics. • Maintaining control is often life-long. • Recent emphasis on restoring epidermal barrier integrity and function.

MEDICATIONS

DRUG(S) OF CHOICE

Shampoos

- Contact time—5–15 minutes required; > 15 minutes discouraged, may result in epidermal maceration, loss of barrier function, and excessive epidermal drying and irritation
- Hypoallergenic—useful only in mild cases of dry scale and to maintain secondary exfoliation after the primary disease has been controlled
- Sulfur/salicylic acid—keratolytic, keratoplastic, and bacteriostatic; excellent first choice for the moderately scaly patient; not overly drying
- Benzoyl peroxide—strongly keratolytic, and antimicrobial; may cause irritation and severe dryness; good for recurrent bacterial infection and/or extreme greasiness
- Ethyl lactate—less effective than benzoyl peroxide for antimicrobial activity, but not as irritating or drying; most useful for moderate bacterial folliculitis and dry scale
- Chlorhexidine—antimicrobial; mildly drying; useful for moderate bacterial folliculitis and *Malassezia* dermatitis
- Tar—keratolytic, keratoplastic, and antipruritic; less degreasing than benzoyl peroxide; use for moderate scale associated with pruritus, can be irritating, might be carcinogenic.

Moisturizers

- Excellent for restoring skin hydration and increasing effectiveness of subsequent shampoos
- Humectants—enhance hydration of the stratum corneum by attracting water from the dermis; at high concentrations may be keratolytic

- Propylene glycol spray (50–75% dilution with water) applied frequently
- Microencapsulation—may improve the residual activity of moisturizers by allowing sustained release after bathing
- Emollients—coat the skin; smooth the roughened surfaces produced by excessive scaling; usually combined with occlusives to promote hydration of the epidermis.

Systemic Therapy

- Specific causes require specific treatments (e.g., thyroxine replacement for hypothyroidism; zinc supplements for zinc-responsive dermatosis)
- Systemic antibiotics—indicated for secondary pyoderma
- Retinoids—varied success for idiopathic or primary seborrhea; reports of individual response to retinoid in refractory cases: isotretinoin (1 mg/kg PO q12–24h); if response is seen, taper dosage (1 mg/kg q48h or 0.5 mg/kg q24h); difficult to dispense due to strict prescription procedures.
- Cyclosporine 5 mg/kg/day until controlled, then decreased to minimal effective maintenance dosage for individual cases of keratinization disorder associated with hypersensitivity, sebaceous adenitis, epidermal dysplasia, ichthyosis, and/or *Malassezia* dermatitis.

PRECAUTIONS

- Corticosteroids—may be used judiciously to control the inflammation resulting from many exfoliative disorders; will mask signs of pyoderma and prevent accurate diagnosis of primary disease • Vitamin A- and D-analogs—side effects can be severe; thus, patients should be referred to a dermatologist before being treated with these drugs; teratogenic.

FOLLOW-UP

PATIENT MONITORING

- Antibiotics and topical therapy—monitor response every 3 weeks; patients may respond differently to the various topical therapies
- Development of additional diseases (especially cutaneous hypersensitivity), and recurrence of pyoderma—may cause previously controlled patients to worsen; reevaluation critical to determine if new factors are involved and if changes in therapy are necessary • Endocrinopathy—routine thyroid monitoring or ACTH-stimulation tests should be used for proper management
- Selective autoimmune disorders—reevaluate frequently during the initial phase of

induction; less often after remission; clinical evaluation and laboratory data required

- Immunosuppressive therapy—frequent hemograms, serum chemistries, and urinalyses with culture to monitor for complications
- Retinoid drugs—serum chemistries, including triglycerides, and Schirmer tear tests
- Ketoconazole—serum chemistries.

MISCELLANEOUS

AGE-RELATED FACTORS

Skin aging might be related to increase in exfoliative disorders or relapses.

ZOONOTIC POTENTIAL

Dermatophytosis and several ectoparasites have zoonotic potential.

PREGNANCY/FERTILITY/BREEDING

Systemic retinoids and vitamin A in therapeutic dosages—extreme teratogen; do not use in intact females because of severe and predictable teratogenicity and extremely long withdrawal period; women of childbearing age should not handle these medications.

SYNONYMS

- Keratinization disorders = seborrhea, idiopathic seborrhea, keratinization defect, dyskeratinization, and incorrect human terms (eczema, psoriasis, dander, dandruff); sebopsoriasis: correct term to describe the similarities between some human and canine keratinization defects • Bacterial folliculitis = pyoderma.

SEE ALSO

- Atopic Dermatitis • Demodicosis
- Hyperadrenocorticism (Cushing's Syndrome)—Cats • Hyperadrenocorticism (Cushing's Syndrome)—Dogs
- Hypothyroidism • *Malassezia* Dermatitis
- Pyoderma • Sarcoptic Mange

ABBREVIATIONS

ACTH = adrenocorticotropic hormone

BASICS

DEFINITION

- Neoplastic proliferation of cells derived from the skin or migrating to the skin.
- Epidermal tumors include those arising from keratinocytes, melanocytes, Merkel cells, and Langerhans cells, and epitheliotrophic lymphoma.
- Adnexal tumors include those arising from hair follicles, sebaceous glands, and sweat glands.
- Dermal and subcutaneous skin tumors include those of mesenchymal origin and tumors of round cell origin.
- Secondary or metastatic skin tumors result from the proliferation of cells from primary neoplasms of other organs in the skin.

PATOPHYSIOLOGY

- Neoplasia develops as a result of changes in genes controlling cell proliferation and homeostasis.
- More than 100 cancer-related genes have been identified
- Oncogenes encode proteins that promote cell growth; tumor-suppressor genes encode proteins that restrict cell proliferation and differentiation.
- Mutations in p53, a tumor-suppressor gene, are found in approximately 50% of cancers in humans and have also been found in many tumors affecting dogs and cats.
- Ultraviolet light promotes tumor development by damaging DNA and suppressing the immune system.
- Many viruses promote tumor growth through stimulating cell proliferation and/or suppressing the immune system.
- Reports of specific cutaneous neoplasia associated with medications and/or vaccinations.

SYSTEMS AFFECTED

Skin/Exocrine

GENETICS

- Breed predispositions have been reported for specific tumors, but the mode of inheritance in these breeds has not been determined.
- Mutations in oncogenes and/or tumor-suppressor genes (e.g., p53) are present in many types of skin tumors

INCIDENCE/PREVALENCE

- The combined incidence rate for skin tumors has been reported as 728/100,000 (0.728%) for dogs and 84/100,000 (0.084%) for cats.
- The skin is the most common site of occurrence of neoplasia in the dog (30% of total tumors) and the second most common site in the cat (20% of total tumors).
- Canine skin tumors are approximately 55% mesenchymal, 40% epithelial, and 5% melanocytic.

- The most frequently reported cutaneous or subcutaneous tumors in dogs are lipoma, sebaceous gland tumor, mast cell tumor, histiocytoma, and papilloma.

- Feline skin tumors are approximately 50% epithelial, 48% mesenchymal, and 2% melanocytic.
- The most frequently reported cutaneous or subcutaneous tumors in cats are basal cell tumor, squamous cell carcinoma, mast cell tumor, and fibrosarcoma.
- Skin tumors in cats are more frequently malignant; skin tumors in dogs are more frequently benign.

GEOGRAPHIC DISTRIBUTION

Geographic regions near the equator, with high altitude, or with sand or other reflective surfaces, have a higher incidence of solar-induced neoplastic dermatoses.

SIGNALMENT

Species

Dogs and cats

Breed Predilections

- Canine breeds with the highest overall incidence of skin tumors include boxer, Scottish terrier, bullmastiff, basset hound, Weimaraner, Kerry blue terrier, and Norwegian elkhound.
- Feline breeds with the highest overall incidence of skin tumors include Siamese and Persian.
- Certain breeds are predisposed to specific types of tumors (see "Suggested Reading").
 - Dog—breeds associated with the most common cutaneous neoplasms:
 - Lipoma—cocker spaniel, dachshund, Doberman pinscher, Labrador retriever, miniature schnauzer, Weimaraner.
 - Sebaceous gland tumor—beagle, cocker spaniel, dachshund, Irish setter, Lhasa apso, malamute, miniature schnauzer, poodle, Shih Tzu, Siberian husky.
 - Mast cell tumor—American Staffordshire terrier, beagle, Boston terrier, boxer, bull terrier, dachshund, English bulldog, fox terrier, golden retriever, Labrador retriever, pug, Shar-Pei, Weimaraner.
 - Histiocytoma—American Staffordshire terrier, Boston terrier, boxer, cocker spaniel, dachshund, Doberman pinscher, English springer spaniel, Great Dane, Labrador retriever, miniature schnauzer, rottweiler, Scottish terrier, Shar-Pei, Shetland sheepdog, West Highland white terrier.
 - Papilloma—cocker spaniel, Kerry blue terrier.
 - Cat—breeds associated with the most common cutaneous neoplasms:
 - Basal cell tumor—Persian, Himalayan (basal cell carcinoma—Siamese).
 - Squamous cell carcinoma—no predisposed breed reported.
 - Mast cell tumor—Siamese.
 - Fibrosarcoma—no predisposed breed reported.

Mean Age and Range

- The median age for cutaneous neoplasia is 10.5 years in dogs and 12 years in cats.
- The peak age period for cutaneous neoplasia in dogs and cats is 6 to 14 years.

Predominant Sex

- Females have a higher incidence of tumors in dogs (56%).
- Males have a higher incidence of tumors in cats (56%).

SIGNS

General Comments

- Most common clinical sign is a cutaneous or subcutaneous nodule; some tumors have an ulcerated surface; others may result in excessive scaling or in the formation of cutaneous plaques.

Historical Findings

- Tumors are most often slow growing; the owner may find them during petting, bathing, or grooming of the pet.
- Tumors may be rapidly growing and appear (or increase in size) quickly (e.g., histiocytoma).

Physical Examination Findings

- Nodules—cutaneous or subcutaneous
- Cutaneous ulcers
- Excessive scaling
- Cutaneous papillomas
- Cutaneous plaques

CAUSES

- Genetic (gene mutations).
- Environmental (e.g., ultraviolet light, radiation exposure).
- Viruses (e.g., papillomaviruses, FeLV, FIV).
- Toxins (e.g., tars).
- Drugs (e.g., immunosuppressive agents, chemotherapeutic agents).
- Epidermal neoplasms:
 - Keratinocytes—papillomas, squamous cell carcinoma, basal cell carcinoma, basosquamous carcinoma
 - Melanocytes—melanoma
 - Merkel cells—Merkel cell carcinoma
 - Langerhans cells—histiocytoma and malignant histiocytosis
 - Epitheliotrophic lymphoma—T lymphocytes.
- Adnexal neoplasms:
 - Hair follicles—trichofolliculoma, trichoepithelioma, infundibular keratinizing acanthoma, tricholemmoma, pilomatricoma, trichoblastoma
 - Sebaceous glands—sebaceous adenoma, sebaceous epithelioma, sebaceous adenocarcinoma, perianal gland epithelioma, perianal gland carcinoma
 - Sweat glands—apocrine cystadenoma, apocrine secretory adenoma/adenocarcinoma, apocrine ductal adenoma/carcinoma, eccrine carcinoma.
- Dermal and subcutaneous neoplasm:
 - Mesenchymal origin—soft tissue sarcoma: fibroma/fibrosarcoma, myxoma/

DERMATOSSES, NEOPLASTIC

(CONTINUED)

D

- myxosarcoma, hemangiopericytoma, lymphangioma/lymphangiosarcoma, hemangioma/hemangiosarcoma, lipoma/liposarcoma, neurofibrosarcoma, leiomyoma/leiomyosarcoma, synovioma/synovial sarcoma, rhabdomyoma/rhabdomyosarcoma
 - Round cell origin—transmissible venereal tumor, mast cell tumor, plasmacytoma, lymphoma, histiocytoma and histiocytic tumors.
- Secondary or metastatic skin tumors result from the metastasis or primary neoplasms in other organs to the skin.

RISK FACTORS

- Hair coat color and length (e.g., hairless breeds, white hair coat, lightly pigmented skin—increased risk for squamous cell carcinoma).
- Age (e.g., young animals highest risk for viral infections, older animals at highest risk for environment-associated neoplasia).
- Sunlight exposure (e.g., dogs and cats that sunbathe or spend time outdoors on reflective surfaces have higher risk of ultraviolet light—induced skin tumors).
- Genetics—certain breeds have higher risk of developing specific types of tumors (see above and in “Suggested Reading”).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cyst
- Abscess
- Inflammatory nodule/granuloma/plaque—sterile granulomatous and pyogranulomatous disease, sterile panniculitis, fungal infection, mycobacterial infection, foreign body
- Trauma/self-induced skin ulceration
- Hamartoma/nevus

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

- Cytology (fine-needle aspirate or impression smear)
- Regional lymph node aspirate (for staging)

IMAGING

Thoracic radiographs and abdominal ultrasonography useful for staging (evaluate for metastatic disease or underlying primary neoplasia).

DIAGNOSTIC PROCEDURES

- Cytology
- Biopsy with histopathologic examination
- Immunohistochemistry (useful in confirming certain types of tumors)

PATHOLOGIC FINDINGS

Varies with tumor type; see specific tumors for additional information.

TREATMENT

APPROPRIATE HEALTH CARE

- Varies with tumor type.
 - Observation is appropriate for some benign tumors.
 - Surgical excision, cryosurgery, radiation therapy, and/or tumor specific chemotherapy or immunotherapy may be curative or palliative.

NURSING CARE

- Varies with tumor type and location.
- Traumatized tumors may become secondarily infected.

ACTIVITY

Varies with tumor type and location.

DIET

Diets high in omega-3 fatty acids, arginine, and protein may be beneficial in boosting the immune response and preventing cancer-associated cachexia.

CLIENT EDUCATION

Varies with tumor type and location.

SURGICAL CONSIDERATIONS

- Varies with tumor type and location—wide margins may be needed to prevent reoccurrence of infiltrative tumors.
- Pretreatment with antihistamines appropriate when excising mast cell tumors.

MEDICATIONS

DRUG(S) OF CHOICE

Varies with tumor type—chemotherapy protocols are useful in some cases.

CONTRAINDICATIONS

Varies with tumor type and presence of concurrent disease.

PRECAUTIONS

Varies with tumor type and location.

POSSIBLE INTERACTIONS

Varies with tumor type and location.

ALTERNATIVE DRUG(S)

Varies with tumor type and location.

FOLLOW-UP

PATIENT MONITORING

Varies with tumor type and location.

PREVENTION/AVOIDANCE

- Varies with tumor type and location.
- Minimize exposure to ultraviolet light to help prevent some types of tumors.

POSSIBLE COMPLICATIONS

Varies with tumor type and location.

EXPECTED COURSE AND PROGNOSIS

Varies with tumor type and location.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Varies with tumor type and location.

AGE-RELATED FACTORS

Varies with tumor type and location.

ZOONOTIC POTENTIAL

None

PREGNANCY/FERTILITY/BREEDING

Varies with tumor type; some may have a genetic predisposition.

SYNONYMS

N/A

SEE ALSO

Specific tumor types

ABBREVIATIONS

- FeLV = feline leukemia virus
- FIV = feline immunodeficiency virus

DERMATOSSES, PAPULONODULAR

D

BASICS

DEFINITION

- Diseases whose primary lesions manifest as papules and nodules.
- Papule: solid, elevated lesions of the skin less than 1 cm in diameter.
- Nodule: solid, elevated lesion of the skin more than 1 cm in diameter that extends into deeper layers of the skin.

PATHOPHYSIOLOGY

- Papules—usually the result of tissue infiltration by inflammatory cells; accompanying intraepidermal edema or epidermal hyperplasia and dermal edema.
- Nodules—usually the result of a massive infiltration of inflammatory or neoplastic cells into the dermis or subcutis.

SYSTEMS AFFECTED

Skin/Exocrine

GENETICS

Determined by cause; specific diseases may be more commonly seen in certain breeds.

INCIDENCE/PREVALENCE

Determined by cause

GEOGRAPHIC DISTRIBUTION

Determined by cause

SIGNALMENT

Species

Dogs and cats

Breed Predilection

Determined by cause

Mean Age and Range

Determined by cause

Predominant Sex

Determined by cause

SIGNS

- Papules and/or nodules with distribution characteristic of the cause.
- Accompanying crusting, inflammation, pigmentation changes, and hair coat changes often noted; also characteristic of the cause.

CAUSES

- Superficial and deep bacterial folliculitis (e.g., *Staphylococcus*)
- Other bacterial (mycobacterial, actinomycetes, nocardiosis, abscess)
- Fungal (dermatophytosis, kerion, histoplasmosis, cryptococcosis, coccidiomycosis, sporotrichosis, phaeohyphomycosis)
- Sebaceous adenitis, granulomatous
- Canine and feline acne
- Parasitic (demodicosis, flea bite hypersensitivity, sarcoptic mange, *Pelodera* dermatitis)
- Sterile nodular (sterile granuloma/pyogranuloma syndrome, reactive histiocytosis)
- Neoplasia

RISK FACTORS

- Bacterial folliculitis, dermatophytosis, and demodicosis—any disease or medication that causes immune compromise or interferes with the barrier function of the skin.
- Pelodera* dermatitis—may be associated with contact with decaying organic debris (straw or hay) containing *Pelodera* *strongyloides*.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Determined by cause.
- These diseases can be differentiated by diagnostic tests (see below).

CBC/BIOCHEMISTRY/URINALYSIS

- Should be normal in most patients unless underlying disease is present.

OTHER LABORATORY TESTS

- Appropriate immunoassays if deep/systemic fungal disease is suspected.
- Determined by cause.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Skin scraping—identify mites or rhabditiform larvae.
- Dermatophyte cultures—identify dermatophytosis.
- Pustule (Tzanck) preparations (if present)—bacteria and degenerative neutrophils compatible with bacterial folliculitis; eosinophils can be compatible with rupturing folliculitis or furunculosis; acantholytic keratinocytes may indicate an inflammatory folliculitis or pemphigus disease.
- Fungal cultures—identify deep/systemic fungal disease.
- Bacterial culture and sensitivity—identify bacteria and appropriate antibiotic therapy.
- Aspirate and cytology from nodule—identify cellular infiltrate; presence of organisms.
- Skin biopsy—useful to determine a definitive diagnosis if baseline diagnostic procedures are normal and/or initial empiric treatment is ineffective.

PATHOLOGIC FINDINGS

Depends upon underlying disease process.

TREATMENT

APPROPRIATE HEALTH CARE

- Outpatient for nearly all causes (except some cases of neoplasia).
- Generalized demodicosis with secondary sepsis requires hospitalization.

NURSING CARE

Depends upon underlying issue

ACTIVITY

No specific alteration of activity recommended.

DIET

No specific alteration of diet recommended.

CLIENT EDUCATION

- For fungal infections, treatment may be expensive and prognosis can be guarded for deep/systemic fungal infections.
- For immune-mediated processes, treatment may be for the duration of the patient's life.

SURGICAL CONSIDERATIONS

Rarely necessary unless neoplasia is diagnosed.

MEDICATIONS

DRUG(S) OF CHOICE

Bacterial Folliculitis

- Superficial pyoderma—appropriate antibiotics based on bacterial culture and sensitivity for at least 3–4 weeks or 1 week beyond resolution of clinical signs.
- Deep pyoderma—appropriate antibiotics based on bacterial culture and sensitivity for at least 6–8 weeks or 2 weeks beyond resolution of clinical signs.
- Identify and control underlying cause to prevent recurrence.
- See specific chapter for additional recommendations.

Sebaceous Adenitis

- Appropriate antibiotics if secondary bacterial infection present.
- Propylene glycol and water (50–75% dilution) once daily as a spray to affected areas helpful in mild cases.
- Essential fatty acid dietary supplements (omega 3 and omega 6 PO).
- Topical therapy: antiseborrheic shampoos, emollient rinses (baby oil) and humectants.
- Cyclosporine (5 mg/kg PO q24h).
- Vitamin A (10,000–30,000 IU Vit A PO daily or 1000 IU Vit A/kg PO daily).
- Refractory cases—isotretinoin (1 mg/kg PO q12–24h); if response is seen, taper dosage (1 mg/kg q48h or 0.5 mg/kg q24h). The synthetic retinoids have become difficult to dispense due to strict prescription procedures.
- Most cases are refractory to corticosteroids.
- See specific chapter for additional recommendations.

Canine and Feline Acne

- May resolve without therapy in mild cases.
- Warm water soaks or Epsom salt solution (2 T/quart or 30 ml/L of water) for 5–10 minutes
- Chlorhexidine-based pads, or acetic acid/boric acid pads/wipes, or benzoyl peroxide gels used daily or alternated daily; topical ceramide/EFA preparations may be helpful.

DERMATOSSES, PAPULONODULAR

(CONTINUED)

D

- Topical creams/ointments: Mupirocin 2% ointment—topical antibiotic; apply q24h; should not be used in cats with deep lesions; metronidazole, 0.05% Vitamin A acid cream, clindamycin are alternative options.
- Secondary bacterial infection: systemic antibiotics.
- Underlying cause(s) should be determined and treated accordingly.
- Refractory cases—isotretinoin (1–2 mg/kg PO q24h). The oral synthetic retinoids have become difficult to dispense due to strict prescription procedures; prednisolone PO (1–2 mg/kg/day for 10–14 days and taper) may reduce scar tissue formation.
- See specific chapter for additional recommendations.

Pelodera Dermatitis

- Remove and destroy bedding.
- Wash kennels, beds, and cages and treat with a premise insecticide or flea spray.
- Bathe affected animal and remove crusts.
- Parasiticidal dip or ivermectin as recommended for sarcoptic mange.
- Corticosteroids as needed for inflammation.
- Severe infection—may require use of antibiotics.

Sterile Nodular Dermatoses

- Attempt to identify underlying cause.
- Cyclosporine 5 mg/kg PO q24h.
- Tetracycline (250 mg < 10 kg, 500 mg > 10 kg q8–12h), doxycycline (10 mg/kg q24h), or minocycline (5 mg/kg q12h) with niacinamide (250 mg < 10 kg, 500 mg > 10 kg q8–12h).
- Corticosteroids at immunosuppressive doses and taper according to response.
- Chemotherapeutic drugs (chlorambucil or azathioprine).

Other

- Dermatophytosis—griseofulvin, itraconazole, ketoconazole, or terbinafine; see specific chapter.
- Kerion—see Dermatophytosis.
- Demodicosis/sarcoptic mange—see specific chapters.
- Other bacterial infection—antibiotics dependent upon culture and sensitivity results.
- Deep/systemic fungal infection—see specific chapter.
- Urticaria—remove triggering factor; may need epinephrine or glucocorticoids depending upon severity; antihistamines may be helpful in chronic cases.
- Feline miliary dermatitis/feline eosinophilic dermatitis—see specific chapters, look for underlying cause.
- Neoplasia—see specific chapter.

CONTRAINDICATIONS

Corticosteroids and immunosuppressive medications should be avoided with folliculitis, dermatophytosis, kerion, and demodicosis.

PRECAUTIONS

- Cats can be sensitive to the irritant effects of benzoyl peroxide.
- Fatty acids—use with caution in dogs with inflammatory bowel disease or recurrent pancreatitis.
- Isotretinoin—may cause keratoconjunctivitis sicca, hyperactivity, pinna pruritus, erythematous mucocutaneous junctions, swollen tongue, lethargy with anorexia or vomiting, abdominal distension, or collapse; CBC and chemistry screen abnormalities include high platelet count, hypertriglyceridemia, hypercholesterolemia, and high alanine transaminase; teratogen.
- Cyclosporine—may cause vomiting and diarrhea, gingival hyperplasia, B lymphocyte hyperplasia, hirsutism, papillomatous skin eruptions, and increased incidence of infection; decreased glucose homeostasis; potential toxic reactions rare and include nephrotoxicity and hepatotoxicity.
- Azathioprine and chlorambucil—potential for bone marrow suppression, gastrointestinal upset; azathioprine can cause hepatotoxicity and possibly pancreatitis.

POSSIBLE INTERACTIONS

- Cyclosporine and corticosteroids interact with several medications; an appropriate drug handbook should be consulted prior to usage.
- An appropriate drug handbook should be consulted when prescribing an unfamiliar medication.

ALTERNATIVE DRUG(S)

N/A

FOLLOW-UP

PATIENT MONITORING

- CBC, chemistry screen, urinalysis, and urine cultures—monitor periodically in patients receiving immunosuppressive medications. Monitoring will depend upon medication and dosage.
- CBC, chemistry screen, and urinalysis—monitor monthly for 4–6 months in patients receiving synthetic retinoid therapy.
- Tear production—monitor monthly for 4–6 months, then every 6 months in patients receiving synthetic retinoid therapy.
- Skin scraping—monitor therapy in patients with demodicosis (see Demodicosis).
- Repeat fungal culture—monitor therapy in patients with dermatophytosis (see Dermatophytosis).
- Resolution of lesions—monitor progress of sebaceous adenitis, actinic conditions, and all other diseases.

POSSIBLE COMPLICATIONS

Dependent on specific disease

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

- Dermatophytosis—incidence in humans reported in 30–50% of cases of *Microsporum canis* cases, but possible with all dermatophytosis cases.
- Sarcoptic mange.

PREGNANCY/FERTILITY/BREEDING

- Synthetic retinoids—teratogens; do not use in pregnant animals, animals intended for reproduction, or intact female animals; should not be handled by women of childbearing age.
- Corticosteroids—avoid use in pregnant animals.
- Cyclosporine—avoid during pregnancy unless absolutely necessary; dosages two to five times normal have been fetotoxic and embryotoxic in rats and rabbits.
- Antifungal agents should be avoided in pregnant animals.
- All drugs should be used with caution in pregnant and breeding animals.

DERMATOSSES, STERILE NODULAR/GANULOMATOUS

BASICS

DEFINITION

Diseases whose primary lesions are nodules and/or plaques that are solid, may be multiple, elevated, and > 1 cm in diameter.

PATHOPHYSIOLOGY

- Nodules/plaques—usually result from an infiltration of inflammatory cells into the dermis and subcutis; may be secondary to endogenous or exogenous stimuli.
- Inflammation is typically, but not always, granulomatous to pyogranulomatous.

SYSTEMS AFFECTED

Skin/Exocrine

GENETICS

Oligogenic transmission is proposed for histiocytic sarcoma for Bernese mountain dogs.

SIGNALMENT

- Can affect any age, breed, or sex.
- Collagenous nevi—German shepherd dogs 3–5 years old. • Calcinosis circumscripta—German shepherd dogs < 2 years old.
- Systemic histiocytosis and malignant histiocytosis—Bernese mountain dogs (primarily), rottweilers, and retriever (golden and Labrador). • Eosinophilic granuloma—Siberian huskies < 3 years, males.

SIGNS

- Characterized by single to multiple dermal to subcutaneous nodules and/or plaques.
- Firm to fluctuant. • Occasionally painful.
- Overlying epidermis may be normal to ulcerated.

CAUSES

- Amyloidosis • Foreign body reaction
- Spherulocytosis • Idiopathic sterile granuloma and pyogranuloma • Canine eosinophilic granuloma • Calcinosis cutis
- Calcinosis circumscripta • Malignant histiocytosis (disseminated histiocytic sarcoma) • Reactive histiocytosis (cutaneous and systemic) • Sterile nodular panniculitis
- Collagenous nevi (nodular dermatofibrosis)
- Cutaneous xanthoma

RISK FACTORS

- Foreign body reaction—induced by exposure to any irritating material (e.g., concrete dust or fiberglass). • Hair foreign bodies—increased risk for large dogs that rest on hard surfaces. • Calcinosis cutis—increased risk with exposure to high doses of exogenous or endogenous glucocorticosteroids.
- Panniculitis—increased risk with vitamin E-deficient diet. • Cutaneous xanthoma—high-fat treats or diet, diabetes mellitus, hyperlipidemia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- See “Causes.” • Sterile nodular dermatoses must be differentiated from deep bacterial and fungal infections and dermal neoplasia.
- Diagnosed by histopathology and deep tissue cultures. • Immunohistochemistry is helpful in differentiating histiocytic conditions. • Immunohistochemical staining is best performed on fresh frozen tissue; PCR may be used to help rule out leishmaniasis and mycobacterial infections.

CBC/BIOCHEMISTRY/URINALYSIS

- Amyloidosis—possible changes in biochemistry and/or urinalysis if internal organs are affected. • Malignant histiocytosis—pancytopenia. • Calcinosis cutis—changes characteristic of hyperglucocorticoidism (e.g., stress leukogram, high ALP, hyperglycemia, low urine specific gravity). • Cutaneous xanthomas—may have glucosuria, hyperglycemia, and/or lipid profile abnormalities. • Sterile panniculitis—may have biochemistry changes associated with pancreatitis, hepatic disease or systemic lupus erythematosus if systemic diseases are present.

OTHER LABORATORY TESTS

Serum ferritin levels—may be high with malignant histiocytosis but not with reactive histiocytosis.

IMAGING

- Radiology and ultrasonography—delineate involvement of internal organs in amyloidosis and histiocytosis. • Radiology—identify other areas of dystrophic calcification in dogs with calcinosis cutis. • Ultrasonography—identifies renal or uterine tumors in German shepherd dogs with collagenous nevi; adrenal tumor or enlargement and liver changes may be seen in dogs with calcinosis cutis.

DIAGNOSTIC PROCEDURES

- Skin biopsy for histopathology and cultures (fungal, aerobic, anaerobic, and mycobacterial); essential for the appropriate diagnosis of nodular dermatoses. • Biopsies should be excisional and taken from an intact or early (non-draining) nodule if possible. • Cultures should be taken from the nodular tissue, not exudates; fungal and mycobacterial organisms can easily be missed. • Special histopathologic stains for bacteria, mycobacteria and fungi can be requested to help rule out any infectious agent.

PATHOLOGIC FINDINGS

- Amyloidosis—accumulation of amorphous eosinophilic deposits that may extend into the subcutis; deposits stain apple green with Congo red in polarized light. • Foreign body reaction—suppurative to pyogranulomatous inflammation that affects the dermis, subcutis, and occasionally the underlying

muscle. The inciting foreign body may or may not be present in the tissue sampled.

- Spherulocytosis—histiocytes surrounding thin-walled parent bodies filled with homogeneous eosinophilic spherules.
- Idiopathic sterile granuloma and pyogranuloma—granulomatous to pyogranulomatous inflammation that can extend from the dermis to the panniculus; the inflammation mimics that seen with nodular infectious diseases; differentiated by obtaining negative aerobic, anaerobic, mycobacterial and fungal tissue cultures. • Canine eosinophilic granuloma—accumulation of numerous eosinophils with edema and possible mucin. Collagen degeneration is common, especially in more acute lesions.
- Calcinosis cutis—diffuse calcium deposition of the dermal collagen and adnexa that may extend into the deeper tissue. • Calcinosis circumscripta—focal to multifocal deposits of mineral that efface the soft tissue. • Reactive histiocytosis (cutaneous and systemic)—markedly angiocentric infiltrate of histiocytes that do not form granulomas or pyogranulomas; cutaneous and systemic disease cannot be differentiated by biopsy.
- Malignant histiocytosis (disseminated histiocytic sarcoma)—dense pleomorphic cell proliferation of spindle or round cells that efface normal tissue architecture; tumors from other spindle and round cell tumors differentiated by immunohistochemistry; histiocytic sarcomas consistently express CD45, CD18, CDI, CD11c, and MHC II.
- Sterile nodular panniculitis—neutrophilic to pyogranulomatous inflammation that affects the deep dermis and panniculus predominately; adipocytes may be necrotic or may be infiltrated by foamy macrophages.
- Collagenous nevi—focal dermal thickening of normal collagen bundles; histopathologic changes are very subtle; it is important to provide the pathologist with signalment and clinical history. • Cutaneous xanthoma—diffuse granulomatous inflammation composed of large foamy macrophages; lakes of extracellular amorphous lipid deposits and cholesterol clefts are not present in all cases.

TREATMENT

APPROPRIATE HEALTH CARE

- Dogs with calcinosis cutis may require hospitalization for treatment of sepsis and intensive topical therapy. • Most of these disorders can be treated on an outpatient basis. • Neoplastic or metabolic disorders may require hospitalization and supportive care.

NURSING CARE

Dogs with any of these diseases in which the nodules have ulcerated or ruptured open will benefit from gentle bathing and soaking to clean the skin and remove debris.

DERMATOSSES, STERILE NODULAR/GANULOMATOUS

(CONTINUED)

ACTIVITY

No restriction in activity indicated.

DIET

Animals with xanthoma should be on low-fat diet.

D**CLIENT EDUCATION**

- Malignant histiocytosis, amyloidosis, collagenous nevi of German shepherd dogs and systemic reactive histiocytosis are almost always fatal.
- Prognoses for cutaneous reactive histiocytic disease, sterile panniculitis and sterile pyogranuloma are guarded since they may require long-term immunosuppressive therapy; a few of these cases will not respond to therapy at all.

**MEDICATIONS****DRUG(S)**

- Amyloidosis—no known therapy, unless the lesion is solitary and can be surgically removed.
- Spherulocytosis—only effective treatment is surgical removal.
- Idiopathic sterile granuloma and pyogranuloma:
 - Prednisolone (2.2–4.4 mg/kg divided PO q12h) is the first line of therapy; continue steroids for 7–14 days after complete remission, then taper dose.
 - Azathioprine (2.2 mg/kg q48h) can be added as a steroid sparing drug.
 - Cyclosporine (5–10 mg/kg q24h) may be effective in cases that are unresponsive to steroids.
- Foreign body reactions—best treated by removal of the offending substance; for hair foreign bodies, the dog should be placed on softer bedding and topical therapy with keratolytic agents should be initiated; many dogs with hair foreign bodies also have secondary deep bacterial infections that require treatment with both topical and systemic antibiotics.
- Canine eosinophilic granuloma—prednisolone (1.1–2.2 mg/kg PO q24h) usually effective.
- Malignant histiocytosis—no effective long-term therapy; lomustine has been used with some short-term success; disease is usually rapidly fatal (mean survival time is usually less than 3 months).
- Cutaneous/systemic histiocytosis—high-dose glucocorticosteroids, cyclosporine, leflunomide, and other cytotoxic drugs can result in remission but long-term therapy is usually necessary and recurrences are common.
- Calcinosis cutis—underlying disease must be controlled if possible; most cases require antibiotics to control secondary bacterial infections; hydrotherapy and frequent bathing in antibacterial shampoos minimize secondary infection; topical DMSO is useful (applied to

no more than one-third of the body once daily until lesions resolve); if lesions are extensive, serum calcium levels should be monitored closely while using DMSO.

- Calcinosis circumscripta—surgical excision is the therapy of choice.
- Sterile nodular panniculitis—single lesions can be removed surgically; prednisolone (2.2–4.4 mg/kg PO q24h or divided PO q12h) treatment of choice; administer until lesions regress, then taper; some dogs remain in long-term remission, others require prolonged alternate-day therapy; a few cases respond to oral vitamin E (400 IU q12h); refractive cases may respond to cyclosporine.
- Collagenous nevi—no therapy for most cases since the cystadenocarcinomas are usually bilateral; for rare unilateral case of cystadenocarcinoma or a cystadenoma, removal of the single affected kidney may be helpful; ovariohysterectomy should be performed in intact females to remove leiomyomas.
- Cutaneous xanthoma—correction of the underlying diabetes mellitus or hyperlipoproteinemia is usually curative.
- Azathioprine (2.2 mg/kg q48h) can be used together with prednisolone as a corticosteroid-sparing agent.
- Cyclosporine (5–10 mg/kg 24h) can be used as an alternative to glucocorticosteroid therapy if the patient is steroid intolerant or steroids are not sufficiently effective.
- Tetracycline (250 mg < 10 kg, 500 mg > 10 kg q8–12h), doxycycline (10 mg/kg q24h), or minocycline (5 mg/kg q12h) with niacinamide (250 mg < 10 kg, 500 mg > 10 kg q8–12h) can also be used as an alternative to glucocorticoid therapy; this is effective only in mild cases.

CONTRAINdications

Corticosteroids and other immunosuppressive drugs should be avoided, if possible, in any animal with secondary bacterial folliculitis.

PRECAUTIONS

DMSO—handle with care; monitor serum calcium levels if used to treat calcinosis cutis.

**FOLLOW-UP****PATIENT MONITORING**

Patients on long-term immunosuppressive therapy should have a CBC, chemistry screen, urinalysis, and urine culture performed at least every 6 months.

- Dogs treated with DMSO for calcinosis cutis should have calcium levels checked every 7–14 days for the first month of therapy if large areas are affected.

POSSIBLE COMPLICATIONS

Long-term use of immunosuppressive therapy (especially glucocorticosteroids) may make patients more susceptible to other dermatoses such as bacterial folliculitis, demodicosis and

dermatophytosis, as well as systemic side effects.

EXPECTED COURSE AND PROGNOSIS

- Systemic amyloidosis, malignant histiocytosis, systemic reactive histiocytosis and nodular dermatofibrosis—invariably fatal.
- Many of the other conditions have a guarded prognosis; many require life-long immunosuppressive therapy to remain in remission.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- Calcinosis cutis—hyperglucocorticoidism, chronic renal failure, and diabetes mellitus.
- Calcinosis circumscripta—(occasionally) hypertrophic osteodystrophy and idiopathic polyarthritis.
- Collagenous nevi—renal cystadenoma/cystadenocarcinoma and uterine, leiomyoma/leiomyosarcoma.
- Cutaneous xanthoma—diabetes mellitus and hyperlipoproteinemia.

DERMATOSSES, SUN-INDUCED

D

BASICS

OVERVIEW

The hair coat and epidermal pigmentation protect the skin from damage caused by ultraviolet light (UV) radiation. Excessive UV exposure damages keratinocytes (producing mutation), causes inflammation, and decreases cutaneous immune system surveillance. UVA (320–400 nm) penetrates more deeply than UVB (290–320 nm). Prolonged and repeated damage leads to pre-neoplastic changes and eventual neoplasia. Prolonged sun exposure in darkly-pigmented individuals may cause thermal burn. UV exposure may also exacerbate symptoms of pemphigus erythematosus, discoid lupus erythematosus, systemic lupus erythematosus, and dermatomyositis.

SIGNALMENT

Dogs—Dalmatian, bull terrier, boxer, bulldog, basset hounds, beagle, whippet, American Staffordshire terrier, Australian shepherd (nasal solar dermatitis).

CAUSES & RISK FACTORS

- White- and lightly-haired individuals with poorly-pigmented skin.
- History of sun-bathing.
- Outdoor housing.
- Regions with greater sun exposure; can be seasonal.

SIGNS

- Dogs—glabrous areas especially axillae, flank folds, ventral abdomen, and lateral aspects of extremities; lesions often multiple.
- Cats—pinnal tips, nasal planum, dorsal muzzle, eyelids, lips (uncommon).
- Solar dermatitis—nasal: erythema and scaling at the junction of the nasal planum and dorsal muzzle; expands caudally followed by scarring; truncal: erythema, scaling, and lichenification; gradual palpable thickening; comedones; secondary deep pyoderma leading to bullae.
- Actinic keratosis—palpable plaques with crusting and hyperkeratosis; cutaneous horns; often multiple; less than 1 cm in diameter.
- Hemangioma—punctate, flat, red to purple discolorations that enlarge to well-circumscribed plaques or nodules.
- Hemangiosarcoma—discrete to poorly-circumscribed, dark red to purple, fluctuant nodules; may become large; commonly ulcerate and bleed.
- Squamous cell carcinoma—proliferative and ulcerated plaques; crateriform; easily traumatized; secondary pyoderma common.
- Radiant thermal burn—large patches of alopecia, erythema and thickening; necrosis when severe; dorsal orientation; affects dark-haired and pigmented skin especially.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Pyoderma
- Dermatophytosis
- Demodicosis
- Discoid lupus erythematosus
- Pemphigus erythematosus
- Pemphigus foliaceus
- Drug eruption
- Contact dermatitis
- Chemical burn

CBC/BIOCHEMISTRY/URINALYSIS

Normal

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Biopsy—only method for definitive diagnosis.
- Solar dermatitis—epidermal hyperplasia, apoptotic keratinocytes, perivascular inflammation, vascular dilatation, dermal fibrosis, solar elastosis.
- Actinic keratosis—parakeratotic hyperkeratosis with epidermal atypia and solar elastosis.
- Hemangioma—well-defined dermal mass of proliferative, blood-filled vascular channels with minimal atypia or mitosis.
- Hemangiosarcoma—poorly-defined vascular channels lined by irregular endothelial cells; pleomorphic nuclei; atypical mitosis.
- Squamous cell carcinoma—invasion of dermis by neoplastic cells; irregular islands, nests, trabeculae; keratin pearls; enlarged nuclei with moderate mitotic activity.
- Radiant thermal burn—epidermal hyperplasia with keratinocyte atypia; hydropic degeneration; pigmentary incontinence; occasional apoptosis; eosinophilic elastin fibers.

TREATMENT

- Outpatient.
- Sun avoidance—keep indoors during the day; avoid reflected sunlight; apply waterproof (> 30 SPF) sunscreen; sun-protective clothing.
- Surgical excision of neoplastic lesions whenever possible.

MEDICATIONS

DRUG(S)

- Cyclooxygenase-2 inhibitors—overexpression by sun-damaged cells; inhibition demonstrated improvement: firocoxib 5 mg/kg/day PO.
- Retinoids—regulate differentiation and growth of epithelial cells; Isotretinoin 1–2 mg/kg q24–48h PO.
- Corticosteroids—reduce inflammation noted in acute cases; prednisolone 0.5 mg/kg PO tapering dosage; discontinue when possible.
- Imiquimod—induces local immune response; for individual lesions, especially actinic keratosis; apply q48h until resolution.
- Diclofenac gel—topical nonsteroidal anti-inflammatory: apply q12h until resolution.
- Antibiotics—control secondary pyoderma (see chapter, Pyoderma).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Retinoids—keratoconjunctivitis sicca; elevated serum triglycerides; teratogen; gastrointestinal upset
- Firocoxib—gastrointestinal upset; elevated liver chemistries

FOLLOW-UP

- Patients should be regularly screened for development of new lesions; when detected early, excision with local anesthesia is possible.
- Sun-induced dermatoses rarely metastasize; prognosis is fair to good with early detection.
- Long-term therapy necessary following extended periods of sun damage.

DERMATOSSES, VESICULOPUSTULAR

BASICS

DEFINITION

- Pustule—small (< 1 cm), circumscribed elevation of the epidermis filled with pus.
- Vesicle—small (< 1 cm), circumscribed elevation of the epidermis filled with clear fluid.

PATHOPHYSIOLOGY

Pustules and vesicles—produced by edema, acantholysis (pemphigus), ballooning degeneration (viral infections), proteolytic enzymes from neutrophils (pyoderma), degeneration of basal cells (lupus), or dermoepidermal separation (bullous pemphigoid).

SYSTEMS AFFECTED

Skin/Exocrine

SIGNALMENT

- Lupus—collies, Shetland sheepdogs, and German shepherd dogs may be predisposed.
- Pemphigus erythematosus—collies and German shepherd dogs may be predisposed.
- Pemphigus foliaceus—Akitas, chow chows, dachshunds, bearded collies, Labrador retrievers, Newfoundlands, Doberman pinschers, and schipperkes may be predisposed.
- Bullous pemphigoid—collies and Doberman pinschers may be predisposed.
- Dermatomyositis—young collies and Shetland sheepdogs.
- Subcorneal pustular dermatosis—schnauzers affected most frequently.
- Linear IgA dermatosis—dachshunds exclusively; very rare.
- Dermatophytosis—young animals.

SIGNS

N/A

CAUSES

Pustules/Vesicles

- Superficial pyoderma—impetigo, superficial spreading pyoderma, superficial bacterial folliculitis, canine or feline acne.
- Pemphigus complex—pemphigus foliaceus, pemphigus erythematosus, panepidermal pemphigus; pemphigus vulgaris produces deep clefts that rapidly erode into ulcers.
- Subcorneal pustular dermatosis.
- Dermatophytosis.
- Demodicosis.
- Sterile eosinophilic pustulosis.
- Linear IgA dermatosis.
- Systemic lupus erythematosus.
- Discoid lupus erythematosus.
- Bullous pemphigoid
- Dermatomyositis.
- Cutaneous drug eruption.
- Epidermolysis bullosa.

RISK FACTORS

- Drug exposure—SLE and bullous pemphigoid.
- Bacterial folliculitis usually secondary to a predisposing factor (e.g. demodicosis, hypothyroidism, allergy, or corticosteroid administration).
- Ultraviolet light—pemphigus erythematosus, bullous pemphigoid, SLE, DLE, and dermatomyositis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Superficial Pyoderma

- Most common cause.
- Readily responds to appropriate antibiotic therapy if the underlying cause is effectively managed.
- Intact pustule—direct smear reveals neutrophils engulfing bacteria; most often *Staphylococcus pseudintermedius*; biopsy demonstrates intraepidermal neutrophilic pustules or folliculitis with bacteria.

Pemphigus Complex

- Group of immune-mediated diseases characterized histologically by disadhesion of keratinocytes within the epidermis (acantholytic keratinocytes).
- Direct smears—many acantholytic keratinocytes, non-degenerate neutrophils, eosinophils, and few to no bacteria.
- Culture of an intact pustule negative.
- Direct immunofluorescence—deposits in the intercellular spaces of the epidermis in approximately 50% of the cases.
- Tends to wax and wane irrespective of antibiotic therapy; responds to immunosuppressive therapy.
- Pemphigus foliaceus and erythematosus: superficial acantholysis leading to erosions; face, pinnae, and footpads (foliaceus) commonly affected; mucous membranes not affected; biopsy—subcorneal acantholysis; interface and lichenoid inflammation with pemphigus erythematosus.
- Pemphigus vulgaris: severe and deep form of pemphigus; characterized by erosions rapidly leading to ulcerations of the oral cavity, mucocutaneous junctions, and skin; biopsy—suprabasal acantholysis and cleft formation.
- Direct immunofluorescence positive at the intercellular spaces of the deeper epidermis.

Subcorneal Pustular Dermatosis

- Rare idiopathic pustular dermatosis of dogs.
- Tends to wax and wane.
- Intact pustules—direct smears reveal numerous neutrophils, no bacteria, and occasional acantholytic keratinocytes; cultures negative.
- Direct immunofluorescence negative.

- Poor response to glucocorticosteroids and antibiotics.

Dermatophytosis

- Common disease of both dogs and cats.
- Dermatophyte culture positive.
- Secondary bacterial folliculitis common.
- Skin biopsy—folliculitis with fungal elements.

Sterile Eosinophilic Pustulosis

- Rare idiopathic dermatosis of dogs.
- Direct smears—numerous eosinophils, non-degenerate neutrophils, occasional acantholytic keratinocytes, and no bacteria.
- Biopsy—eosinophilic intraepidermal pustules, folliculitis, and furunculosis.
- Direct immunofluorescence negative.
- Rapid response to glucocorticosteroids.

Linear IgA Dermatosis

- Rare idiopathic dermatosis of dachshunds.
- Tends to wax and wane.
- Pustules—sterile and subcorneal.
- Direct immunofluorescence positive for IgA at the basement membrane zone.

Systemic Lupus Erythematosus

- Multisystemic disease with variable clinical signs and cutaneous manifestations, including mucocutaneous ulceration.
- Direct immunofluorescence positive at the basement membrane zone.
- ANA positive.

Discoid Lupus Erythematosus

- Affects only the skin; lesions usually confined to the face.
- Depigmentation, erythema, and ulceration of the nasal planum common.
- Skin biopsy—interface and lichenoid dermatitis.
- Direct immunofluorescence positive at the basement membrane zone.
- ANA negative.

Bullous Pemphigoid

- Ulcerative disorder of the skin and/or mucous membranes.
- Skin biopsy—subepidermal cleft formation.
- Direct immunofluorescence positive at the basement membrane zone.
- No acantholysis.

Dermatomyositis

- Idiopathic inflammatory disease of the skin and muscle of young collies and Shetland sheepdogs; seen rarely in adult animals.
- Lesions affect the face, ear tips, tail tip, and pressure points of the extremities.
- Characterized by alopecia, crusting, pigmentation disturbances, erosions/ulceration, and scarring.
- Skin biopsy—follicular atrophy, perifolliculitis, and hydropic degeneration of the basal cells.
- Direct immunofluorescence negative.
- Muscle biopsy and EMG—evidence of inflammation.

(CONTINUED)

DERMATOSSES, VESICULOPUSTULAR**CBC/BIOCHEMISTRY/URINALYSIS**

- Usually unremarkable.
- SLE—possible anemia, thrombocytopenia, or glomerulonephritis.
- Eosinophilic pustular dermatosis—most affected dogs have peripheral eosinophilia.

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Direct smear from intact pustule/vesicle.
- Culture of intact pustule/vesicle.
- Skin biopsy for histopathology.
- Direct immunofluorescence, including IgA.
- ANA titer: may be positive with SLE.
- EMG: fibrillation potentials (rapid, irregular, and unsynchronized contraction of muscle fibers) and positive sharp waves in dermatomyositis.
- Muscle biopsy—myofibril degeneration, characterized by fragmentation, vacuolation, atrophy, fibrosis, and regeneration in dermatomyositis.

**TREATMENT****APPROPRIATE HEALTH CARE**

- Periodic bathing with an antimicrobial shampoo—helps remove surface debris and control secondary bacterial folliculitis.
- Usually treated as an outpatient.
- SLE, pemphigus vulgaris, and bullous pemphigoid may be life-threatening and require inpatient intensive care.

**MEDICATIONS****DRUG(S) OF CHOICE*****Bacterial Folliculitis***

- Empiric choices: cephalixin 22 mg/kg q12h; clindamycin 11 mg/kg q24h; amoxicillin-clavulanic acid 15 mg/kg q12h.
- Appropriate antibiotic choice based on cultures from intact pustules.

Pemphigus Complex/Bullous Pemphigoid

Azathioprine (2 mg/kg PO q48h to twice weekly).
 Chlorambucil 2 mg/m² PO q48h
 Tetracycline (250 mg < 10 kg, 500 mg > 10 kg PO q8-12h), doxycycline (10 mg/kg PO q24h), or minocycline (5 mg/kg PO q12h) with niacinamide (250 mg < 10 kg, 500 mg > 10 kg PO q8-12h).
 Cyclosporine (5 mg/kg PO q24h).

Subcorneal Pustular Dermatosis

- Dapsone 1 mg/kg PO q8h until remission (usually 1–4 weeks); tapered to 1 mg/kg q24h or twice weekly.
- Sulfasalazine 10–20 mg/kg PO q8h until remission; then as needed.

Linear IgA Dermatoses

- Prednisolone 2.2–4.4 mg/kg PO q24h until remission; taper to alternate-day therapy.
- Dapsone—1 mg/kg PO q8h until remission; taper and give as needed; individual patients may respond to one drug and not the other.

Sterile Eosinophilic Pustulosis

- Prednisolone 2.2–4.4 mg/kg PO q24h until remission (usually 5–10 days); then as needed to prevent relapses (usually long-term, alternate-day therapy required).
- See specific diseases.

CONTRAINdications

N/A

PRECAUTIONS***Prednisolone***

- Secondary infection
- Iatrogenic Cushing disease
- Muscle wasting
- Steroid hepatopathy
- Behavioral changes
- Polydipsia, polyuria
- Polyphagia

Dapsone

- Dogs—mild anemia, mild leukopenia, and mild elevation of ALT, not associated with clinical signs; usually return to normal when dosage is reduced for maintenance.
- Rare fatal thrombocytopenia or severe leukopenia.
- Occasional vomiting, diarrhea, or pruritic skin eruption.
- Cats—more susceptible to dapsone toxicity; hemolytic anemia and neurotoxicity reported.

Sulfasalazine

Keratoconjunctivitis sicca.

Azathioprine and Chlorambucil

Potential for bone marrow suppression, gastrointestinal upset; azathioprine can cause hepatotoxicity and possibly pancreatitis.

Cyclosporine

May cause vomiting and diarrhea, gingival hyperplasia, B-lymphocyte hyperplasia, hirsutism, papillomatous skin eruptions, and increased incidence of infection; decreased glucose homeostasis; potential toxic reactions rare and include nephrotoxicity and hepatotoxicity.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

N/A

**FOLLOW-UP****PATIENT MONITORING**

- Dapsone—monitor hemogram, platelet count, and ALT every 2 weeks initially and if any clinical side effects develop.
- Long-term sulfasalazine therapy—monitor tear production.
- Immunosuppressive therapy—monitor every 1–2 weeks initially; then every 3–4 months during maintenance therapy.

POSSIBLE COMPLICATIONS

N/A

DERMATOSSES, VIRAL (NON-PAPILLOMATOSIS)

BASICS

OVERVIEW

- Dermatoses caused by viral infection within keratinized structures.
- Viral replication within keratinized structures may cause cytosuppressive effects or upregulate keratinization resulting in hyperplastic or crusted conditions.

SIGNALMENT

- Dogs and cats
- Uncommon dermatoses
- No breed, sex, or geographic predilections reported
- No genetic basis for these diseases
- Young to young adult dogs
- Cats of any age

SIGNS

- Facial involvement or involvement of the head is common.
 - Lesions are often asymmetrical in distribution.
 - Paws and/or paw pads may be affected as well as other mucocutaneous junctions.
 - Acute or gradual onset; lesions may be associated with the history of a bite wound or fight.
 - Variable pruritus; can progress to self-mutilation with some viral infections.
 - Crusts.
 - Associated superficial bacterial folliculitis.
 - Abscess.
 - Paronychia.
 - Poor wound healing.
 - Seborrhea.
 - Exfoliative dermatitis.
 - Cutaneous horns.
 - Gingivitis/stomatitis.
 - Cutaneous or oral ulceration.
 - Nasodigital hyperkeratosis.
 - Impetigo in young dogs, without expected inflammation.
 - Pigmented macules or plaques.
 - Progression to bowenoid *in situ* carcinoma (FIV, papillomavirus).
 - Multiple mast cell tumors (FIV).
 - Systemic signs of illness may be present.
 - Signs consistent with an upper respiratory infection may or may not be present prior to the development of skin lesions.

CAUSES & RISK FACTORS

- FeLV • FIV • Feline cowpox virus infection
- Feline infectious peritonitis • Feline papillomavirus • Canine papillomavirus
- Canine distemper • Contagious viral pustular dermatitis (orf [parapoxvirus])
- Pseudorabies (α -herpesvirus) • Feline rhinotracheitis infection (α -herpesvirus-1)
- Feline calicivirus infection • Fighting or hunting behavior, multiple animal households, exposure to infected animals, and/or ingestion of infected material increases risk of exposure.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Crusting diseases—if crust formation precedes other symptoms, consider drug eruption, actinic keratoses, pemphigus foliaceus, systemic lupus erythematosus, other causes for exfoliative dermatitis.
- Allergic disorders—usually pruritic: flea allergic

dermatitis, cutaneous adverse reaction to food, or atopic dermatitis. Feline herpesvirus dermatitis lesions can mimic lesions of the eosinophilic granuloma complex and are also pruritic. Skin biopsy may not distinguish the syndromes unless viral inclusion bodies are present.

- Parasitic diseases—canine and/or feline scabies, demodicosis, cheyletiellosis.
- Infectious diseases—superficial and deep bacterial and fungal infections, leishmaniasis.
- Dogs—zinc deficiency syndromes, hepatocutaneous syndrome, nasal hyperkeratosis.
- Neoplasia—with extensive crusting and ulceration; squamous cell carcinoma, mast cell tumor, and epitheliotrophic lymphoma.

CBC/BIOCHEMISTRY/URINALYSIS

Nonspecific

OTHER LABORATORY TESTS

- Skin biopsy—necessary to prove viral origin of skin lesions; not always conclusive. If considering herpesvirus dermatitis, inform pathologist of suspicion.
- Virus isolation.
- Serology—confirms FeLV, FIV, or other viral infection.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Skin scrapings, trichograms—parasitic infestations.
- Dermatophyte culture—fungal infections.
- Epidermal cytology—bacterial folliculitis.
- Skin biopsy is the definitive diagnostic test.
- Immunohistochemical staining for viral particles.
- Viral serology and/or PCR.

PATHOLOGIC FINDINGS

- Irregular hyperplasia.
- Ballooning degeneration.
- Hydropic interface dermatitis.
- Syncytial-type giant cell formation within the epidermis and/or outer root sheath of the hair follicle with associated apoptotic keratinocytes.
- Keratinocyte inclusion bodies.
- Epidermal ulceration with dermal necrosis, necrosis of epidermal sweat glands, neutrophilic and/or eosinophilic inflammation.

TREATMENT

- Usually outpatient, except for systemically ill patients.
- Prevent exposure to other animals that could become infected.

MEDICATIONS

DRUG(S)

- Supportive care and treatment of secondary infections.
- Cats—herpesvirus: L-lysine 200–500 mg/cat q12h; interferon- α 30 units/cat/day

orally, famcyclovir 125 mg q12h, use of topical acyclovir has been reported.

- Cats—bowenoid *in situ* carcinoma: imiquimod.
- Dogs—individual papillomas—surgical excision; imiquimod.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Immunosuppressive therapies.

FOLLOW-UP

PATIENT MONITORING

Varies based upon viral infection and presence or absence of systemic involvement.

PREVENTION/AVOIDANCE

Prevent hunting behavior and exposure to potentially infectious materials and infected animals.

POSSIBLE COMPLICATIONS

Bacteremia and septicemia

EXPECTED COURSE AND PROGNOSIS

- Skin lesions may not respond to therapy.
- Systemic signs may eventually develop as a result of viral infection.
- Dependent upon the causal virus, animals may self-cure.
- In cats, papillomavirus infection may progress to bowenoid *in situ* carcinoma.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

Dependent on viral cause.

ZOONOTIC POTENTIAL

Feline cowpox virus and contagious viral pustular dermatitis (parapoxvirus) can be transmitted to other dogs, humans, and cats.

DESTRUCTIVE AND SCRATCHING BEHAVIOR—CATS

BASICS

OVERVIEW

- Behavior that causes damage to an owner's home or belongings.
- Primary destructive behavior is a normal behavior that includes exploratory and play-based behavior as well as scratching of surfaces for marking and claw maintenance.
- Secondary destructive behavior is a clinical sign reflecting other behavioral conditions and disease states.

SYSTEMS AFFECTED

- Gastrointestinal—damage to teeth; vomiting and diarrhea, obstruction if target items are ingested.
- Musculoskeletal—traumatic damage caused by intense scratching or chewing.
- Ingestion of toxic material could affect any organ system.

SIGNALMENT

- Any breed or gender; probable genetic basis in Oriental breeds that present for sucking or chewing fabric.
- Primary destructive behavior seen in cats < 6 months of age.
- Secondary destructive behavior more often in mature animals.

SIGNS

Primary Destructive Behavior

- May occur in the presence or absence of the owner.
- No specific environmental trigger.
- Common targets for scratching are furniture, door frames and speakers.
- May chew houseplants.
- Items resembling string, including shoelaces, necklaces, and rubber bands are often chewed and ingested. Small items that are batted, may be accidentally swallowed.

Secondary Destructive Behavior

- Attention-seeking—destructive behavior in the presence of the owner, often when owners are preoccupied.
- Compulsive behavior—excessive licking, chewing, and/or ingesting non-food items; fabrics particularly wool are targeted; occurs in the presence or absence of the owner.
- Stress related scratching may occur secondary to household conflict or change or in response to outside triggers, such as non-household cats.

CAUSES & RISK FACTORS

- Primary destructive behavior represents normal behavior; inadequate supervision and insufficient access to appropriate scratching posts or toys are risk factors.
- Owners may reinforce or increase stress by scolding cats scratching inappropriate items.
- Compulsive chewing or wool sucking most common in Oriental breeds.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Rule out medical conditions.
- If pica accompanies destructive chewing rule out conditions affecting digestion, absorption, and appetite, including recent diet change.
- For sudden onset of chewing in a mature cat rule out oral, gastrointestinal and medical disease and medical conditions associated with pain or anxiety.

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal

OTHER LABORATORY TESTS

As indicated to rule out medical condition (T_4).

IMAGING

As needed to rule out medical conditions.

DIAGNOSTIC PROCEDURES

Physical examination with attention to oral cavity.

TREATMENT

Treat any underlying disease.

PRIMARY DESTRUCTIVE BEHAVIOR

- Keep claws trimmed.
- Supervise/confine until appropriate behavior patterns have been established.
- Assure access to acceptable scratching substrate; place posts in prominent locations and in target area; select suitable substrate—sisal, cardboard and loosely woven carpet are preferred; avoid posts covered with tightly woven carpet; position vertical or horizontal based on cat's preference.
- Reward appropriate behavior.
- Interrupt inappropriate behavior—apply non-toxic bitter-tasting product to deter chewing or double-sided sticky tape to deter scratching.
- Provide regular interactive play.
- Provide access to appealing toys.
- Declawing should not be a first-line therapy for normal scratching; while behavior modification is being implemented, plastic claw covers may be applied to prevent further damage.

SECONDARY DESTRUCTIVE BEHAVIOR

- Attention-seeking behavior—provide owner-initiated interactions; clicker training; review principles of learning and reinforcement.
- Compulsive disorder—identify and reduce sources of anxiety; offer interactive play and appropriate chewable items; some cats will chew rawhide bones; prevent access to target items.
- Reduce household conflict, manage intercat aggression.
- Block view of outside cats.

MEDICATIONS

DRUGS

- Medication complements behavior modification when treating anxiety-based conditions.
- Compulsive behavior may require SSRI or clomipramine.
- Medication is not indicated for primary destructive behaviors or attention-seeking behavior.
- Obtain informed consent when prescribing medication not approved for use in cats.

Tricyclic Antidepressants

Clomipramine: 0.5 mg/kg q24h

Selective Serotonin Reuptake Inhibitors

Fluoxetine: 0.5 mg/kg q24h

Nutraceuticals

- Novifit (SAMe): anxiety related to cognitive decline
- Zylkene • Royal Canin Calm Feline
- Anxitane

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- TCAs and SSRIs should not be used with monamine oxidase inhibitors, e.g., selegiline.

FOLLOW-UP

PATIENT MONITORING

Weekly follow-up during initial treatment.

EXPECTED COURSE AND PROGNOSIS

- Resolution of normal exploratory behavior is usually rapid.
- Anxiety-based conditions often require long-term management, including long-term psychotropic medication.

MISCELLANEOUS

AGE-RELATED FACTORS

Rule out medical in adult or senior onset.

PREGNANCY/FERTILITY/BREEDING

Preparturient destructive behavior (nesting).

SEE ALSO

- Compulsive Disorders—Cats

ABBREVIATIONS

- SSRI = selective serotonin reuptake inhibitor
- TCA = tricyclic antidepressant

DESTRUCTIVE BEHAVIOR—DOGS

BASICS

OVERVIEW

- Behavior that causes damage to an owner's home or belongings.
- Primary destructive behavior is a normal behavior that includes exploratory and play-based behavior.
- Secondary destructive behavior is a clinical sign of another behavior condition.

SYSTEMS AFFECTED

- Gastrointestinal—damage to teeth; vomiting and diarrhea, obstruction if ingested.
- Musculoskeletal—traumatic damage caused by scratching or chewing.
- Ingestion of toxic material could affect any organ system.

SIGNALMENT

- Any breed or gender.
- Primary destructive behavior seen in dogs < 1 year of age.
- Secondary destructive behavior can be seen at any age.

SIGNS

Primary Destructive Behavior

- Initially occurs in the presence or absence of the owner.
- Not preceded by a specific environmental trigger.
- Absence of anxiety or aggression.

Secondary Destructive Behavior

- Attention-seeking behavior—destructive behavior in the presence of the owner.
- Separation-related anxiety—destructive behavior consistently occurs in the absence of the owner, and rarely in the presence of the owner; target items may include personal belongings, furniture, or points of egress.
- Storm phobia, noise phobia—destructive behavior and/or anxiety-related behavior in response to stimuli whether or not owner is present. Intensity may be greater during owner absence.
- Territorial aggression—arousal is observed in presence of owner; destructive behavior is intermittent based on presence of triggers; window frames and doorways are damaged.

CAUSES & RISK FACTORS

- Primary destructive behavior represents normal behavior; inadequate supervision and insufficient access to appropriate outlets may affect destructive behavior.
- Owner scolding, leading to either fear or attention seeking.
- Risk factors for anxiety-based conditions not clearly identified.
- Territorial aggression may have genetic and learned components.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Identify pathologic conditions.
- If pica accompanies destructive chewing—rule out

conditions affecting digestion, absorption, polyphagia and appetite, including recent diet change.

- If licking surfaces, rule out upper GI disease.
- For sudden onset in a mature pet with no notable environmental changes—rule out medical conditions.
- For age-related onset, rule out cognitive dysfunction syndrome.

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal

OTHER LABORATORY TESTS

As indicated to rule out medical condition.

IMAGING

May be indicated if sudden onset in mature pet.

DIAGNOSTIC PROCEDURES

Physical examination with attention to GI tract.

TREATMENT

Treat underlying disease.

PRIMARY DESTRUCTIVE BEHAVIOR

- Supervise, confine or dog proof until appropriate behavior has been established.
- Assure access to acceptable chew toys.
- Reward appropriate behavior—select toys that dispense food or can be stuffed with food.
- Interrupt inappropriate behavior, apply non-toxic bitter-tasting product, then offer appropriate activity.
- Provide adequate interactive play.
- Use caution in applying any form of punishment. Any correction must be applied humanely, without causing pain or fear that could trigger anxiety or aggression.

SECONDARY DESTRUCTIVE BEHAVIOR

- Attention-seeking—provide owner-initiated interactions; teach sit for all interactions.
- Compulsive disorder—reduce sources of anxiety; offer interactive play and appropriate chew items; prevent access to target items.
- Separation-related anxiety—behavior modification; punishment is contraindicated.
- Noise phobia—behavior modification; reduce access to triggers.
- Territorial aggression—behavior modification, prevent access to doors and windows.

MEDICATIONS

DRUGS

- Medication complements behavior modification and may provide more rapid resolution when treating anxiety-based conditions.
- Medication is not indicated for primary destructive behaviors or attention-seeking behavior.

Tricyclic Antidepressants

Clomipramine: 1–3 mg/kg PO q12h

Selective Serotonin Reuptake Inhibitors

Fluoxetine: 0.5–2 mg/kg PO q24h

For situational anxiety (alone or together with SSRI or TCA)

Alprazolam: 0.01–0.1 mg/kg PO prior to event. Trazodone: 3–10 mg/kg PO prior to event. Clonidine: 0.01–0.05 mg/kg PO prior to event.

CONTRAINdicATIONS/POSSIBLE INTERACTIONS

- Psychotropic medication is not indicated for primary destructive behavior.
- TCAs and SSRIs should not be used with monoamine oxidase inhibitors including amitraz and selegiline.
- Benzodiazepines may disinhibit aggression; use with caution in dogs with a history of aggressive behavior.

FOLLOW-UP

PATIENT MONITORING

Weekly follow-up during initial phase of treatment.

EXPECTED COURSE AND PROGNOSIS

- Resolution of normal exploratory behavior is usually rapid.
- Anxiety-based conditions often require long-term management, including medication.

MISCELLANEOUS

AGE-RELATED FACTORS

Age of onset may aid in diagnosis.

PREGNANCY/FERTILITY/BREEDING

Preparturient destructive behavior (nesting).

SEE ALSO

- Compulsive Disorders—Dogs
- Separation Distress Syndrome
- Thunderstorm and Noise Phobias

ABBREVIATIONS

- SSRI = selective serotonin reuptake inhibitor
- TCA = tricyclic antidepressant

DIABETES INSIPIDUS

BASICS

DEFINITION

Diabetes insipidus (DI) is a disorder of water metabolism characterized by polyuria, urine of low specific gravity or osmolality (so-called insipid, or tasteless, urine), and polydipsia.

PATHOPHYSIOLOGY

- Central DI—deficiency in the secretion of ADH
- Nephrogenic DI—renal insensitivity to ADH

SYSTEMS AFFECTED

- Endocrine/Metabolic • Renal/Urologic

GENETICS

N/A

INCIDENCE/PREVALENCE

- Central DI—rare • Nephrogenic—rare

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Dog and cat

Breed Predilections

None

Mean Age and Range

- Congenital forms < 1 year • Acquired forms (e.g., neoplastic, traumatic, and idiopathic), any age

Predominant Sex

None

SIGNS

- Polyuria • Polydipsia
- Incontinence—occasional

CAUSES

Inadequate Secretion of ADH

- Congenital defect • Idiopathic • Trauma
- Neoplasia

Renal Insensitivity to ADH

- Congenital • Secondary to drugs (e.g., lithium, demeclocycline, and methoxyflurane)
- Secondary to endocrine and metabolic disorders (e.g., hyperadrenocorticism, hypokalemia, pyometra, and hypercalcemia)
- Secondary to renal disease or infection (e.g., pyelonephritis, chronic renal failure, pyometra)

RISK FACTORS

N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Polyuric Disorders

- Hyperadrenocorticism • Diabetes mellitus
- Liver disease—portosystemic shunt
- Hyperadrenocorticism • Pyometra
- Pyelonephritis • Hyperthyroidism—cats

- Hypercalcemia • Psychogenic polydipsia
- Renal failure

CBC/BIOCHEMISTRY/URINALYSIS

- Usually normal, hypernatremia in some patients • Urinary specific gravity low (usually < 1.012, often < 1.008)

OTHER LABORATORY TESTS

Plasma ADH

IMAGING

MRI or CT scan if a pituitary tumor is suspected

DIAGNOSTIC PROCEDURES

- Modified water deprivation test (see Appendix II-A for protocol) • ADH supplementation trial—therapeutic trial with synthetic ADH (DDAVP); a positive response (water intake decreases by 50% in 3–5 days)
- Rule out all other causes of PU/PD before conducting an ADH trial.

PATHOLOGIC FINDINGS

Degeneration and death of neurosecretory neurons in the neurohypophysis (CDI)

TREATMENT

APPROPRIATE HEALTH CARE

Patients should be hospitalized for the modified water deprivation test; the ADH trial is often performed as an outpatient procedure.

ACTIVITY

Not restricted

DIET

Normal, with free access to water

CLIENT EDUCATION

- Review dosage of DDAVP and administration technique • Importance of having water available at all times

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUG(S) OF CHOICE

- CDI—DDAVP (1–2 drops of the intranasal preparation in the conjunctival sac q12–24h to control PU/PD); alternatively, the intranasal preparation may be given SC (2–5 µg q12–24h). An oral preparation of DDAVP is available in 0.1–0.2 mg tablets with each 0.1 mg comparable to 1 large drop of the intranasal preparation
- NDI—hydrochlorothiazide (2–4 mg/kg PO q12h)

CONTRAINdications

None

PRECAUTIONS

Overdose of DDAVP can cause water intoxication.

FOLLOW-UP

PATIENT MONITORING

- Adjust treatment according to the patient's signs; the ideal dosage and frequency of DDAVP administration is based on water intake.
- Laboratory tests such as PCV, total solids, and serum sodium concentration to detect dehydration (inadequate DDAVP replacement)—usually not necessary

PREVENTION/AVOIDANCE

Circumstances that might markedly increase water loss

POSSIBLE COMPLICATIONS

Anticipate complications of primary disease (pituitary tumor).

EXPECTED COURSE AND PROGNOSIS

- The condition is usually permanent, except in rare patients in which the condition was trauma induced.
- Prognosis is generally good, depending on the underlying disorder.
- Without treatment, dehydration can lead to stupor, coma, and death.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

- Congenital CDI and NDI usually manifest before 6 months of age • CDI related to pituitary tumors is usually seen in dogs > 5 years old

PREGNANCY/FERTILITY/BREEDING

N/A

SYNONYMS

- Central diabetes insipidus • Cranial diabetes insipidus • ADH-responsive diabetes insipidus • Nephrogenic diabetes insipidus

SEE ALSO

Hyposthenuria

ABBREVIATIONS

- ADH = antidiuretic hormone • CDI = central diabetes insipidus • DDAVP = brand name of desmopressin • DI = diabetes insipidus • MRI = magnetic resonance imaging • NDI = nephrogenic diabetes insipidus • PCV = packed cell volume • PU/PD = polyuria/polydipsia

DIABETES MELLITUS WITH HYPEROSMOLAR COMA

BASICS

DEFINITION

Disease characterized by severe hyperglycemia, hyperosmolarity, severe dehydration, lack of urine or serum ketones, lack of or mild-to-moderate metabolic acidosis, and CNS depression.

PATHOPHYSIOLOGY

- Insulin deficiency causes reduced use of glucose and excessive glucose production.
- The resultant high extracellular blood glucose concentration causes a hyperosmolar state with a reduced extracellular fluid volume.
- Intracellular dehydration, azotemia, and uremia develop, and intracellular dehydration becomes more pronounced as the glomerular filtration rate decreases; tissue hypoxia ensues.
- Azotemia, hyperglycemia, and hyperosmolarity worsen as a result of glucose retention and glucose-induced osmotic diuresis.
- Although ketonemia and ketonuria usually are not features of this syndrome, anorexia (especially when prolonged) may cause mild ketoacidosis in some patients, but increased lactic acid is a major contributor to the metabolic acidosis that may develop in these patients.

SYSTEMS AFFECTED

- Renal/Urologic—prerenal and primary renal azotemia develop because of reduced extracellular fluid volume, reduced tissue perfusion, or diabetic glomerulonephropathy; urinary specific gravity is low because of osmotic diuresis, diabetic glomerulonephropathy, or concurrent renal insufficiency.
- Cardiovascular—hypotension because of low extracellular fluid volume, vascular collapse, and depressed myocardial contractility.
- Nervous—depression, disorientation or mental confusion, seizures, and coma are caused by intracellular dehydration and hyperosmolarity; CNS dysfunction worsens as serum osmolarity rises.

GENETICS

N/A

INCIDENCE/PREVALENCE

Uncommon

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Mostly cat, rarely dog

Breed Predilections

N/A

Mean Age and Range

- Dogs—peak prevalence, 7–9 years of age
- Cats—any age; most > 6 years old

Predominant Sex

- Dogs—female
- Cats—neutered males

SIGNS

Historical Findings

- Polydipsia/polyuria, polyphagia, and weight loss.
- Late signs—weakness, vomiting, anorexia, depression, stupor, and coma.

Physical Examination Findings

- Dehydration (severe 10–15%)
- Hypothermia
- Prolonged capillary refill time
- Lethargy, depression
- Seizures (severe hyperosmolarity)
- Stupor or coma (severe hyperosmolarity)
- Cataracts (dogs)

CAUSES

Diabetes mellitus associated with severe hyperosmolarity, severe hyperglycemia, prerenal azotemia, and severe dehydration.

RISK FACTORS

- Concurrent problems such as heart disease, renal insufficiency, pneumonia, acute pancreatitis, neoplasia and other severe diseases.
- Drugs—anticonvulsants, glucocorticoids, and thiazide diuretics may precipitate or aggravate this syndrome.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Myxedema coma—similar clinical findings, low TT₄, high TSH.
- Uncomplicated diabetes mellitus—mentally alert with fasting hyperglycemia and glucosuria.
- Ketoacidotic diabetes mellitus—fasting hyperglycemia with glucosuria, ketonuria, and metabolic acidosis.
- Extreme lethargy and depression with severe hyperosmolarity, severe hyperglycemia, severe dehydration without ketonemia and ketonuria usually differentiate diabetes mellitus non-ketotic hyperosmolar syndrome from uncomplicated and ketoacidotic diabetes mellitus.

CBC/BIOCHEMISTRY/URINALYSIS

- Severe hyperglycemia—usually > 600 mg/dL.
- High BUN and creatinine concentration.
- Hypernatremia.
- Normokalemia (despite total body potassium depletion) or hypokalemia.
- Hyperkalemia is expected in patients with anuric or oliguric renal failure.
- Low TCO₂.
- High anion gap.

- Glucosuria.

- Low urinary specific gravity.

OTHER LABORATORY TESTS

- Severe hyperosmolarity—usually > 350 mOsm/L.
- Estimated serum osmolarity may be calculated from serum chemistries as follows: 1.86(Na + K) + BUN/2.8 + glucose/18.
- High plasma lactate concentration may help confirm metabolic lactic acidosis in the absence of ketonemia and ketonuria.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Pancreatic islet cell atrophy (dogs)
- Pancreatic amyloid (cats)
- Cerebral necrosis, thromboembolism

TREATMENT

APPROPRIATE HEALTH CARE

A life-threatening medical emergency requiring inpatient treatment.

NURSING CARE

- Fluid therapy is a major component of medical management. Nasogastric tube allows for slow replacement of water orally (caution in comatose patients).
- Replace one-half the fluid deficits in the first 12 hours and the remainder during the next 24 hours.
- Administer normal saline (0.9%) IV if the patient is hypotensive or hyponatremic; use 0.45% saline if hypernatremic (caution to lower Na by only 2.2 mEq/kg/day).
- Add potassium (20 mEq/L) to the initial fluids unless the patient has hyperkalemia.
- Switch to IV administration of 0.45% saline after restoration of normal blood pressure and urine output.
- Switch to 2.5%–5% dextrose plus 0.45% saline when blood glucose < 250 mg/dL, and continue until the patient is eating and drinking on its own.

ACTIVITY

N/A

DIET

- A low-fat, high-fiber, high-complex carbohydrate diet is recommended for dogs once the patient is stabilized.
- A low carbohydrate, high protein diet is recommended for cats once the patient is stabilized.

CLIENT EDUCATION

- Poor-to-guarded prognosis.
- Intensive care and frequent monitoring are required during hospitalization.

SURGICAL CONSIDERATIONS

N/A

(CONTINUED)

DIABETES MELLITUS WITH HYPEROSMOLAR COMA**MEDICATIONS****DRUG(S) OF CHOICE**

- Administer regular insulin 2–4 hours after initiating IV fluid therapy.
- IV constant-rate infusion of regular insulin may be used at a dosage of 1.1 U/kg/24h. Add 1.1 U/kg regular insulin to 250 mL 0.9% NaCl and administer at 10 mL/h (0.045 U/kg/h) in a separate line. Discard the first 50 mL of the solution to compensate for insulin binding to the plastic tubing.
- Reduce the dosage/rate of the constant-rate infusion when the blood glucose is < 250 mg/dL.
- Once the patient is stabilized (eating and drinking on its own without vomiting), discontinue fluids and regular insulin; glargine PZI, or Lente insulin can then be administered SC in a routine manner.
- Other concurrent diseases must be treated appropriately.

CONTRAINDICATIONS

N/A

PRECAUTIONS

Avoid rapid reduction of serum osmolarity and glucose because the brain will become hyperosmolar compared with serum; fluid may then shift from extracellular to intracellular spaces, resulting in cerebral edema and worsening of neurologic status.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

Once stable, oral hypoglycemics (e.g., glipizide) may be used in cats.

**FOLLOW-UP****PATIENT MONITORING**

- Blood glucose concentrations, closely, to avoid hypoglycemia and abrupt, precipitous decreases.

- Ideally, the blood glucose should drop 50–100 mg/dL/h until a concentration of 250 mg/dL is reached.

- Blood glucose hourly before administering the next dose of regular insulin IM during initial stabilization.
- Urine output for early detection of acute renal failure.
- Hydration status, ECG, CVP, serum electrolytes, BUN, and urine glucose every 2 hours during the initial stabilization period.
- Long-term glucose control by determining serum glycosylated hemoglobin and serum fructosamine concentrations.
- Watch for return of clinical signs such as polydipsia, polyuria, and polyphagia.

PREVENTION/AVOIDANCE

- Avoid inappropriate, insufficient insulin therapy.
- Avoid hypoglycemia, hypokalemia, and hyponatremia.

POSSIBLE COMPLICATIONS

- Irreversible coma and death are possible, especially in patients with renal insufficiency.
- Acute renal failure.

EXPECTED COURSE AND PROGNOSIS

Clinical signs and laboratory values may improve within the initial 24 hours of treatment, but these patients have a guarded prognosis.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Congestive heart failure, renal disease, infection, gastrointestinal hemorrhage, and other serious illnesses.

D

DIABETES MELLITUS WITH KETOACIDOSIS

BASICS

DEFINITION

A true medical emergency secondary to absolute or relative insulin deficiency, characterized by hyperglycemia, ketonemia, metabolic acidosis, dehydration, and electrolyte depletion.

PATHOPHYSIOLOGY

- Insulin deficiency causes an increase in lipolysis, which results in excessive ketone body production and acidosis; an inability to maintain fluid and electrolyte homeostasis causes dehydration, prerenal azotemia, electrolyte disorders, obtundation, and death.
- Many diabetic ketoacidosis patients have underlying conditions such as infection, inflammation, or heart disease that cause stress hormone (e.g., glucagon, cortisol, growth hormone, and epinephrine) secretion; this probably contributes to the development of insulin resistance and diabetic ketoacidosis by promoting lipolysis, ketogenesis, gluconeogenesis, and glycogenolysis.
- Dehydration and electrolyte abnormalities result from osmotic diuresis, promoting the loss of total body water and electrolytes.

SYSTEMS AFFECTED

- Endocrine/metabolic • Gastrointestinal
- Hematologic (cats)

GENETICS

None

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

None

SIGNALMENT

Species

Dog and cat

Breed Predilections

- Dog—miniature poodle and dachshund
- Cat—none

Mean Age and Range

- Dog—mean age 8.4 years • Cat—median age 11 years (range 1–19 years)

Predominant Sex

- Dogs—females 1.5 times males
- Cats—males 2 times females

SIGNS

- Polyuria • Polydipsia or adipsia
- Diminished activity • Anorexia • Weakness
- Vomiting • Lethargy and depression
- Muscle wasting and weight loss • Unkempt haircoat • Tachypnea • Dehydration • Thin body condition • Hypothermia • Dandruff
- Thickened bowel loops • Hepatomegaly
- Ketone odor on breath • Icterus

CAUSES

- Insulin-dependent diabetes mellitus
- Infection (e.g., skin, respiratory, urinary

tract, prostate gland, pyelonephritis, pyometra, and pneumonia) • Concurrent disease (e.g., heart failure, pancreatitis, renal insufficiency or failure, asthma, neoplasia, acromegaly, and estrus) • Idiopathic

- Medication noncompliance • Stress
- Surgery

RISK FACTORS

- Any condition that leads to an absolute or relative insulin deficiency • History of corticosteroid or β -blocker administration

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hyperosmolar nonketotic coma • Acute hypoglycemic coma • Uremia • Lactic acidosis

CBC/BIOCHEMISTRY/URINALYSIS

- Leukocytosis with mature neutrophilia
- Hyperglycemia—blood glucose usually > 250 mg/dL • High liver enzyme activity
- Hypercholesterolemia and lipemia
- Azotemia • Hypochloremia • Hypokalemia
- Hyponatremia • Hypophosphatemia
- High anion gap—anion gap = (sodium + potassium) – (chloride + bicarbonate); normal is 16 ± 4 • Glucosuria and ketonuria
- Variable urinary specific gravity with active or inactive sediment • Hyperproteinuria
- Heinz body anemia (cats)

OTHER LABORATORY TESTS

- Metabolic acidosis—venous $\text{TCO}_2 < 15$ mEq/L caused by ketosis • Hyperosmolarity (> 330 mOsm/kg) • Bacterial culture of urine and blood

DIAGNOSTIC PROCEDURES

ECG may help evaluate potassium status; prolonged Q-T interval in some patients with hypokalemia; tall, tented T waves in some patients with hyperkalemia.

PATHOLOGIC FINDINGS

Pancreatic islet cell atrophy

TREATMENT

APPROPRIATE HEALTH CARE

- If the animal is bright, alert, and well hydrated, intensive care and intravenous fluid administration are not required; start subcutaneous administration of insulin (short- or intermediate-acting insulin), offer food, and supply constant access to water; monitor closely for signs of illness (e.g., anorexia, lethargy, vomiting). • Treatment of “sick” diabetic ketoacidotic dog or cat requires inpatient intensive care; this is a life-threatening emergency; goals are to correct the depletion of water and electrolytes, reverse ketonemia and acidosis, and increase
- the rate of glucose use by insulin-dependent tissues.

NURSING CARE

- Fluids—necessary to ensure adequate cardiac output and tissue perfusion and to maintain vascular volume; also reduce blood glucose concentration. • IV administration of 0.9% saline supplemented with potassium is the initial fluid of choice. Volume determined by dehydration deficit plus maintenance requirements; replace over 24–48h.

ACTIVITY

N/A

DIET

A low-fat, high-fiber, high-complex-carbohydrate diet recommended once the patient is stabilized.

CLIENT EDUCATION

Serious medical condition requiring life-long insulin administration in most patients.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUG(S) OF CHOICE

Insulin

- Necessary to inhibit lipolysis, inhibit hepatic gluconeogenesis, and promote peripheral glucose uptake.
- Regular insulin is the insulin of choice.
- Initial dosage—0.2 U/kg IM (or SC if hydration is normal).
- Subsequent dosage 0.1–0.2 U/kg given 3–6h later—may be given hourly if patient is closely monitored; response to previous insulin dosage should be considered when calculating subsequent dosages. Ideally, glucose concentration should drop to 50–100 mg/dL/h.
- Regular insulin can also be administered as a continuous-rate infusion via a designated catheter. For dogs, place 2.2 units/kg into 250 mL of 0.9% NaCl fluid. For cats, place 1.1 units/kg into 250 mL 0.9% NaCl fluid. Then, allow 50 mL of the dilute insulin to flow through the IV tubing and discard. If blood glucose is > 250 mg/dL, administer at 10 mL/hour. If blood glucose is 200–250 mg/dL, administer at 7 mL/hour. If blood glucose is 150–200 mg/dL, administer at 5 mL/hour. If blood glucose is 100–150 mg/dL, administer at 5 mL/hour and add 2.5% dextrose to the IV crystalloid fluids. If blood glucose is < 100 mg/dL, discontinue IV insulin infusion and continue 2.5–5% dextrose in IV crystalloid infusion.
- Check blood glucose every 1–3 hours with Chemstrip BG reagent strips and an automated test strip analyzer (Accu-Chek III, Boehringer Mannheim; Alpha Trak glucometer, Abbott Laboratories).

(CONTINUED)

DIABETES MELLITUS WITH KETOACIDOSIS

D

- Monitor urine glucose and ketones daily.
- Start administering longer-acting insulin when the patient is eating, drinking, and no longer receiving IV fluids and ketosis is resolved or greatly diminished; the dosage is based on that of short-acting insulin given in hospital.

Potassium Supplementation

- Total body potassium is depleted and treatment (e.g., fluids and insulin) will further lower serum potassium; potassium supplementation is always necessary.
- If possible, check potassium concentration before initiating insulin therapy to guide supplementation dosage; if it is extremely low, insulin therapy may need to be delayed (hours) until serum potassium concentration increases.
- Refractory hypokalemia may indicate magnesium depletion, requiring magnesium replacement at 0.75–1 mEq/kg/day as magnesium chloride or magnesium sulfate as a continuous-rate infusion.
- If potassium concentration is unknown, add potassium (40 mEq/L) to the IV fluids, obtain results of pretreatment biochemical analysis ASAP, and draw blood for follow-up biochemical analysis 24 hours after treatment is initiated.

Dextrose Supplementation

- Must give insulin, regardless of the blood glucose concentration, to correct the ketoacidotic state.
- Whenever blood glucose is < 200–250 mg/dL, 50% dextrose should be added to the fluids to produce a 2.5% dextrose solution (increase to 5% dextrose if needed). Discontinue dextrose once glucose is maintained above 250 mg/dL.
- Do not stop insulin therapy.

Bicarbonate Supplementation

- Controversial; consider if patient's venous blood pH is < 7.0 or total CO₂ is < 11 mEq/L; bicarbonate is of no benefit if the pH is > 7.0.
- Dosage—body weight (kg) × 0.3 × base deficit (base deficit =; normal serum bicarbonate – patient's serum bicarbonate); slowly administer one-quarter to one-half of the dose IV and give the remainder in fluids over 3–6 hours.
- Recheck blood gas or serum TCO₂ before further supplementation.

Phosphorus Supplementation

- Pretreatment serum phosphorus usually is normal; however, treatment of ketoacidosis reduces phosphorus, and serum concentrations should be checked every 12–24 hours once supplementation is initiated.
- Dosage—0.01–0.03 mmol/kg/h for 6–12 hours in IV fluids (may need to increase dose to 0.03–0.06 mmol/kg/h).

CONTRAINDICATIONS

If the patient is anuric or oliguric or if potassium is > 5 mEq/L, do not supplement potassium until urine flow is established or potassium concentration decreases.

PRECAUTIONS

Use bicarbonate with caution in patients without normal ventilation because of their inability to excrete carbon dioxide created during treatment.

POSSIBLE INTERACTIONS

None

ALTERNATIVE DRUG(S)

None

FOLLOW-UP

PATIENT MONITORING

- Attitude, hydration, cardiopulmonary status, urine output, and body weight • Blood sugar q1–3h initially; q6h once stable
- Electrolytes q4–8h initially; q24h once stable • Acid–base status q8–12h initially; q24h once stable

PREVENTION/AVOIDANCE

Appropriate insulin administration

POSSIBLE COMPLICATIONS

- Hypokalemia • Hypoglycemia
- Hypophosphatemia • Cerebral edema
- Pulmonary edema • Renal failure • Heart failure

EXPECTED COURSE AND PROGNOSIS

Guarded

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Pancreatitis • Hyperadrenocorticism
- Diestrus • Bacterial infection • Electrolyte depletion

DIABETES MELLITUS WITHOUT COMPLICATION—CATS

BASICS

DEFINITION

- Disorder of carbohydrate, fat, and protein metabolism caused by an absolute or relative insulin deficiency, insulin resistance, and insulin amyloidosis.
- Type II (non-insulin-dependent DM) is characterized by inadequate or delayed insulin secretion relative to the needs of the patient; many of these patients live without exogenous insulin and are less prone to ketoacidosis; most common form in cats.

PATHOPHYSIOLOGY

- Insulin resistance impairs the ability of tissues (especially muscle, adipose tissue, and liver) to use carbohydrates, fats, and proteins.
- Impaired glucose utilization and ongoing hepatic gluconeogenesis cause hyperglycemia.
- Glucosuria develops, causing osmotic diuresis, polyuria, and compensatory weight loss; mobilization of free fatty acids to the liver causes both hepatic lipidosis and ketogenesis.

SYSTEMS AFFECTED

- Endocrine/Metabolic—electrolyte depletion and metabolic acidosis.
- Hepatobiliary—hepatic lipidosis; liver failure may develop.
- Nervous—peripheral neuropathy.
- Renal/Urologic—urinary tract infection and osmotic diuresis.

INCIDENCE/PREVALENCE

Prevalence in cats is 1:200

SIGNALMENT

Species

Cat

Mean Age and Range

75% are 8–13 years; range 1–19 years

Predominant Sex

Male

SIGNS

- Early signs—obesity is typical.
- Dorsal muscle wasting and an oily coat with dandruff—common.
- Hepatomegaly; jaundice—more prevalent in cats than dogs.
- Less common findings—a plantigrade stance (diabetic neuropathy).
- Later signs—polyuria and polydipsia, polyphagia, weight loss, anorexia, lethargy, depression, and vomiting.

CAUSES

- Genetic susceptibility
- Amyloid
- Pancreatitis
- Predisposing diseases (e.g., hyperadrenocorticism and acromegaly)
- Drugs (e.g., glucocorticoids and progestogens)

RISK FACTORS

- Obesity for type II DM
- See “Causes”

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Renal glucosuria—usually does not cause PU/PD, weight loss, or hyperglycemia.
- Stress hyperglycemia in cats—no PU/PD or weight loss; blood glucose concentration normal if sample taken when cat is not stressed. Fructosamine normal.

CBC/BIOCHEMISTRY/URINALYSIS

- Results of hemogram usually normal.
- Glucose > 150 mg/dL.
- High SAP, ALT, AST activities, and hypercholesterolemia and lipemia common.
- Electrolytes vary, but hypernatremia, hypokalemia, and hypophosphatemia indicate severe decompensation.
- Total CO₂ or HCO₃ is low if the patient has ketoacidosis or severe dehydration.
- Glucosuria is a consistent finding.
- Ketonuria is uncommon.
- Urinary specific gravity often is low.

OTHER LABORATORY TESTS

- Anion gap—high in patients with ketoacidosis
- Fructosamine > 350 μmol/L

IMAGING

- Radiography—useful to evaluate for concurrent or underlying disease (e.g., cystic or renal calculi, emphysematous cystitis or cholecystitis, and pancreatitis).
- Ultrasonography—indicated in selected patients, particularly those with jaundice, to evaluate for hepatic lipidosis, cholangiohepatitis, and pancreatitis.

DIAGNOSTIC PROCEDURES

Liver biopsy (percutaneous)—indicated in some jaundiced patients.

PATHOLOGIC FINDINGS

- Usually no gross necropsy changes.
- Histopathologic findings may be normal or reveal vacuolar degeneration of the islets of Langerhans or low numbers of islet cells; usually see amyloid deposits in the islets.

TREATMENT

APPROPRIATE HEALTH CARE

- Compensated cats can be managed as outpatients; they are alert, hydrated, and eating and drinking without vomiting.
- For management of decompensated patients, see Diabetes Mellitus with Ketoacidosis.

NURSING CARE

Fluid therapy—see Diabetes Mellitus with Ketoacidosis.

ACTIVITY

Strenuous activity may lower insulin requirement; a consistent amount of activity each day is helpful.

DIET

- Studies suggest that ultra-low-carbohydrate canned diets may induce diabetic remission in 70–95% of newly diagnosed diabetic cats; monitor closely for change in insulin requirement following any adjustment in diet.
- Avoid soft, moist foods because they cause severe post-prandial hyperglycemia.

CLIENT EDUCATION

- Discuss daily feeding and medication schedule, home monitoring, signs of hypoglycemia and what to do, and when to call or visit veterinarian.
- Clients are encouraged to keep a chart of pertinent information about the pet, such as urine dipstick results, daily insulin dose, and weekly body weight.

SURGICAL CONSIDERATIONS

Intact females should have an ovariohysterectomy when stable; progesterone secreted during diestrus makes management of DM difficult.

MEDICATIONS

DRUG(S) OF CHOICE

- Insulin—treatment of choice for most cats.
- Pork Lente insulin (Vetsulin)—intermediate duration; given SC; initial dosage 2 U q12h. Availability may be limited.
- Protamine zinc (PZI, U-40)—long-acting insulin; given SC, usually q24h; some cats require injections q12h, starting with a dose of 2 U q12h.
- Glargin (Lantus, U-100)—basal peakless human recombinant insulin gives best results when combined with a low-carbohydrate, high-protein diet. Remission rates of 70–100% reported with this combination. Dose: 2 U SC q12h.
- Oral administration of hypoglycemic agent—glipizide is useful with dietary therapy in cats with type II DM; the cat should have uncomplicated DM and no history of ketoacidosis; initial dosage, 2.5 mg PO q12h; monitoring is the same as for patients on insulin; if hyperglycemia is not controlled, 5 mg PO q12h may be tried; potential side effects are hypoglycemia, hepatic enzyme alterations, icterus, and vomiting.

PRECAUTIONS

- Glucocorticoids, megestrol acetate, and progesterone cause insulin resistance. If steroid therapy is necessary use oral medrol. Avoid injectable steroids.

(CONTINUED)

DIABETES MELLITUS WITHOUT COMPLICATION—CATS

D

- Hyperosmotic agents (e.g., mannitol and radiographic contrast agents) if the patient is already hyperosmolar from hyperglycemia.

POSSIBLE INTERACTIONS

Many drugs (e.g., NSAIDs, sulfonamides, miconazole, chloramphenicol, monoamine oxidase inhibitors, and β -blockers) potentiate the effect of hypoglycemic agents given orally; consult the product insert.

ALTERNATIVE DRUG(S)

Acarbose 12.5 mg PO q12h

**FOLLOW-UP****PATIENT MONITORING**

- Glucose curve—not helpful in cats.
- Urinary glucose monitoring—urine is tested for glucose and ketones before the meal and insulin injection; to use this as a regulatory method, the pet must be allowed to have trace to 1/4% glucosuria to avoid hypoglycemia.
- Fructosamine—maintain < 400 $\mu\text{mol/L}$. Recheck monthly during initial regulation, then every 3 months.
- Clinical signs—owner can assess degree of PU/PD, appetite, and body weight; if these are normal, the disease is well regulated.

PREVENTION/AVOIDANCE

Prevent or correct obesity; avoid unnecessary use of glucocorticoids or megestrol acetate.

POSSIBLE COMPLICATIONS

- Seizure, blindness, or coma with insulin overdose
- Diabetic nephropathy
- Diabetic neuropathy

EXPECTED COURSE AND PROGNOSIS

- Some cats recover but may relapse at a later time.
- Prognosis with treatment is good; most animals have a normal lifespan.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Urinary tract infection

AGE-RELATED FACTORS

Juvenile DM is rare and may be more difficult to manage.

ZOONOTIC POTENTIAL

None

SEE ALSO

- Diabetes Mellitus with Ketoacidosis

DIABETES MELLITUS WITHOUT COMPLICATION—DOGS

BASICS

DEFINITION

- Fasted hyperglycemia of sufficient severity to result in concurrent glucosuria.
- Disorder of carbohydrate, fat, and protein metabolism caused by an absolute or relative insulin deficiency.
- Generally canine diabetes mellitus is characterized by loss of insulin-secreting ability through presumed immune-mediated destruction of pancreatic β cells resulting in a dependence on exogenous insulin (insulin-dependent diabetes mellitus or IDDM).
- Far less frequently, canine DM can develop as a result of the combination of a relative insulin deficiency with concurrent peripheral insulin resistance. This combination of events may result in IDDM, non-insulin dependent diabetes mellitus (NIDDM), or both.

PATHOPHYSIOLOGY

- Absolute or relative insulin deficiency results in accelerated tissue catabolism, an impaired ability to maintain carbohydrate, lipid, and protein homeostasis, as well as insulin resistance.
- Hypoinsulinemia, peripheral insulin resistance, and continued hepatic gluconeogenesis results in persistent hyperglycemia of sufficient severity to overload renal tubular glucose resorption leading to glucosuria, a resultant osmotic diuresis and polyuria and compensatory polydipsia.
- Loss of insulin-dependent glucose-mediated hypothalamic satiation signal results in polyphagia.
- Decreased insulin-dependent utilization of glucose results in catabolic protein breakdown with weight loss and increased lipid mobilization (hyperlipidemia, hepatic lipidosis, ketone production).
- Insulin is most efficient at inhibiting peripheral lipolysis so uncontrolled ketone body production only occurs in animals with IDDM.
- Accumulations of large amounts of ketone bodies leads to metabolic acidosis and depletion of total body potassium.

SYSTEMS AFFECTED

- Endocrine/Metabolic—electrolyte depletion and metabolic acidosis.
- Hepatobiliary—hepatocellular lipidosis.
- Ophthalmic—cataracts.
- Renal/Urologic—glucosuria resulting in osmotic diuresis and increased likelihood of bacterial urinary tract infection.

GENETICS

Certain breeds dramatically over- and under-represented, suggesting inherited susceptibility to immune-mediated "isletitis."

INCIDENCE/PREVALENCE

- Prevalence varies between 1:400 and 1:500.
- Onset has a seasonal incidence; more animals diagnosed in the autumn and winter.

SIGNALMENT

Species

Dog

Breed Predilections

- Breeds overrepresented include Samoyed, Tibetan terrier, cairn terrier, and golden retriever (United States only).
- Possibly higher risk than other breeds—Keeshond, poodle, dachshund, miniature schnauzer, and beagle.
- Breeds underrepresented include boxer, German shepherd, and golden retriever (UK only).

Mean Age and Range

Mean ~ 8 years; range 4–14 years (excluding rare juvenile form)

Predominant Sex

Female

SIGNS

- Polyuria and polydipsia, polyphagia with weight loss.
- Hepatomegaly.
- Cataracts are a common finding in chronic cases or in dogs that have had poor control of their disease.
- Lethargy, depression, inappetance, anorexia and vomiting may occur in animals with marked ketoacidosis.

CAUSES

- Primary immune-mediated isletitis.
- Disorders that predisposing to secondary immune-mediated isletitis such as pancreatitis, various viral illnesses.

RISK FACTORS

- Diestrus
- Genetic susceptibility to immune-mediated isletitis
- Drugs such as glucocorticoids and progestins

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Renal glucosuria—does not cause hyperglycemia and usually no signs of weight loss with polyphagia.

CBC/BIOCHEMISTRY/URINALYSIS

- Hemogram usually normal.
- Glucose > 200 mg/dL.
- High SAP and ALT with generally a greater proportionate increase in SAP, consistent with an obstructive hepatopathy.
- Hypercholesterolemia, lipemia and ketonemia are common.
- Electrolyte alterations vary, although hypokalemia and hypophosphatemia indicate severe decompensation.
- Total CO₂ or HCO₃ will be low with ketoacidosis or severe dehydration.
- Glucosuria consistently present.
- Ketonuria is common.
- Urinary specific gravity can be variable depending upon the level of glucosuria.

OTHER LABORATORY TESTS

- Anion gap—high in patients with ketoacidosis.
- Plasma insulin concentrations are not particularly helpful. While a low insulin concentration suggests an absolute

insulin deficiency this may be a reflection of reversible islet exhaustion as persistent hyperglycemia can impair insulin secretory activity, even if functional β cells are present.

IMAGING

- Radiography—useful to evaluate for concurrent or underlying disease (e.g., cystic or renal calculi, emphysematous cystitis or cholecystitis, and pancreatitis).
- Ultrasonography—indicated in selected patients, particularly those with jaundice, to evaluate possible other causes for a significant obstructive hepatopathy or concurrent complicating pancreatitis.

DIAGNOSTIC PROCEDURES

Liver biopsy (percutaneous)—indicated in some jaundiced patients to evaluate possible other causes for an obstructive hepatopathy.

PATHOLOGIC FINDINGS

- Necropsy findings—hepatomegaly with significant hepatic lipid accumulation.
- Histopathologic findings generally reveal dramatic reduction in the size and numbers of pancreatic islets with relatively normal exocrine tissue architecture except in dogs with concurrent exocrine pancreatic disease.

TREATMENT

APPROPRIATE HEALTH CARE

- Compensated dogs are generally alert, well hydrated, eating and drinking without vomiting and should be managed as outpatients.
- For management of decompensated patients, see Diabetes Mellitus with Ketoacidosis.

DIET

- The diet must be consistent—the food should be calorically and constitutionally controlled and consistent and the animal should consume the same caloric intake every morning and night.
- Match the glucose lowering effects of the insulin with glucose raising effects of the meal. As most insulins act maximally two to four hours after SC administration, and normally most food is being absorbed within an hour of consumption; glycemic control is almost always improved if the dog is fed 60–90 minutes AFTER q12h insulin dosing.
- Animals that "graze" throughout the day can be fed dry food ad libitum and given two small meals of canned food as described. If insulin can only be administered once daily, feed the total daily caloric intake in two or three meals within the first 6–8 hours after insulin dosing.
- Feed a caloric quantity appropriate for the animal's ideal body weight (~ 50–70 kcal/kg). The food should be something that the dog will eat reliably and within a short period of time.
- Obese diabetic dogs—feed a restricted caloric intake to ensure their ideal body weight is achieved

(CONTINUED)

DIABETES MELLITUS WITHOUT COMPLICATION—DOGS

D

within 2–4 months using a high-fiber, low-calorie food. While a high-fiber diet may improve patient satiety and possibly owner satisfaction, it has no role in improving diabetic control. • No snacks should be provided unless they have virtually no calories.

CLIENT EDUCATION

- Discuss daily feeding and medication schedule, home monitoring, signs of hypoglycemia and what to do, and when to call or visit veterinarian.
- Clients are encouraged to keep a chart of pertinent information about the pet, such as daily water consumption, weekly body weight, current insulin dose and amount of food consumed.

SURGICAL CONSIDERATIONS

Intact females should have an ovariohysterectomy when stable; progesterone secreted during diestrus makes management of DM more unpredictable.

MEDICATIONS

DRUG(S) OF CHOICE

- Insulin—required for IDDM; frequently utilized as part of management of NIDDM.
- Vetsulin (porcine-origin Lente) 0.75 units/kg SC q12h initial dose. **Note:** U-40 insulin; must use with U-40 insulin syringe. Availability may be limited.
- Humulin N—intermediate-acting, human insulin; 0.75 units/kg SC q12h initial dose.
- Novolin N—intermediate-acting, human insulin; 0.75 units/kg SC q12h initial dose.
- PZI Vet (Idexx) rarely used in dogs; intermediate- to longer-acting protamine/zinc, human insulin. NOTE: U-40 insulin, must use with U-40 syringe.
- Glargine and detemir insulins: intermediate- to longer-acting synthetic insulins that have a “peakless” level of activity and delayed release from subcutaneous injection sites. These are rarely used in dogs.
- Species of origin of the insulin may affect pharmacokinetics; canine and porcine insulin have identical amino acid sequence, hence Vetsulin does not produce a significant insulin antibody response, whereas most other commercially available insulins do. However, there is no evidence that the development of insulin antibodies has any clinical significance.

PRECAUTIONS

- Glucocorticoids, megestrol acetate, and progesterone cause insulin resistance.
- Hyperosmotic agents (e.g., mannitol and radiographic contrast agents) if the patient is already hyperosmolar from hyperglycemia.

ALTERNATIVE DRUG(S)

Oral hypoglycemic agents are generally not recommended. The rare dog with NIDDM may be amenable to treatment with oral hypoglycemic agents but must be strictly monitored as this is generally a progressive

disease and ineffective management can have disastrous consequences.

FOLLOW-UP

PATIENT MONITORING

- Diabetic dogs need to be managed with regular contact between the owner and their veterinary team. The frequency should be approximately 3–4 months if the animal is stable and clinical signs are controlled; or more frequently if control is poor or variable. Criteria effective in assessing adequate control are listed below.
- Clinical signs—assess degree of PU/PD, appetite, and body weight; if within acceptable limits, the disease is likely to be well regulated.
- Glycated proteins—fructosamine or glycosylated hemoglobin; the extent of glycation is directly related to the blood glucose concentration over the lifespan of the protein in the circulation (normally 10–20 days for fructosamine, 4–8 weeks for hemoglobin); thus they are not affected by vagaries of single blood glucose level nor by the effects of travel and/or hospitalization on gastric emptying and thus the interplay between the effects of the insulin and the meal on blood glucose levels.
- Glycated protein levels are modified by changes in albumin or hemoglobin concentrations and the amount of time they spend in circulation; anything that accelerates albumin turnover (e.g., glomerulonephropathy, liver dysfunction, GI disease) will lower the fructosamine level for a given average blood glucose.
- Glycated protein levels are best used for ongoing management of a relatively stable diabetic patient; a fructosamine in the upper third of the reference range reflects excellent diabetic control; a fructosamine in the lower third is more suggestive of overzealous diabetic control and possible increased risk of clinically significant hypoglycemia.
- Glucose curve—can provide information on insulin effectiveness, duration of action, nadir (lowest blood glucose level achieved during dosing interval), and potential for rebound hyperglycemia; results subject to outside influences; stress of hospitalization and multiple blood draws; used most frequently when establishing initial control, changing insulin type, dose, or frequency, or problem solving the difficult diabetic; duration of curve ideally matches dosing interval (12 or 24 hours); identification of nadir (to avoid iatrogenic hypoglycemia) and glucose level at the time of dosing are the most important aspects of curve; mimic “normal” conditions as closely as possible; can have owner feed and administer insulin at home prior to hospitalization although not ideal as introduces additional confounding factors related to gastric emptying; measure blood glucose q2h or q4h; goal is effective insulin

dose (decline in blood glucose to 100–200 mg/dL) for appropriate duration (majority of 12- or 24-hour dosing interval) with a nadir > 80 mg/dL and < 150 mg/dL.

- Home-glucose monitoring using serial blood glucose estimations with home-glucose monitoring kits; requires significant owner commitment, compliance, and competence; most useful as early indicator of need for reduction in dose in patients with well controlled clinical signs; should never be used by the owner to make independent adjustment of insulin dose. Owner-measured urine glucose levels are not particularly useful.

PREVENTION/AVOIDANCE

- Neuter females; avoid unnecessary use of megestrol acetate.
- No evidence exists to suggest obesity increases the risk of DM in neutered dogs.

POSSIBLE COMPLICATIONS

- Cataracts can occur even with good glycemic control.
- Weakness, especially with exercise; seizures or coma may occur with insulin overdose.

EXPECTED COURSE AND PROGNOSIS

- Dogs generally have permanent disease unless affected during an estrus cycle where neutering may resolve the diabetes for a period.
- Prognosis with twice daily insulin treatment and feeding aligned with insulin's maximum effects is excellent.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Urinary tract infection
- Cataracts

AGE-RELATED FACTORS

Juvenile DM is rare and may be more difficult to manage

PREGNANCY/FERTILITY/BREEDING

- DM can develop during pregnancy, in which case the pregnancy is difficult to maintain.
- Exogenous insulin administration may cause fetal oversize and dystocia.
- Insulin resistance develops, making hyperglycemia difficult to control.
- The pregnant bitch is prone to ketoacidosis; an emergency ovariohysterectomy may be necessary.
- Do not breed dogs with DM.

ABBREVIATIONS

- DM = diabetes mellitus
- IDDM = insulin-dependent diabetes mellitus
- NIDDM = non-insulin dependent diabetes mellitus

DIABETIC HEPATOPATHY

BASICS

OVERVIEW

D

- Liver lesion—severe degenerative vacuolar hepatopathy (VH, macrovesicular lipid and glycogen), parenchymal collapse causing marked hepatic nodularity; associated with syndromic pressure point dermatosis and usually diabetes mellitus (DM).
- Liver lesions—may precede cutaneous lesions and DM.
- May develop in some dogs treated chronically with phenobarbital.

SIGNALMENT

- Middle-aged to older dogs
- Males may have greater predilection
- Syndrome in Shih Tzu dogs recognized

SIGNS

Historical Findings

- Acute onset; may be few signs initially.
- Common signs—weight loss, lethargy, PU/PD, anorexia, diarrhea, vomiting, anicteric or jaundiced, lameness due to painful foot pad fissures.

Physical Examination Findings

- Lethargy, poor body condition, painful feet and elbow lesions compromise recumbent and standing postures, may be jaundiced.
- Cutaneous lesions—see Superficial Necrolytic Dermatitis.
- Normal, small to large hepatic size—rarely, may palpate irregular liver margin.
- Rare abdominal effusion.

CAUSES & RISK FACTORS

- Etiology—associated with hypoaminoacidemia; causal role in cutaneous lesions and possibly liver lesions.
- Secondary causal role—suggested for ill-defined deficiencies: zinc, fatty acid, or niacin.
- Hyperglucagonemia—originally proposed causal mechanism but inconsistent (~ 30%–40% of tested dogs demonstrate high plasma glucagon); poor correlation may reflect assay specificity or high hepatic glucagon extraction; pancreatic glucagon-producing tumor confirmed in < 25% of dogs.
- Insulin resistant DM.
- Similar cutaneous lesions described with primary hepatopathies caused by: phenobarbital or rarely, with chronic mycotoxicosis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cirrhosis—regenerative nodular hyperplasia with extensive connective tissue deposition and loss of architectural organization.

- Chronic hepatitis—inflammatory infiltrates; individual hepatocyte necrosis.
- Copper associated hepatopathy—high tissue copper associated initially with zone 3 necroinflammatory injury.
- Diffuse nodular hyperplasia—rare.
- Degenerative glycogen-type VH.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC—mild to moderate non-regenerative to mild regenerative anemia; RBC microcytosis; neutrophilic leukocytosis reflects cutaneous lesions (infections).
- Biochemistry—high liver enzymes (especially ALP); hypoproteinemia with hypoalbuminemia; euglycemic to fasting hyperglycemia; variable cholesterol and BUN.
- Urinalysis—ammonium biurate crystalluria may reflect hepatic insufficiency.

OTHER LABORATORY TESTS

- Total serum bile acids—often increased.
- Insulin—inappropriately increased.
- Plasma glucagon—inconsistently high.
- Plasma amino acids—30%–50% of normal in dogs with cutaneous lesions; moderate reductions in dogs with liver lesions preceding skin lesions.

IMAGING

- Abdominal radiography—variable liver size, small, normal, to large liver; rare effusion.
- Abdominal ultrasonography—may see irregular liver margin; characteristic nodular pattern: hypoechoic foci in background hyperechoic parenchyma, “Swiss cheese pattern”; although suggested as pathognomonic, other severe degenerative VH also demonstrates this pattern; occasional diffuse nodularity cannot be imaged; pancreatic mass imaged < 20% of dogs.

DIAGNOSTIC PROCEDURES

- Aspiration sampling—hepatocytes show VH associated with glycogen and lipid.
- Liver biopsy—needle biopsy may compromise definitive diagnosis by limiting detection of proliferative foci of hepatocytes between massive vacuolated parenchyma; needle biopsy may be best option for dogs with extensive skin lesions; larger laparoscopic samples preferred; avoid laparotomy as dogs with cutaneous lesions may not promptly heal.
- If pancreatic mass imaged, resect for histology and immunohistochemical staining for glucagon and other products.
- Skin biopsy—see Superficial Necrolytic Dermatitis.

TREATMENT

- Diet—use high good-quality protein, energy-dense diet; but enteral or parenteral feeding may be required for inappetent dogs.

- If HE—improve nitrogen tolerance with lactulose and metronidazole (see Hepatic Encephalopathy) and use liver-specific diet.
- Oral protein hyperalimentation and periodic parenteral IV amino acid infusions need in most.
- Amino acid supplementation—egg yolk (3–6 yolks per day); anabolic whey protein powder (e.g., Beneprotein, used for body building muscle accretion) one serving ~ 7 g protein, 25–35 kcal; one serving/5–7 kg body weight; mix with diet; if HE use baseline diet formulated for hepatic insufficiency; IV infusion (3.5% to 10% solutions), e.g., 10% crystalline amino acid solution (Aminosyn, Abbott Laboratories; 100 mL delivers 10 g amino acids), 25 mL/kg body wt. over 8–12 h through a large central vein (i.e., jugular vein), unless coagulopathy; then use long jugular catheter threaded deeply into a peripheral vein); rare HE induction. Cutaneous lesions may resolve after only one amino acid treatment; if little response, repeat q7–10 days for 4 treatments; if no response, grave prognosis.
- Essential fatty acid supplementation—omega-3 fatty acids; double normal dose.
- Metastatic pancreatic tumors secreting glucagon may be controlled with long-acting somatostatin analog (octreotide: 2–3.7 µg/kg q6–12 h); prohibitively expensive.

MEDICATIONS

DRUG(S)

- Manage DM with insulin.
- See Dietary recommendations above.
- Cutaneous or nail bed infections—systemic antimicrobials or antifungals; germicidal baths.
- Zinc supplementation—2–4 mg/kg elemental zinc q24h; avoid zinc methionine if HE.
- Niacinamide—250–500 mg/dog q12h (500 mg for dogs > 10 kg); watch for toxic effects; avoid extended-release form.
- Topical glucocorticoids—if unresponsive inflammatory skin lesions, after infection managed (**caution:** systemic glucocorticoids may promote HE, enteric ulceration, infection, complicate DM management).
- Ketoconazole—for secondary yeast infection; anti-inflammatory and antipruritic effects
- Somatostatin—long-acting octreotide theorized as possible treatment; based on speculated endocrinologic cause; prohibitively expensive.
- Ursodeoxycholic acid—10–15 mg/kg PO daily, divided dose given with food.
- Antioxidants—Vitamin E (10 IU/kg daily PO); S-adenosylmethionine (SAMe) 20 mg/kg PO daily on empty stomach, other

(CONTINUED)

DIABETIC HEPATOPATHY

D

beneficial effects additional to antioxidant influence.

- If associated with phenobarbital, discontinue.

POSSIBLE INTERACTIONS

- HE induction: high protein diet supplements and amino acid infusions.
- Toxic effects of ketoconazole and its interference in drug metabolism.
- Toxic effects of niacinamide and zinc.

**FOLLOW-UP****PATIENT MONITORING**

- Weekly to monthly physical exam to assess need for amino acid supplements and treatment for secondary infections.
- Daily glucose monitoring at home.
- Fastidious management of diabetes mellitus.
- Weekly to monthly CBC, biochemistry, and urinalysis, initially.

POSSIBLE COMPLICATIONS

- Hyperosmolar amino acid solutions may cause thrombophlebitis.
- Ketoacidosis—uncommon.
- Hepatic encephalopathy.
- Sepsis—due to diabetes and skin lesions.
- Pain—from skin lesions require analgesics.

EXPECTED COURSE AND PROGNOSIS

- Some dogs achieve cutaneous remission ~ 2 year with described therapies; most have unremitting progression, necessitating euthanasia; improved liver lesions with treatment.

**MISCELLANEOUS****SYNONYMS**

- Superficial necrolytic dermatitis
- Necrolytic migratory erythema
- Metabolic epidermal necrosis
- Glucagonoma syndrome
- Hepatocutaneous syndrome

ABBREVIATIONS

- DM = diabetes mellitus
- HE = hepatic encephalopathy
- VH = vacuolar hepatopathy

Suggested Reading

Oberkirchner U, Linder KE, Zadronzny L, et al. Successful treatment of canine necrolytic migratory erythema (superficial necrolytic dermatitis) due to metastatic glucagonoma with octreotide. *Vet Dermatol* 2010, 21:510–516.

Author Sharon A. Center

Consulting Editor Sharon A. Center

DIAPHRAGMATIC HERNIA

BASICS

OVERVIEW

- D** • Protrusion of an abdominal organ through an abnormal opening in the diaphragm either as an acquired injury or as a congenital defect.
- Traumatic—most common acquired cause; usually the result of automobile trauma but also any forceful blow; sudden increase of pressure results in an abdominal-thoracic pressure gradient, causing a tear in the diaphragm, usually at a muscular portion.
 - Congenital—pleuroperitoneal or peritoneopericardial diaphragmatic hernia (PPDH); may note other congenital defects (e.g., umbilical hernia, cranoventral abdominal wall defects, cryptorchidism, cleft palate, ventricular septal defect, aortic stenosis, and portosystemic shunting).
 - Impaired lung expansion—because of lack of lung contact with parietal pleura.
 - Intrapulmonary changes (e.g., lung contusion, atelectasis, and capillary permeability changes causing edema)—contribute to poor gas exchange.
 - Rib fractures due to trauma—may contribute to hypoventilation because of pain or mechanical (flail chest) factors.
 - Myocardial trauma can result in various dysrhythmias—ventricular tachyarrhythmias: most common; seen within 24–72 hours after trauma; difficult to control with conventional treatment; commonly resolve within 5 days.
 - Various stages of shock—can cause multiple organ system failure.

SIGNALMENT

- Dogs and cats.
- Acquired—no breed predilection.
- Congenital (PPDH)—Weimaraners may be predisposed; Maine Coon and other longhaired cats may be overrepresented; can be diagnosed at any age because clinical signs are variable and intermittent; often diagnosed incidentally.
- Young animals at higher risk for both congenital and traumatic causes.

SIGNS

Traumatic

- Can be acute, subacute, or chronic (with no known history of trauma).
- Low-grade respiratory signs or vague history of gastrointestinal problems possible.
- Signs may be progressive.
- Tachypnea and respiratory distress—most common; acutely affected patients often in shock.
- Arrhythmias—may be detected.
- Muffled heart and lung sounds along with intestinal sounds—may be auscultated in the thorax.
- Abdomen—may feel empty on palpation.
- Acute incarceration of bowel or stomach—can cause vomiting, diarrhea, retching, bloating, pain, and acute collapse.

Congenital

- May not have clinical signs or develop clinical signs later in life.
- Referable to the

respiratory, cardiac, or gastrointestinal system.

- Difficulty breathing, muffled heart sounds, murmurs, and concurrent ventral abdominal wall defects—most common.
- Signs can be acute from strangulation of incarcerated bowel, liver, or spleen or rapid formation of pleural or pericardial effusion.

CAUSES & RISK FACTORS

Traumatic—lack of confinement and exposure to automobiles; any blunt trauma; roaming animals and male dogs at higher risk than others.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- See Dyspnea and Respiratory Distress
- See Panting and Tachypnea
- See Pleural Effusion

CBC/BIOCHEMISTRY/URINALYSIS

Non-specific changes due to ischemia or shock may be noted

IMAGING

- Standard two-view thoracic and abdominal radiography
- Horizontal beam radiography
- Ultrasonography
- Contrast radiography—upper gastrointestinal series or peritoneography
- CT sometimes needed

DIAGNOSTIC PROCEDURES

Thoracocentesis for pleural effusion.

TREATMENT

TRAUMATIC

- Inpatient—treat shock; improve ventilation and cardiac output; manage concurrent injury; stabilize patient before surgery.
- Surgery—early intervention indicated with persistent hypotension despite adequate fluid therapy, severe respiratory failure from excessive lung compression, severe liver failure secondary to organ entrapment, bowel rupture, or enlarging gas-filled bowel seen on radiographs; if patient cannot be stabilized, surgical repair will not necessarily improve cardiovascular and respiratory status.
- Intrathoracic gastric dilation—requires immediate decompression.

CONGENITAL

- Surgical repair—perform as early as possible to avoid adhesion formation and organ entrapment.
- Stabilize patients before surgery.

MEDICATIONS

DRUG(S)

Antiarhythmic agents—as indicated

CONTRAINdications/POSSIBLE INTERACTIONS

Take care when treating for shock with concurrent severe pulmonary contusion due to the risk for fluid overload; products such as hetastarch may be beneficial.

FOLLOW-UP

PATIENT MONITORING

Frequent or continuous electrocardiographic monitoring—advised; evaluate for postoperative arrhythmias.

POSSIBLE COMPLICATIONS

- Pneumothorax—may develop from excessive pressure on damaged lung tissue during anesthetic bagging or from failure to remove air from the chest cavity after diaphragmatic closure.
- Postoperative hyperthermia common in cats.
- Pulmonary edema—can develop from excessive fluid administration in the face of low oncotic pressure from blood loss, capillary permeability changes secondary to inflammation in response to pulmonary contusion, or lung reexpansion.

EXPECTED COURSE AND PROGNOSIS

Prognosis—always initially guarded; favorable after successful control of shock, elimination of any cardiac arrhythmias, successful surgery, and the lack of reexpansion pulmonary edema. Older cats with traumatic diaphragmatic hernia are less likely to survive surgical repair.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Congenital peritoneopericardial diaphragmatic hernias may be associated with other congenital midline defects, such as septal defects, cleft palates, umbilical hernias and abdominal wall defects.

ABBREVIATIONS

- CT = computed tomography
- PPDH = peritoneal pericardial diaphragmatic hernia

Suggested Reading

Burns CG, Bergh MS, McLoughlin MA. Surgical and nonsurgical treatment of peritoneopericardial diaphragmatic hernia in dogs and cats: 58 cases (1999–2008). J Am Vet Med Assoc 2013, 242:643–650.

Gibson TW, Brisson BA, Sears W. Perioperative survival rates after surgery for diaphragmatic hernia in dogs and cats: 92 cases (1990–2002). J Am Vet Med Assoc 2005, 227:105–109.

Author Catriona M. MacPhail

Consulting Editor Lynelle R. Johnson

DIARRHEA, ACUTE

D

BASICS

DEFINITION

Abrupt or recent onset of abnormally increased fecal water and/or solid content.

PATHOPHYSIOLOGY

- Caused by imbalance in the absorptive, secretory, and/or motility actions of the intestines.
- Mechanisms of diarrhea:
 - (1) Osmotic—excess molecules in the intestinal lumen draw in water, overwhelming the intestinal absorptive capacity (e.g., diet changes, malabsorption or overeating).
 - (2) Secretory—stimulation of small intestinal secretion that overwhelms the intestinal absorptive capacity (e.g., toxins). Stimulation of the parasympathetic nervous system or exposure to a variety of secretagogues can increase intestinal secretion.
 - (3) Exudative/permeability—leakage of tissue fluid, serum proteins, blood, or mucus from sites of infiltration or ulceration.
 - (4) Dysmotility—hypomotility (ileus) is more common than hypermotility. Hypermotility can be primary (irritable bowel syndrome) or secondary (obstruction, malabsorption leading to intestinal distention).
 - (5) Mixed.

SYSTEMS AFFECTED

- Cardiovascular—hypovolemia, tachycardia, pale mucous membranes, prolonged CRT and weak pulses; hypokalemia can cause arrhythmias.
- Endocrine/Metabolic—electrolyte and acid-base abnormalities, dehydration, and prerenal azotemia.
- Gastrointestinal—abdominal pain, hypokalemia can lead to decreased motility.
- Musculoskeletal—hypokalemia can lead to muscle weakness.

GENETICS

No genetic basis

INCIDENCE/PREVALENCE

Acute diarrhea is more common in younger animals and is more likely to resolve on its own. A fairly common problem, especially in dogs with dietary indiscretion.

GEOGRAPHIC DISTRIBUTION

Some infectious causes (e.g., salmon poisoning) may be regional.

SIGNALMENT

- Dogs and cats.
- Any animal can suffer from acute diarrhea; kittens and puppies are most frequently affected.

SIGNS

General Comments

- Acute diarrhea is usually self-limiting and is often isolated episode. Most animals with acute diarrhea are not affected systemically unless the animal has acute hemorrhagic diarrheal syndrome that can cause severe dehydration and hypovolemic shock.
- Sometimes an acute or peracute severe

disease, more common in dogs than cats (e.g., Parvovirus, *Clostridium perfringens*-associated acute hemorrhagic diarrheal syndrome).

- Signs of more severe illness (e.g., concurrent vomiting, abdominal pain, hematochezia, hemoptysis, severe dehydration, or lethargy) should prompt more aggressive diagnostic and therapeutic measures.

Historical Findings

- Increased fecal fluidity and/or volume and/or frequency of short duration.
- Owner may report fecal accidents, changes in fecal consistency and volume, blood or mucus in the feces, or straining to defecate.
- Owners may be able to report exposure to toxins, dietary changes, or dietary indiscretion.

Physical Examination Findings

- Varies with the disease severity.
- Dehydration or lethargy often present.
- Abdominal pain or discomfort, fever, signs of hypotension, nausea, and weakness may occur in more severely affected individuals.
- Rectal exam may reveal blood, mucous or altered consistency of stool.

CAUSES

- Systemic illness may also result in diarrhea as a secondary event.
- Dietary indiscretion—ingestion of garbage, non-food material, or spoiled food.
- Dietary changes—abrupt changes in amount or type of foodstuffs.
- Dietary intolerance—malassimilation of food, dietary hypersensitivity.
- Metabolic diseases—hypoadrenocorticism, liver disease, renal disease, and pancreatic disease can cause acute or chronic diarrhea.
- Obstruction—foreign bodies, intussusception, or intestinal/mesenteric volvulus.
- Idiopathic—hemorrhagic gastroenteritis.
- Viral—parvovirus, coronavirus, rotavirus, canine distemper virus.
- Bacterial—*Salmonella*, *Campylobacter*, *Clostridium* spp., *Escherichia coli*, etc.
- Parasitic—verminous (hookworms, ascarids, whipworms, and cestodes) or protozoal (*Giardia*, coccidia, *Tritrichomonas* and *Entamoeba*).
- Rickettsial—Salmon poisoning (*Neorickettsia*).
- Fungal—histoplasmosis.
- Drugs and toxins—heavy metals (e.g., lead), organophosphates, nonsteroidal anti-inflammatories, steroids, antimicrobials, antineoplastic agents, etc.

RISK FACTORS

Young dogs and cats present for diarrhea from dietary indiscretion, intussusception, foreign bodies, and infectious causes more often than older patients.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Patients should have a complete physical examination, fecal flotation, and assessment of their hydration status.
- Further diagnostic

tests depend on the extent of illness and other clinical signs.

CBC/BIOCHEMISTRY/URINALYSIS

- Generally normal; not necessary unless systemic involvement.
- Can see neutropenia with parvoviral enteritis and marked hemoconcentration with a discordant normal or low-normal plasma protein concentration with *C. perfringens* and *C. difficile*-associated hemorrhagic diarrhea.
- Electrolytes are commonly abnormal because of intestinal losses (hypokalemia, hypochloremia, hyponatremia).

OTHER LABORATORY TESTS

- Spec cPL (pancreatitis), TLI (EPI), cobalamin, and folate (altered absorption)—the latter are more commonly performed with chronic diarrhea.
- ELISA and IFA fecal testing is available for *Giardia* and *Cryptosporidium* spp.
- Diarrhea PCR panel—to evaluate for common specific infectious diseases (e.g., *Salmonella*, *Parvovirus*)

IMAGING

- Radiographs—generally not necessary in patients with mild illness.
- Abdominal radiographs can help identify or rule out intestinal foreign bodies or obstruction.
- More severe signs (e.g., abdominal pain or persistent vomiting) may increase the likely diagnostic benefit of abdominal imaging.
- Contrast abdominal radiography and ultrasonography may be useful with some patients, especially looking for an obstruction.

DIAGNOSTIC PROCEDURES

- Perform fecal flotation for parasites on all patients.
- Because helminth ova and *Giardia* cysts can be shed in low numbers or intermittently, multiple fecal analyses are recommended, and empiric treatment is advisable.
- The *Giardia* ELISA is a sensitive assay and should be combined with fecal flotation to increase the diagnostic yield of *Giardia* spp.
- Can perform fecal ELISA tests for parvovirus antigen in dogs.
- Endoscopy and biopsy—useful in select cases; more commonly needed in chronic diarrhea.

PATHOLOGIC FINDINGS

Dependent on etiology

TREATMENT

APPROPRIATE HEALTH CARE

Depends largely on the severity of illness; patients with mild illness can often be handled as outpatients with symptomatic therapy; patients with more-severe illness or that fail to respond to therapy should be treated more aggressively.

NURSING CARE

- Fluid therapy and correction of electrolyte imbalances is the mainstay of treatment in most cases.
- Can give crystalloid fluid

DIARRHEA, ACUTE

(CONTINUED)

D therapy (PO, SC or IV) as required. • Aim to return the patient to proper hydration status (over 12–24 hours) and replace ongoing losses. • Severe volume depletion can occur with acute diarrhea; aggressive fluid therapy may be necessary. • Use potassium supplementation (potassium chloride 20–40 mEq/L) in most patients, but not during shock fluid therapy. Hypokalemia can worsen ileus.

ACTIVITY

Animals should have limited activity until the diarrhea has stopped.

DIET

Patients with mild illness that are not vomiting can be managed with a fat-restricted, digestible intestinal diet, either homecooked (boiled rice and chicken in 4:1 ratio) or low-fat cottage cheese (1%) and rice or a commercial prescription intestinal diet.

CLIENT EDUCATION

- Limiting exposure to garbage, foods other than the patient's normal diet, and potential foreign bodies.
- Proper puppy and kitten vaccination and deworming schedules.

SURGICAL CONSIDERATIONS

Patients with obstructions may require surgery to evaluate the intestine and remove the foreign objects.

MEDICATIONS

DRUG(S) OF CHOICE

- Antidiarrheal drugs can be classified as motility-modifying drugs, antsecretory drugs, or intestinal protectants.
- Motility-modifying drugs generally operate by increasing segmental motility and thus increasing transit time (i.e. narcotic such as loperamide; 0.1 mg/kg PO q8–12h in dogs; 0.08 mg/kg PO q12h in cats) or by decreasing forward motility (i.e., anticholinergics); these medications are not necessary in mild disease, as it is generally self-limiting. Do not use these medications longer than 1–2 days because of adverse effects.
- Acute diarrhea that does not resolve with antidiarrheal drugs merits further investigation.
- Anthelmintics (e.g., fenbendazole 50 mg/kg PO q24h for 5 days) and antiprotozoal drugs (e.g., metronidazole 10–20 mg/kg PO q12h for 5 days) are recommended as empiric treatment for patients with acute diarrhea or those with positive fecal analyses. Can use coccidiostatic (e.g., sulfadimethoxine, ponazuril) drugs if fecal analysis warrants.
- Antibiotic therapy is unnecessary for most cases of mild illness and may actually exacerbate the diarrhea.
- Patients with bacterial enteritis, severe illness, concomitant leukopenia, or suspected breakdown of the gastrointestinal mucosal

barrier (as evidenced by blood in the feces) should be treated with antimicrobial agents.

- Probiotics may also be useful (*Lactobacillus*, *Enterococcus*). Probiotics have been shown to shorten the duration of acute, nonspecific diarrhea in some studies. Use probiotics from premium pet food companies in light of studies showing suboptimal quality of probiotics that have not undergone rigorous testing.

CONTRAINdications

- Anticholinergics in patients with suspected intestinal obstruction, glaucoma, or intestinal ileus.
- Narcotic analgesics—can cause CNS depression; undesirable in patients with more severe illness that are already depressed or lethargic.
- Narcotic analgesics in patients with liver disease and bacterial or toxic enteritis.

PRECAUTIONS

- Most cases of acute mild diarrhea resolve with minimal treatment; be cautious of excessive diagnostics and overtreating.
- Almost any drug can produce adverse effects (often including diarrhea and vomiting); these may be more severe than the initial problem.
- Cats can be sensitive to subsalicylates and should not be given high or frequent doses.

POSSIBLE INTERACTIONS

- Long term use of metronidazole can lead to neurologic complications.
- Some animals are sensitive to sulfa containing medications used for treatment of Coccidia.

ALTERNATIVE DRUG(S)

Kaolin pectin

FOLLOW-UP

PATIENT MONITORING

- Most acute diarrhea resolves within a few days.
- If clinical signs persist, additional diagnostics and treatments may be necessary.
- Upon completion of medication, recheck patients that exhibited parasites by fecal analysis.

PREVENTION/AVOIDANCE

- Animals should be fed a consistent high-quality diet.
- Owners should attempt to control indiscriminate eating and monitor for foreign body ingestion.

POSSIBLE COMPLICATIONS

- Intussusception is thought to be associated with increased intestinal motility.
- Monitor for this complication in patients with acute diarrhea, especially young dogs with parvoviral enteritis and parasitism.

EXPECTED COURSE AND PROGNOSIS

Most cases of acute diarrhea resolve spontaneously without treatment or with minimal treatment.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Acute vomiting commonly occurs concurrently with acute diarrhea.

AGE-RELATED FACTORS

- Young dogs and cats present for diarrhea from dietary indiscretion, intussusception, foreign bodies, and infectious causes more often than older patients.
- Younger and smaller animals are also more prone to dehydration and may require more-aggressive fluid therapy.

ZOONOTIC POTENTIAL

- *Campylobacter jejuni* is a zoonosis; however, most other *Campylobacter* spp. are non-pathogenic.
- Some strains of *Giardia* are zoonotic; however, this is uncommon.
- Parasitic larvae can cause visceral larval migrans (ascariids) and cutaneous larval migrans (hookworms) in humans, particularly children.

PREGNANCY/FERTILITY/BREEDING

Always be cautious using medication in pregnant animals.

DIARRHEA, ANTIBIOTIC RESPONSIVE

D

BASICS

OVERVIEW

- Defined as antibiotic-responsive diarrhea without an identifiable underlying etiology.
- Antibiotic-responsive diarrhea was previously termed idiopathic (primary) small intestinal bacterial overgrowth (SIBO). This term is not used anymore as it was based on quantitative culture of bacteria in the upper GI tract which could not be confirmed by newer PCR-based methods. Secondary SIBO is a result of concurrent gastrointestinal diseases (e.g., exocrine pancreatic insufficiency).
- Current theories center on the possibility of immune dysregulation, possibly associated with abnormal CD4+ T-cells, IgA plasma cells, cytokine expression, and, in German shepherd dogs, mutations in pattern recognition receptors.

SIGNALMENT

Species

Dog

Breed Predilections

May be increased incidence in German shepherds, boxers, and Chinese Shar-peis.

Mean Age and Range

Recent studies show that the condition is more common in young dogs, with a median age of 2 years.

Predominant Sex

N/A

SIGNS

Historical Findings

- Small bowel signs—inappetence or anorexia, vomiting, weight loss, large-volume diarrhea.
- Large bowel signs—tenesmus, hematochezia, increased frequency of defecation.

Physical Examination Findings

Weight loss, poor body condition, borborygmus and flatulence may be detected; hematochezia may be present if there is large bowel involvement.

CAUSES & RISK FACTORS

- Genetic risk factors of mutations in pattern recognition genes (*TLR4* and *TLR5*) have been associated with the disease.
- Certain enteropathogenic bacteria (*Clostridium perfringens*, *E. coli*, and *Lawsonia intracellularis*) have been suspected but not proven to be etiologic agents.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Secondary SIBO
- EPI

- Parasitic infection
- IBD (including food-responsive diarrhea)
- Neoplasia

CBC/BIOCHEMISTRY/URINALYSIS

- Typically normal.
- Hypoalbuminemia is an uncommon finding.

OTHER LABORATORY TESTS

- Fecal examination for parasites should be performed.
- Serum cobalamin levels may be low and folate levels may be increased or decreased.
- Serum TLI levels (measured to rule out EPI) are normal.

IMAGING

Routine abdominal imaging (radiographs and ultrasound) should be performed to rule out other causes for diarrhea. Results of these tests are unremarkable in cases of ARD.

DIAGNOSTIC PROCEDURES

- There is no definitive test for the diagnosis of ARD other than resolution of gastrointestinal signs following antibiotic administration.
- Diagnosis depends upon ruling out all other causes for chronic diarrhea (especially food-responsive diarrhea) and a clinical response to an appropriate course of antibiotic therapy.

TREATMENT

- Hospitalization is generally not indicated and dogs may be managed on an outpatient basis.
- Restriction of physical activity is not indicated.
- The role of diet in ARD is unknown. Current recommendations are to feed a low-fat, highly digestible food or an elimination or hydrolyzed diet.

MEDICATIONS

DRUG(S)

- Several options for antibiotics are available:
 - Tylosin (5–10 mg/kg PO q24h); metronidazole (10–20 mg/kg PO q12h); oxytetracycline (10–20 mg/kg PO q8h).
 - In some cases, combination therapy may be necessary.
 - Antibiotic therapy should be administered for 4–6 weeks.
 - If serum cobalamin levels are decreased, cobalamin supplementation should be pursued. Dogs < 15 kg body weight: 500 µg parenteral cobalamin; dogs > 15 kg body weight: up to 1,500 µg parenteral cobalamin. Doses are given as subcutaneous injections once weekly for 6 weeks, then once every other week for 6 weeks. Serum

cobalamin levels should be reassessed at the end of therapy. Limited information is available regarding the effectiveness of oral cobalamin supplementation.

CONTRAINdicATIONS/POSSIBLE INTERACTIONS

- Oxytetracycline may cause staining of tooth enamel. Doses should be decreased in animals with hepatic or renal insufficiency. Oxytetracycline has been associated with a high incidence of bacterial transfer of resistance genes.
- Metronidazole undergoes extensive hepatic metabolism; dosages should be reduced in animals with hepatic insufficiency.

FOLLOW-UP

- Clinical resolution of diarrhea is the most important criterion.
- Weight gain may also be seen; hypoalbuminemia (if present) should resolve.
- Relapses usually occur when the antibiotics are discontinued. Many dogs can be maintained on very low doses of antibiotics long term, although long-term studies assessing antibiotic resistance are lacking.

MISCELLANEOUS

ABBREVIATIONS

- ARD = antibiotic responsive diarrhea
- EPI = exocrine pancreatic insufficiency
- IBD = inflammatory bowel disease
- SIBO = small intestinal bacterial overgrowth
- TLI = trypsin like immunoreactivity

DIARRHEA, CHRONIC—CATS

BASICS

DEFINITION

- A change in the frequency, consistency, and volume of feces for more than 3 weeks or with a pattern of episodic recurrence.
- Can be either small bowel, large bowel, or mixed in origin.

PATHOPHYSIOLOGY

- High solute and fluid secretion—secretory diarrhea
- Low solute and fluid absorption—osmotic diarrhea
- High intestinal permeability
- Abnormal GI motility
- Many cases involve various combinations of these four basic pathophysiologic mechanisms for the development of diarrhea.

SYSTEMS AFFECTED

- Endocrine/Metabolic—fluid, electrolyte, and acid–base
- Exocrine • Gastrointestinal
- Lymphatic • Nutritional

SIGNALMENT

Cat

SIGNS

General Comments

- Underlying disease process determines extent of clinical signs.
- Normal feces is composed of about 68–75% water. As little as a 2–3% increase of water content results in poor stool quality and the gross description of diarrhea.
- Classification of small bowel and large bowel types of diarrhea is a convenient clinical tool but there is a significant overlap of these entities.

Historical Findings

Small Bowel

- Normal to increased volume
- Frequency of defecation—normal to moderately increased (2–4 times/day)
- Weight loss
- Normal to increased appetite (polyphagia)
- May be melena
- May have flatulence and borborygmus
- Vomiting—variable

Large Bowel

- Smaller volume.
- Frequency of defecation is moderately to markedly increased (> 4 times per day).
- Weight loss is less commonly seen.
- Often hematochezia and mucus.
- Tenesmus, urgency, dyschezia (painful defecation).
- Flatulence and borborygmus—variable.
- Vomiting—variable.

Physical Examination Findings

A complete physical examination, including rectal examination, auscultation and abdominal palpation is needed to assist in diagnosis of possible causes for diarrhea.

Small Bowel

- Poor body condition associated with malabsorption, maldigestion, and PLE.

- Variable dehydration.
- Abdominal palpation may reveal segmental or diffusely thickened small bowel loops associated with infiltrative disease, abdominal effusion, foreign body, neoplastic mass, intussusception, or enlarged mesenteric lymph nodes.
- Rectal palpation typically unremarkable.

Large Bowel

- Body condition is more typically unremarkable.
- Dehydration—uncommon.
- Abdominal palpation may reveal thickened large bowel, foreign body, neoplastic mass, intussusception, or enlarged mesocolic lymph nodes.
- Rectal palpation may reveal irregularity of the rectal mucosa, intraluminal or extraluminal rectal masses, rectal stricture, or sublumbar lymphadenopathy.

CAUSES

Small and Large Intestinal Diseases

Primary Disease

- Inflammatory bowel disease (e.g., lymphoplasmacytic enteritis, eosinophilic enteritis, granulomatous enteritis)
- Neoplasia (e.g., lymphoma, adenocarcinoma, mast cell neoplasia)
- Bacterial (e.g., *Salmonella* spp., enterotoxic *Escherichia coli*, other enterobacteriaceae species, *Clostridia* spp.)
- Viral (e.g., enteric corona virus, FIP, FeLV-associated, FIV-associated)
- Mycotic (e.g., histoplasmosis)
- Other (e.g., protothecosis, pythiosis)
- Parasites (e.g., *Giardia*, *Toxocara* spp., *Ancylostoma*, *Toxascaris leonina*, *Cryptosporidium* spp., *Cystoisospora* spp., *Tritrichomonas foetus*)
- Partial obstruction (e.g., foreign body, intussusception, neoplasia)
- Secondary lymphangiectasia
- Small intestinal bacterial overgrowth, intestinal microbial dysbiosis
- Short bowel syndrome
- Villous atrophy
- Duodenal ulcers

Maldigestion

- Hepatobiliary disease—lack of bile salts needed for intraluminal digestion.
- Exocrine pancreatic insufficiency

Dietary

- Dietary intolerance (food-responsive diarrhea)
- Food allergy
- Rapid diet change

Metabolic Disorders

- Hyperthyroidism
- Cobalamin deficiency
- Renal disease—uremia
- Hepatobiliary disease—liver failure
- Toxins (e.g., enterotoxins, aflatoxins, food poisoning)
- Adverse drug reactions

Congenital Anomalies

- Short colon
- Portosystemic shunt
- Persistent pancreaticomesojejunal ligament

RISK FACTORS

Dietary changes, feeding poorly digestible or high-fat diets

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

First localize the origin of the diarrhea to the small or large bowel (or both) on the basis of historical signs.

CBC/BIOCHEMISTRY/URINALYSIS

- Eosinophilia in some cats with parasitism, eosinophilic enterocolitis, hypereosinophilic syndrome, or mast cell tumor.
- Macrocytosis in some cats with hyperthyroidism or FeLV infection.
- Anemia that is variably regenerative and has microcytosis suggests chronic GI bleeding and iron deficiency.
- Leukopenia in some cats with FeLV or FIV infection.
- Panhypoproteinemia caused by protein-losing enteropathy is uncommon in cats with intestinal disease but can occur. Hypoalbuminemia can be seen.
- Biochemical profiles, hormonal assays, serum bile acid panel, and urinalysis abnormalities may suggest renal disease, hypoproteinemia, hepatobiliary disease, or endocrinopathy.

OTHER LABORATORY TESTS

Fecal and/or Rectal Scraping Exam

- Direct wet prep, routine centrifugation fecal flotation, fecal ELISA testing may indicate GI parasites.
- Cytologic examination of rectal scrapings may reveal specific organisms, such as *Histoplasma* or rare *Prototheca*.
- PCR fecal testing should be interpreted with caution because positive results for toxin genes or infectious agents may or may not correlate with clinical disease. Interpret PCR results in light of patient signalment, history, clinical presentation, vaccination history and other laboratory data.
- Culture feces if *Salmonella* is suspected—special media required.

Thyroid Function Tests

- High total T₄ or free T₄ concentration indicates hyperthyroidism.
- If hyperthyroidism is suspected but the T₄ is normal, perform a T₃ suppression test, repeat the T₄ a few months later, or perform a technetium scan of the thyroid glands.

Serologic Testing

Test for FeLV and FIV—especially if hematologic abnormalities are present.

Test for Exocrine Pancreatic Function

Feline-specific TLI—test of choice for diagnosis of EPI.

IMAGING

- Survey abdominal radiography may indicate intestinal obstruction, abnormal intestinal pattern, organomegaly, mass, foreign body, pancreatic disease, hepatobiliary disease, urinary disease, or abdominal effusion. Low yield in most cats with chronic diarrhea.

(CONTINUED)

- Contrast radiography (upper GI series or barium enema) may indicate bowel wall thickening, intestinal ulcers, mucosal irregularities, mass, radiolucent foreign body, or stricture. Procedure is performed infrequently in cats in light of advantages of abdominal ultrasonography. • Abdominal ultrasonography may demonstrate bowel wall thickening, abnormal bowel wall layering, GI or extra-GI masses, intussusception, foreign body, ileus, abdominal effusion, hepatobiliary disease, renal disease, or mesenteric or mesocolic lymphadenopathy. Abdominal sonography is used in conjunction with abdominal radiography.

DIAGNOSTIC PROCEDURES

- If malabsorptive (EPI), metabolic, parasitic, dietary, and infectious causes have been excluded, consider empiric dietary therapy utilizing an elimination diet for 2 weeks before performing endoscopy and biopsy or a laparotomy for definitive diagnosis. Consider PCR on intestinal biopsies (fluorescent in situ hybridization; FISH) to rule out infectious enteropathies with neutrophilic or granulomatous enteropathies.

Endoscopy/Laparoscopy

- Upper GI flexible endoscopy allows examination and biopsy of the gastric and duodenal mucosa; always obtain multiple (8–10) mucosal specimens from each segment/area. • Flexible colonoscopy allows examination of the entire rectum, colon, cecum; rigid coloproctoscopy limits examination to the descending colon and rectum and is done less frequently due to its limitation; always obtain multiple mucosal specimens (8–10) from each segment.
- Visual impressions of gastrointestinal mucosal detail may not reflect histopathologic changes; always take biopsies. • Endoscopic biopsies rely upon infiltrative and inflammatory diseases being represented in the first two layers of the intestinal wall, and the segments biopsied being representative of the disease process. • Full thickness biopsies can be obtained via laparoscopy from one or more segments of small intestine (not large intestine) via exteriorization of the segment(s).

Surgical Biopsy

A surgical approach is beneficial if biopsies of multiple organs (small intestine, lymph nodes, stomach, pancreas, liver) are desired.

Ultrasound-Guided GI Aspiration or Biopsy

- Can perform ultrasound-guided fine-needle aspiration on most GI lesions that present as reasonable targets but cytologic interpretation accuracy is subject to sample quality, expertise, and limitations of the technique
- Ultrasound guided microcore (true-cut) biopsy on non-cavitated lesions > 2 cm in diameter are performed less frequently.

- Paracentesis of peritoneal fluid for fluid analysis, culture, and cytology is recommended. • Concern has been expressed for risk of translocation of cancer cells or infective organisms with these procedures.

TREATMENT

APPROPRIATE HEALTH CARE

- Treat the underlying cause—Administration of an elimination diet (intact protein source or hydrolyzed protein) will resolve diarrhea in approximately 40–60% of cats with chronic enteropathies. Response should be detected within 2–3 weeks following dietary implementation. • Complete resolution of signs is not always possible in cats with IBD, neoplasia, or fungal disease despite proper treatment. Measurement of serum cobalamin is important in all cats with chronic enteropathies. Supplementation with cyanocobalamin at 250 µg SC per cat on a weekly basis for 6 consecutive weeks followed by every 3 weeks for the indefinite future.
- Repeated changes of diet that are made in order to maintain a symptom-free situation suggests that further testing is needed.

NURSING CARE

- Give fluid therapy with balanced electrolyte solution. • Correct electrolyte and acid-base imbalances.

SURGICAL CONSIDERATIONS

Pursue exploratory laparotomy and surgical biopsy if there is evidence of obstruction, an intestinal mass, mid-small bowel disease unreachable via ultrasound-guided procedure, or if a diagnosis based on endoscopic biopsy or ultrasound-guided procedure is questioned because of poor response to therapy.

MEDICATIONS

DRUG(S) OF CHOICE

- Disease-specific.
- Prednisolone or budesonide for management of IBD. Chlorambucil should be considered with prednisolone for management of small cell intestinal lymphoma.
- Cyanocobalamin.
- Probiotics can be beneficial in some patients with chronic nonspecific diarrhea.

CONTRAINdicATIONS

Anticholinergics exacerbate most types of chronic diarrhea and should not be used for empirical treatment.

PRECAUTIONS

Opiate antidiarrheals such as diphenoxylate and loperamide can cause hyperactivity and respiratory depression in cats and should not be used for more than 3 days.

DIARRHEA, CHRONIC—CATS

FOLLOW-UP

PATIENT MONITORING

- Assess changes in frequency and severity of diarrhea and body weight. • Resolution usually occurs within 2–3 weeks following successful implementation of dietary therapy, consider re-evaluating the diagnosis if diarrhea does not resolve.

D

POSSIBLE COMPLICATIONS

- Dehydration. • Lowered body condition.
- Abdominal effusions as related to specific cause of chronic diarrhea.

MISCELLANEOUS

ZOONOTIC POTENTIAL

- Toxoplasmosis • Giardiasis (low zoonotic potential) • Cryptosporidiosis • Salmonellosis • *Campylobacter jejuni*

SEE ALSO

Under "Causes"

ABBREVIATIONS

- B₁₂ = vitamin B₁₂, cobalamin • ELISA = enzyme-linked immunosorbent assay • EPI = exocrine pancreatic insufficiency • FeLV = feline leukemia virus • FIP = feline infectious peritonitis • FIV = feline immunodeficiency virus • GI = gastrointestinal • PCR = polymerase chain reaction • PLE = protein-losing enteropathy • TLI = trypsin-like immunoreactivity • TSH = thyroid stimulating hormone

DIARRHEA, CHRONIC—DOGS

BASICS

DEFINITION

- A change in the frequency, consistency, and volume of feces for more than 3 weeks.
- Can be small bowel, large bowel, or mixed.

PATHOPHYSIOLOGY

- Secretory diarrhea • Osmotic diarrhea
- Increased permeability • Abnormal GI motility • Many cases involve combinations of these pathophysiologic mechanisms.

SYSTEMS AFFECTED

- Endocrine/Metabolic • Exocrine • Fluid Balance • Gastrointestinal • Lymphatic

SIGNALMENT

Dog

SIGNS

General Comments

- Disease processes determines extent of clinical signs.
- Normal feces is composed of about 68–75% water. A 2–3% increase of water content results in gross description of diarrhea.
- Classification of small, large and mixed bowel types of diarrhea may also have overlap of descriptive findings.

Historical Findings

Small Bowel

Can include:

- Normal to increased volume • Normal to moderately increased (2–4 times/day) defecation frequency • Weight loss
- Polyphagia • May be melena • No tenesmus or dyschezia (excepting irritation) • May be flatulence and borborygmus • Vomiting—variable

Large Bowel

- Smaller volume • Frequency of defecation is increased (> 4 times/day) • Typically little to no weight loss • Often hematochezia and mucus • Tenesmus, urgency, dyschezia
- Flatulence and borborygmus—variable
- Vomiting—variable

Physical Examination Findings

A complete physical examination, including rectal examination, auscultation, and abdominal palpation is needed to assist in diagnosis of possible causes for diarrhea.

Small Bowel

- Poor body condition associated with malabsorption, maldigestion, and PLE.
- Variable dehydration. • Abdominal palpation may reveal thickened small bowel loops (diffuse or segmental) associated with infiltrative disease, abdominal effusion, foreign body, neoplastic mass, intussusception, or enlarged mesenteric lymph nodes. • Rectal palpation typically unremarkable.

Large Bowel

- Body condition is more typically normal.
- Dehydration—uncommon. • Abdominal

palpation may reveal thickened large bowel, foreign body, neoplastic mass, intussusception, or enlarged mesocolic lymph nodes. • Rectal palpation may reveal irregularity of the colorectal mucosa, intraluminal or extraluminal rectal masses, rectal stricture, or sublumbar lymphadenopathy.

CAUSES

Small Bowel

Primary Small Intestinal Disease

- Inflammatory bowel disease (e.g., lymphoplasmacytic enteritis, eosinophilic enteritis, granulomatous segmental enteritis, immunoproliferative enteropathy of Basenjis)
- Primary or secondary lymphangiectasia
- Neoplasia • Bacterial (*Campylobacter jejuni*, *Salmonella* spp., invasive adherent or enterotoxic *Escherichia coli*, other enterobacteriaceae species) • Viral (e.g., coronavirus, parvoviruses, distemper virus, rotavirus) • Mycotic (e.g., histoplasmosis, aspergillosis) • Other (e.g., protothecosis, pythiosis) • Parasites (e.g., *Giardia*, *Toxocara* spp., *Ancylostoma*, *Toxascaris leonina*, *Cryptosporidium* spp., *Cystoisospora* spp.)
- Other (e.g., pythiosis) • Partial obstruction (e.g., foreign body, intussusception, and neoplasia) • Antibiotic-responsive diarrhea (ARD) (intestinal microbial dysbiosis) • Short bowel syndrome

Maldigestion

- Exocrine pancreatic insufficiency
- Hepatobiliary disease—lack of intraluminal bile

Dietary

- Food-responsive enteropathy. • Food allergy. • Gluten-sensitive enteropathy.
- Rapid diet change.

Metabolic Disorders

- Hepatobiliary disease
- Hypoadrenocorticism • Uremic gastroenteritis • Toxins—enterotoxins, aflatoxins, exotoxins, food poisoning
- Adverse drug reactions

Large Bowel

Primary Large Intestinal Disease

- Inflammatory bowel disease (e.g., lymphoplasmacytic colitis, eosinophilic colitis, histiocytic ulcerative colitis)
- Neoplasia • Infection (e.g., histoplasmosis, *Clostridium perfringens* and *C. difficile*, enteropathic adherent invasive *E. coli*, *Campylobacter jejuni*, *Prototheca*, and pythiosis) • Parasites (e.g., *Trichuris vulpis*, *Entamoeba histolytica*, and *Balantidium coli*) • Ileocolic intussusception and cecal inversion

Dietary

- Diet—dietary indiscretion, diet changes, food-responsive enteropathy, and foreign material (e.g., bones, plastic, wood, hair) • Fiber-responsive large bowel diarrhea

Miscellaneous

Irritable bowel syndrome

RISK FACTORS

Small Bowel

- Dietary changes, feeding poorly digestible or high-fat diets.
- Large-breed dogs, especially German shepherds, have the highest incidence of antibiotic-responsive diarrhea (ARD).
- Large-breed dogs have a higher risk of intestinal volvulus/torsion; may be seen in association with EPI.
- Pythiosis occurs most often in young, large-breed dogs living in rural areas with a higher incidence bordering the Gulf of Mexico.

Large Bowel

- Dietary changes or indiscretion, stress, and psychological factors may play a role.
- Histiocytic ulcerative colitis (invasive adherent *Escherichia coli*-associated)—boxers, French bulldogs < 3 years old.
- Pythiosis is more common in large-breed dogs that spend more time outside (roaming, hunting).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

First localize the origin to the small or large bowel (or both).

CBC/BIOCHEMISTRY/URINALYSIS

- Eosinophilia may be associated with parasitism, eosinophilic enterocolitis, hypoadrenocorticism, paraneoplastic causes, or pythiosis.
- Lymphopenia and hypocholesterolemia may be associated with lymphangiectasia.
- Anemia and microcytosis suggest chronic GI bleeding and iron deficiency.
- Panhypoproteinemia resulting from PLE is associated with infiltrative small bowel disorders and lymphangiectasia.
- Biochemical profiles, hormonal assays, serum bile acid panel, and urinalysis abnormalities may suggest renal disease, hepatobiliary disease, or endocrinopathy.

OTHER LABORATORY TESTS

Fecal and/or Rectal Scraping Exam

- Direct wet-prep examination, fecal ELISA testing, and zinc sulfate centrifugation (for *Giardia*) may indicate GI parasites. Multiple samples may be required for whipworm infestations.
- Cytologic examination of rectal scrapings may reveal specific organisms, such as *Histoplasma* or *Prototheca*.
- PCR fecal testing can be helpful when screening for uncommon or difficult to diagnose infections; interpret with caution as many of the microorganisms can be found in healthy, non-diarrheic animals (e.g., viral enteritis, cryptosporidiosis, Giardia, *Salmonella*, *C. perfringens* enterotoxin gene, *C. difficile*, *Campylobacter jejuni*). PCR testing should be interpreted in light of patient signalment, history, clinical presentation, vaccination history and other laboratory data.
- Culture feces if *Campylobacter* or *Salmonella* is

(CONTINUED)

DIARRHEA, CHRONIC—DOGS

D

suspected—special media required; check with your laboratory prior to submission.

Tests of Exocrine Pancreatic Function

Canine-specific TLI—test of choice for confirming EPI.

Tests for Malabsorption

- Serum folate—low serum folate may be associated with jejunal malabsorption; elevated folate may occur due to small intestinal bacterial overgrowth.
- Cobalamin (B_{12})—low serum B_{12} may be associated with EPI or ileal malabsorption; primary cobalamin deficiency syndromes are rare.

Tests for Metabolic Disease

- Resting cortisol—a value $< 2.0 \mu\text{g/dL}$ should be followed up with ACTH stimulation test to evaluate for hypoadrenocorticism.
- Fasting and 2-hour post-prandial serum bile acids—test if hepatobiliary disease is suspected; significantly increased values suggest hepatic dysfunction or portosystemic shunting.

IMAGING

- Survey abdominal radiography may indicate intestinal obstruction, abnormal intestinal pattern, organomegaly, mass, foreign body, pancreatic disease, hepatobiliary disease, urinary disease, or abdominal effusion.
- Contrast radiography (upper GI series or barium enema) may indicate bowel wall thickening, intestinal ulcers, mucosal irregularities, mass, radiolucent foreign body, or stricture. Utility of contrast radiography has been replaced with ultrasound in most patients.
- Abdominal ultrasonography may demonstrate bowel wall thickening, abnormal bowel wall layering, GI or extra-GI masses, intussusception, foreign body, ileus, abdominal effusion, hepatobiliary disease, or mesenteric or mesocolic lymphadenopathy.

DIAGNOSTIC PROCEDURES

If maldigestive (EPI), metabolic, parasitic, dietary, and infectious causes have been excluded, then consider a dietary trial using an elimination diet (novel, single protein source) for 2 weeks in stable dogs prior to performing advanced diagnostics (endoscopy or laparotomy and biopsy).

Endoscopy/Laparoscopy

- Upper GI flexible endoscopy allows examination and biopsy of the gastric and duodenal mucosa; always obtain multiple (8–10) mucosal specimens from each segment.
- Flexible colonoscopy allows examination of the rectum, colon, cecum, and variably ileum; always obtain multiple mucosal specimens (8–10) from each segment.
- The gross appearance of the mucosa does not always correlate with histopathology. Always take biopsies.
- Endoscopic biopsies rely upon diseases being represented in the first two layers of the intestinal wall and the segments biopsied being representative of others not reached.

- Full thickness biopsies can be obtained via laparoscopy from one or more segments of small intestine (not large intestine) via enlargement of puncture site and exteriorization of the segment(s) using punch biopsy(s) and sutures.

Surgical Biopsy

- Full-thickness biopsies can be obtained from clearly visualized segments/locations of the intestinal tract.
- A surgical approach can be the most advantageous/pragmatic approach if biopsies of multiple organs (e.g., small intestine, lymph nodes, stomach, pancreas, liver) are desired with the ability to correct abnormal findings.

Ultrasound-Guided GI Aspirates

- Ultrasound-guided fine-needle aspiration of GI mass lesions can be helpful for diagnosing mast cell tumors, carcinomas, and large-cell lymphoma.
- Seeding of neoplastic cells is a concern.

**TREATMENT****APPROPRIATE HEALTH CARE**

- Treat the underlying cause symptomatic or empirical therapy with elimination diets can be beneficial in 40–60% of dogs with uncomplicated chronic enteropathies.
- Complete resolution of signs is not always possible in dogs with severe IBD, lymphangiectasia, intestinal neoplasia, and pythiosis.
- Feeding lower-fat, novel (for the patient) protein and carbohydrate source, highly digestible, or fiber supplemented diets for 3–4 weeks may resolve diarrhea that is due to dietary intolerance or allergy. Repeated changes of diet to maintain a symptom-free situation suggests further testing is needed.

NURSING CARE

- Fluid therapy with balanced electrolyte solutions as needed.
- Consider colloids for hypoproteinemic patients requiring fluid therapy.
- Correct electrolyte and acid-base imbalances.

SURGICAL CONSIDERATIONS

Pursue laparotomy and biopsy if there is evidence of obstruction, intestinal mass, or mid-small bowel disease unreachable via ultrasound-guided procedure or if a diagnosis based on endoscopic biopsy or ultrasound-guided procedure is questioned because of poor response to therapy.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Disease-specific.
- Prednisone and budesonide for IBD.
- Cyclosporine or Azathioprine as adjunctive therapy with corticosteroids for dogs with refractory IBD.

- The need for cyanocobalamin supplementation must be assessed in all dogs with chronic enteropathy.
- Tylosin or metronidazole for dogs with antibiotic-responsive enteropathy.
- Probiotics are beneficial in some dogs with chronic enteropathy.

CONTRAINDICATIONS

Anticholinergics can exacerbate the situation with many causes of chronic diarrhea; they are sometimes used to relieve cramping associated with irritable bowel syndrome.

**FOLLOW-UP****PATIENT MONITORING**

- Frequency and consistency of the stool, appetite, and body weight.
- In dogs with PLE—serum proteins, cholesterol and clinical signs (ascites, subcutaneous edema, pleural effusion).
- Resolution of diarrhea is usually gradual with treatment; if it does not resolve reevaluate the diagnosis.

POSSIBLE COMPLICATIONS

- Dehydration.
- Lowered body condition.
- Abdominal effusions as related to specific cause of chronic diarrhea.
- Ascites, subcutaneous edema and/or pleural effusion with hypoalbuminemia from PLEs.

**MISCELLANEOUS****ZOONOTIC POTENTIAL**

- Giardiasis (low risk of transmission)
- Salmonellosis • *Campylobacter jejuni*
- Ascaridiasis

DIGOXIN TOXICITY

BASICS

OVERVIEW

Not uncommon because of digoxin's narrow therapeutic index and prevalence of renal impairment in elderly patients with cardiac disease.

SIGNALMENT

- Dog and cat
- More common in geriatric patients

SIGNS

Historical Findings

- Anorexia
- Vomiting
- Diarrhea
- Lethargy
- Depression

Physical Examination Findings

Heart rate may range from severe bradycardia to severe tachycardia.

CAUSES & RISK FACTORS

- Renal disease—impairs digoxin elimination.
- Chronic pulmonary disease—results in hypoxia and acid-base disturbances.
- Obesity—if dosage not calculated on lean body weight.
- Hypokalemia, hypercalcemia, hypomagnesemia, and hypoxia predispose to arrhythmias.
- Drugs and conditions that alter digoxin metabolism or elimination (e.g., quinidine and hypothyroidism).
- Rapid IV digitalization.
- Overdosage or accidental ingestion of owner's medication.
- Administration of diuretic leading to hypokalemia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Arrhythmias and conduction disturbances—may reflect structural heart disease, not digoxin toxicity.
- Anorexia—common in animals with heart failure.

CBC/BIOCHEMISTRY/URINALYSIS

Animals with hypokalemia, hypercalcemia, hypomagnesemia, and renal failure are predisposed to toxicity.

OTHER LABORATORY TESTS

- Consider checking thyroid status.
- Obtain digoxin serum concentration 8–10 hours after an oral dose—therapeutic

range is 0.5–1.5 ng/mL. A recent study in humans found digoxin levels greater than 1 mg/ml were associated with increased mortality; not all patients with concentrations > 1.5 ng/mL have signs of toxicity; some with values in the normal range have signs of toxicity, especially if hypokalemic. To minimize the risk of toxicity, I aim to achieve a digoxin level between 0.5 and 1 ng/mL.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Electrocardiographic Findings

- Conduction disturbances—AV block, arrhythmias, and ST segment depression in some patients.
- Digoxin can cause any arrhythmia.

TREATMENT

- Discontinue digoxin until signs of toxicity resolve (24–72 hours); reevaluate need for the medication; if necessary, resume treatment at a dosage based on the serum digoxin concentration.
- Maintain hydration and correct any electrolyte disturbance (especially hypokalemia) with parenteral fluid administration.
- Discontinue drugs that slow digoxin metabolism or elimination (e.g., quinidine, verapamil, amiodarone).
- Severe arrhythmias (ventricular tachycardia) and conduction disturbances—can be life-threatening; require hospitalization for treatment and monitoring.

MEDICATIONS

DRUG(S)

- Treat clinically important bradyarrhythmias with atropine or a temporary transvenous pacemaker.
- Treat clinically important ventricular arrhythmias with lidocaine or phenytoin; phenytoin also reverses high-degree AV block.
- Digoxin-binding antibodies (e.g., Digibind) rapidly drop digoxin concentration in critically ill animals; the use of these products is limited in veterinary practice by their exorbitant cost.
- Thyroxin supplementation if hypothyroidism confirmed.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Avoid or discontinue drugs that slow digoxin elimination or metabolism (e.g., quinidine, verapamil, and diltiazem).
- Avoid drugs that could worsen conduction disturbances (e.g., beta-blockers and calcium channel blockers).
- Class 1A antiarrhythmic drugs (e.g., quinidine and procainamide) may worsen AV block.

FOLLOW-UP

- Monitor renal function and electrolytes frequently in patients receiving digoxin; lower digoxin dose if renal disease develops.
- Monitor serum digoxin concentration periodically.
- Monitor ECG periodically to assess for arrhythmias or conduction disturbances that may suggest digoxin toxicity.
- Monitor body weight frequently; alter digoxin dosage accordingly; patients with congestive heart failure often lose weight.

MISCELLANEOUS

SEE ALSO

DIISOCYANATE GLUE (GORILLA GLUE) TOXICOSIS

BASICS

OVERVIEW

- Diisocyanate wood glue rapidly expands in the moist environment of the stomach causing bloat and foreign body obstruction. The glue is not absorbed and does not cause a systemic toxicity. Ingestions as small as 2 ounces (56 g) can require surgical intervention to resolve obstruction. Glue is also adhesive and an irritant to the paws, oral cavity, and stomach lining.
- Gorilla Glue is just one brand name. There are non-gorilla brand glue types that contain diisocyanate as the active ingredient and not all types of Gorilla Glue contain it. Confirm the actual product with the owner, using the packaging if necessary.
- Typically the owner finds a chewed bottle of glue and/or glue on the animal.

SIGNALMENT

Dogs and less commonly cats, birds, and small mammals. Young animals are more commonly affected.

SIGNS

- Ingestion: Lethargy, vomiting, hematemesis, abdominal distension, abdominal pain, anorexia, drooling.
- Inhalation: Coughing, sneezing, and increased secretions within 4–8 hours.
- Dermal: Irritation, redness, and rash.

CAUSES & RISK FACTORS

Pets with access to glue bottle.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

History of exposure and clinical signs generally facilitate diagnosis. Presenting signs are consistent with GDV, bloat, pancreatitis,

inflammatory bowel disease and other causes of foreign body obstruction. Radiographs are highly suggestive (see Web Figure 1).

CBC/BIOCHEMISTRY/URINALYSIS

- Leukocytosis—Inflammation.
- Elevated total proteins/prerenal azotemia—if pet is dehydrated due to vomiting or unable to eat and drink.
- Electrolyte disturbances—consistent with GI obstruction and anorexia.

IMAGING

Survey radiographs—Glue will appear as a mottled gas and soft tissue opacity distending the stomach. The appearance can resemble recent food ingestion (see Web Figure 1).

TREATMENT

- Emesis only if immediately after the ingestion. Gastric lavage rarely of benefit as glue expands rapidly.
- Stabilize patient with IV fluids as needed.
- Surgically remove the expanded glue foreign body.
- Wash exposed skin with warm soapy water, rub vegetable oil into the hair or clip hair to remove as much glue as possible. Glue can be left adhered to the skin if non-irritating and will fall off over time.

MEDICATIONS

- Antiemetic—Maropitant citrate 1 mg/kg SC q24h.
- H2 Blocker—to aid in the healing of gastric inflammation or ulceration. Famotidine 0.5 mg/kg PO or SQ BID.
- Sucralfate: If a gastric ulcer is present, 0.5–1 g PO TID on an empty stomach.

CONTRAINdications

- Emetics—emesis should not be performed unless done immediately after a witnessed ingestion. Expansion of the glue is rapid, late emesis stresses the stomach wall and could damage the esophagus.
- Do not dilute with water as exposure to moisture leads to rapid expansion of the glue.

FOLLOW-UP

PATIENT MONITORING

Monitor in hospital until eating and drinking normally. Recheck 10–14 days post surgery.

PREVENTION/AVOIDANCE

Prevent exposure.

EXPECTED COURSE AND PROGNOSIS

With removal of obstructive foreign body, prognosis is excellent. Without surgical removal the foreign body is not expected to resolve on its own.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Gastritis
- Dermatitis

ABBREVIATION

GDV = gastric dilatation-volvulus

DIOCTOPHYMA RENALE (GIANT KIDNEY WORM)

BASICS

OVERVIEW

- In dogs, adult female *D. renale* are significantly larger than males, reaching up to 100 cm in length and 1.2 cm in width. In contrast, males are only 20–40 cm in length and 6 mm in width.
- Adult male and female *D. renale* are typically blood red in color when they are alive but become brownish-black after they die and degenerate. The characteristic red color may be associated with a hemoglobin-like blood pigment (erythrocytokeratin).
- The eggs are lemon-shaped and constant in size. They have a light tan or rust color with deep pits in their shells except at the poles, which contain opercula. A typical female *D. renale* has been estimated to produce approximately 18–20 million eggs in its lifetime. The eggs may remain viable for up to 5 years. Desiccation and freezing temperatures are lethal to infective eggs of *D. renale*.
- Free-living annelids (*Lumbriculus variegatus*) are essential intermediate hosts. *Lumbriculus* spp. (aka blackworms and mudworms) are phylogenetically related to the earthworm. They can be readily found in Europe, North America, and South America. They often inhabit shallow water of the edges of ponds, lakes, and marshes where they feed on decaying vegetation and microorganisms. Any mammal that drinks water containing infected annelids has the potential of ingesting the infective third stage of *D. renale*.

EPIDEMIOLOGY

Cases of *D. renale* have been encountered in virtually every part of the world with a temperate climate. In North America, cases have frequently been encountered in Mississippi, Louisiana, Minnesota, Wisconsin, Michigan, and the central and eastern provinces of Canada. The giant kidney worm has been reported in many species of animals, including dogs, mink, coyotes, jackals, raccoons, foxes, wolves, beech martens, pine martens, otters, and weasels. Humans are accidental hosts; because of the aquatic portion of its life cycle, water is an essential element of the habitat of *D. renale*. Therefore it is not surprising that semiaquatic fish-eating mammals are the most common definitive hosts of *D. renale*. Fish and frogs often serve as paratenic hosts for this parasite. Mink are the most commonly infected mustelids, and are the principal definitive host in North America.

LIFE CYCLE

- To complete the life cycle, both males and females must be located in the same kidney of the host, and the urinary tract must be patent. Fertile eggs are passed with urine voided by

the host, and then embryonate in water. After 1–7 months, they produce first-stage larvae. The rate of their development is dependent on the temperature of the water. The optimal temperature for eggs to embryonate is 25–30°C. The eggs hatch only after being swallowed by the intermediate host, *L. variegatus*. This annelid is the only intermediate host needed to complete the life cycle. A period of ≥ 100 days in *L. variegatus* is required for the second and third (infective) stage of the parasite to develop. The definitive host becomes infected by ingesting the infective larvae in annelids.

- Paratenic hosts may also become a part of the life cycle. In the United States, frogs and northern black bullheads are paratenic hosts. The larvae encyst in the liver, mesentery, stomach wall, or abdominal muscles of the paratenic hosts.

• The definitive host becomes infected by ingesting raw fish, frogs, other paratenic hosts, or by ingesting *L. variegatus*. After being swallowed by the definitive host, the infective larvae penetrate the walls of the stomach or intestines and migrate to the submucosa. After approximately 5–7 days, they migrate to the liver and remain there for about 50 days. Migration to the right or the left kidney and invasion of the renal pelvis follows.

• *D. renale* have been found more frequently in the right kidney than in the left. The predilection for the right kidney has been attributed to the close anatomic relationship of the right kidney to the duodenum. According to some investigators, adult *D. renale* are found in the left renal pelvis when they penetrate the stomach at the greater curvature. Finding encysted *D. renale* around the liver is associated with larval penetration at the lesser curvature of the stomach. On occasion, *D. renale* have been encountered in the urinary bladder and/or ureter. The highest number of adults found in one dog is 34. The time required for infective larvae to become mature gravid females in the definitive host is 3.5–6 months. The entire life cycle requires approximately 2 years.

PATHOPHYSIOLOGY

Kidney

• Adult parasites have attained substantial size by the time they penetrate the kidney. The exact mechanisms involved with gaining access to the renal pelvis have not been reported. Entry of the parasite into the kidney probably results from the effects of enzymes released by the parasite. Potent collagenases, hyaluronidases, and cysteine proteases released by nematodes can easily digest host tissues. Glands containing these enzymes may be located adjacent to the esophagus.

• Available evidence does not support the theory that adult *D. renale* slowly devour the renal tissue of the host, reducing it to a hollow sack. The buccal cavity of the parasite is not

used for the ingestion of intact renal tissues; solid particles have not been detected in the esophagus of *D. renale*. Although the exact mechanism(s) of destruction is not known, obstruction caused by the growing adult parasite(s) and secondary hydronephrosis (or pyonephrosis) plays a major role. Light microscopic examination of sections of kidneys from dogs with unilateral renal infection reveals changes typical of advanced hydronephrosis (i.e., obliteration of the majority of renal tubules surrounded by chronic inflammatory tissue and persistence of the structural architecture of many glomeruli).

- Ova of *D. renale* may be observed in the renal parenchyma adjacent to the renal pelvis. The urothelium lining the renal pelvis is often hyperplastic in some areas and ulcerated in other areas.
- If only one kidney is affected with *D. renale*, the host retains adequate renal function due to compensatory hypertrophy and hyperplasia of the remaining kidney. If both kidneys are parasitized, or if one kidney is parasitized and the opposite kidney has substantial co-morbid dysfunction, varying stages of renal failure and uremia may occur. Eggs that are released by female worms pass through the urinary tract and provoke inflammation in the mucosa of the ureter and urinary bladder.

Peritoneal Cavity

• In dogs, viable parasites located in the abdominal cavity and/or between lobes of the liver have frequently been reported as an incidental finding during ovariohysterectomies. It is possible that under certain conditions the adult worms may remain in the peritoneal cavity for extended periods prior to penetration of a kidney.

• Eggs present in the peritoneal cavity can trigger development of chronic peritonitis. Examination of the abdominal viscera from dogs with *D. renale* in the peritoneal cavity revealed hemorrhage, granulomatous inflammation, and fibrosis frequently involving the omentum, the surface of the liver, and less frequently the surface of the spleen. Viable adult males (but not females) have been found in the peritoneal cavity of dogs without an associated inflammatory response, suggesting that females and/or their eggs stimulate a greater host inflammatory response than males.

• Ascites may occur in dogs with *D. renale* in the peritoneal cavity. The fluid detected in the abdominal cavity is usually hemorrhagic. The quantity of ascitic fluid reported to be removed from dogs infected with *D. renale* ranged from approximately 20 mL to 3.2 L.

SIGNALMENT

Species

Dog and cat

Breed Predilections

N/A

(CONTINUED)

DI OCTOPHYMA RENALE (GIANT KIDNEY WORM)**Mean Age and Range**

N/A

Predominant Sex

N/A

CLINICAL SIGNS

- The feeding of *L. variegatus* infected with *D. renale* to dogs typically induces vomiting due to effects of the parasite on the gastric mucosa.
- If only one kidney has been invaded with *D. renale* and the opposite kidney is normal, signs are often absent.
- Silent hematuria may be the first indication of an abnormality.
- Palpation of the abdomen may reveal an enlarged and/or misshapen hydronephrotic kidney.
- If both kidneys are parasitized, clinical signs attributable to renal failure or uremia may occur. However, the host will die before extensive hydronephrosis of both kidneys has time to develop. The degree of renal dysfunction is influenced by (1) number of parasites in the kidney, (2) duration of infection, (3) number of kidneys parasitized, and (4) presence and severity of co-morbid renal diseases.

CAUSES & RISK FACTORS

See "Life Cycle" and "Pathophysiology"

**DIAGNOSIS****DIFFERENTIAL DIAGNOSIS**

Any cause of hydronephrosis or renomegaly

CBC/BIOCHEMISTRY/URINALYSIS

- When a gravid female worm is present in one or both kidneys that have a patent track to the exterior, microscopic examination of urine voided by the host usually reveals ova of *D. renale*.
- Hematuria, pyuria, and proteinuria with or without eggs are indicative of an inflammatory response.
- Findings typical of chronic renal failure when both kidneys are parasitized or when one only kidney contains parasites and the contralateral kidney is diseased.

OTHER LABORATORY TESTS

N/A

IMAGING

- Radiography may reveal an enlarged hydronephrotic kidney. If intravenous urography is performed, it may be characterized by inability of the parasitized kidney to excrete the contrast agent.
- Ultrasonography may reveal that the affected kidney is hydronephrotic and contains excessive fluid. Ultrasound may also reveal characteristic hypoechoic loops associated with one or more of these parasites in the renal pelvis. Transverse plane sonographs of the affected kidney may reveal a thin hyperechoic rim that contains multiple circular structures of uniform diameter. The outer layers of these structures are hyperechoic; the inner portions are hypoechoic. In the longitudinal plane, the structures appear as elongated hyperechoic bands alternating with elongated hypoechoic bands. If viable parasites are in the peritoneal cavity, sonography may reveal hyperechoic curvilinear bands in the region of the right caudal lobe of the liver and/or the cranial pole of the right kidney. Serially performed sonographs may reveal movement of the parasite(s) from one location to another.
- CT and MRI scans may also be used to detect *D. renale* in the renal pelvis of one or both kidneys, in the peritoneal cavity, or in varying positions between the lobes of the liver.

DIAGNOSTIC PROCEDURES

N/A

**TREATMENT**

Nephrectomy is usually the treatment of choice when only one kidney is affected and the opposite kidney is capable of sustaining homeostasis. In patients with parasites in both kidneys, nephrotomy and removal of the parasites may be indicated if sufficient functional tissue remains in both kidneys to maintain a reasonable quality of life. Unfortunately by the time *D. renale* affecting both kidneys is recognized, the patients often have moderate-to-severe irreversible renal failure. Parasites that are incidental findings in the peritoneal cavity during celiotomy may be removed without further morbidity.

**MEDICATIONS****DRUG(S)**

Pharmacologic treatment of adults and/or infective larvae discovered in any species has been virtually non-existent. A report of a 44-year-old man with recurrent lumbar pain attributed to *D. renale* was cured following two regimens of ivermectin.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

**FOLLOW-UP****PREVENTION/AVOIDANCE**

Dogs and cats should not be fed raw fish or fish viscera, especially in areas where *D. renale* is known to exist. Likewise, they should not be given access to lake or pond water likely to contain infective stages of *D. renale*.

**MISCELLANEOUS****ABBREVIATIONS**

- CT = computed tomography
- MRI = magnetic resonance imaging

D

DISCOLORED TOOTH/TEETH

BASICS

DEFINITION

- Any color change from the norm—the normal color varies and depends on the shade, translucency, and thickness of enamel.
- Translucent enamel is bluish-white; opaque enamel is gray-white.
- Extrinsic—from surface accumulation of exogenous pigment.
- Intrinsic—secondary to endogenous factors discoloring the underlying dentin.

PATHOPHYSIOLOGY

Extrinsic Discoloration

- Bacterial stains—chromogenic bacteria give a green to black-brown to orange color, which is usually 1 mm above the gingival margin on the tooth.
- Plaque related—a black-brown stain; usually secondary to the formation of ferric sulfide from the interaction of bacterial ferric sulfide and iron in the saliva. Plaque on the dentition is usually white.
- Foods—charcoal biscuits and similar products penetrate the pits and fissures of the enamel; food that contains abundant chlorophyll can produce a green discoloration.
- Gingival hemorrhage—gives a green staining; results from the breakdown of hemoglobin into green biliverdin.
- Dental restorative materials—amalgam gives a black-gray discoloration.
- Medications—products containing iron or iodine give a black discoloration; those containing sulfides, silver nitrate, or manganese give a gray-to-yellow to brown-to-black discoloration; those containing copper or nickel give a green discoloration; products containing cadmium give a yellow-to-golden brown discoloration (e.g., 8% stannous fluoride combines with bacterial sulfides, giving a black stain; chlorhexidine gives a yellowish-brown discoloration).
- Metals—wear from chewing on cages or food dishes.
- From removed orthodontic brackets or bands.
- Crown fragments—less translucency due to dehydration of fragment.
- Discolored restorations.
- Tooth wear with dentin exposure—tertiary dentin, reparative dentin, secondary dentin.
- A calculus-covered crown ranges in color from a dark yellow to dark brown.

Intrinsic Discoloration

- Hyperbilirubinemia—affects all teeth; occurs during the developmental stages of the dentition (during dentin formation); bilirubin accumulation in the dentin occurs from excess red blood cell breakdown; extent of tooth discoloration depends on the length of hyperbilirubinemia (one can see lines of resolution on the teeth once the condition has been resolved); gives a green discoloration.
- Localized red blood cell destruction, usually one tooth—usually follows a traumatic injury to the tooth; discoloration comes from

hemoglobin breakdown within the pulp from a pulpitis and secondary release into adjacent dentinal tubules; discoloration goes from pink (pulpitis) to gray (pulpal necrosis or resolution) to black (liquefactive necrosis); blood factors that cause tooth discoloration are hemoglobin, methemoglobin, hematoidin, hemosiderin, hematin, hemin, and sulfmethemoglobin.

• Amelogenesis imperfecta—developmental alteration in the structure of enamel affecting all teeth; teeth have a chalky appearance and a pinkish hue; can be a problem in the formation of the organic matrix, mineralization of the matrix, or the maturation of the matrix.

- Dentinogenesis imperfecta—developmental alteration in the dentin formation; enamel separates easily from the dentin, resulting in grayish discoloration.
- Infectious agents (systemic)—parvovirus, distemper virus, or any infectious agent that causes a sustained body temperature rise; affects the formation of enamel; a distinct line of resolution is visible on the teeth; affects all teeth; results in enamel hypoplasia where the pitted areas have black edges and the dentin is brownish.
- Dental fluorosis—affects all teeth; excess fluoride consumption affects the maturation of enamel, resulting in pits (enamel hypoplasia) with black edges; the enamel is a lusterless, opaque white, with yellow-brown zones of discoloration.
- Tooth erosion from constant vomiting results in enamel pitting and darkened staining.
- Attrition—tooth-to-tooth wear results in crown loss and reparative dentin formation (yellow-brown color).
- Abrasion—tooth wear against another surface; chewing on tennis balls or chewing itself from a dermatologic condition. Reparative dentin (yellow-brown color) forms.
- Aging—older animals' dentition is more yellow and less translucent.
- Malnutrition (generalized, vitamin D deficiency, and vitamin A deficiency)—if severe can result in demarcated opacities on the enamel.

Internal/External Resorption

- Internal—follows pulpal injury (trauma) causing vascular changes with increased oxygen tension and a decreased pH, resulting in destruction (resorption) of the tooth from within the pulp from dentinoclasts; tooth has pinkish hue; usually one tooth affected.
- External—many factors cause this, such as trauma, orthodontic treatment, excessive occlusal forces, periodontal disease as well as treatment, tumors, and periapical inflammation; reabsorption can occur anywhere along the periodontal ligament and can extend to the pulp; osteoclasts resorb the tooth structure. Often the area is repaired by deposition of osteodentin.

Medications and Discoloration

- Tetracycline—binds to calcium, forming a calcium orthophosphate complex that is laid

down into the collagen matrix of enamel; occurs on all teeth; occurs only when the enamel is being formed; results in a yellow-brown discoloration. With long-term use of tetracycline drugs in mature animals, discoloration of the tooth occurs secondarily to the involvement of the underlying secondary dentin formation.

- Amalgam (as with extrinsic stains).
- Iodine/essential oils.
- From endodontically treated teeth with the mendicants penetrating the dentinal tubules.
- Macrolide antibiotic (reported in humans): due to increased number of karyopcytosis of the ameloblast at the transitional stage of development, resulting in vacuolar degeneration of the ameloblast and cystic change at maturation and hypocalcification, giving a white discolored lesion with horizontal stripes on the enamel.
- Bacterial "creeping" (leakage)—occurs around the margins of a restoration and usually is blackish in color.

SYSTEMS AFFECTED

Gastrointestinal—oral cavity

GENETICS

- Both amelogenesis imperfecta and dentinogenesis imperfecta in humans are inherited conditions that have many modes of inheritance: X-linked dominant, X-linked recessive, autosomal dominant, autosomal recessive. The mode of inheritance in animals has not been studied.
- Congenital hypothyroidism.
- Metabolic diseases.

INCIDENCE/PREVALENCE

- Discoloration of the teeth or a tooth is extremely common in all animals.
- Extrinsic staining is very common, especially bacterial stains; others are less common.
- Intrinsic staining is likewise very common, especially internal and external resorption, followed by localized red blood cell destruction; the other causes are rare.

GEOGRAPHIC DISTRIBUTION

- Heavy metals from mining operations.
- Fluoridation forms areas of excessive fluoride in the drinking water.
- Otherwise none.

SIGNALMENT

Species

Dogs and cats

Breed Predilections

None

Mean Age and Range

The reported age range varies—when the condition affects the maturing enamel or dentin it can be first noted after 6 months.

Predominant Sex

None

SIGNS

Historical Findings

Owner reports a variation in color of a tooth or teeth.

(CONTINUED)

DISCOLORED TOOTH/TEETH

D

Physical Examination Findings

- Abnormal coloration of tooth or teeth.
- Pitted enamel with staining. • Fractured tooth.
- Rings or lines of discoloration around tooth or teeth.
- Wear on crowns of the dentition or in selected areas as in behavioral causes (cage bitters—distal aspect of the canines is affected).
- Erosion of enamel.

CAUSES & RISK FACTORS

- Extrinsic discoloration—bacterial stains from plaque and calculus; foods; gingival hemorrhage; dental restorative materials, medications (chlorhexidine, 8% stannous fluoride), metal.
- Intrinsic discoloration—internal (trauma); external (feline osteoblastic resorptive lesions) resorption; localized red blood cell destruction in the tooth (trauma); systemic infections; medications (tetracycline); fluorosis; hyperbilirubinemia; amelogenesis imperfecta; dentinogenesis imperfecta.

**DIAGNOSIS****DIFFERENTIAL DIAGNOSIS**

- Calculus on the teeth.
- Normal tooth aging—increased translucence
- Food debris lodged in the diastimal spaces

CBC/BIOCHEMISTRY/URINALYSIS

- Anemia—blood-related disorders
- Bilirubin—increased with liver diseases

OTHER LABORATORY TESTS

- T₃/T₄—low in congenital hypothyroidism
- Specific metabolic enzyme decrease or absence—tyrosinemia

IMAGING

Dental radiography is extremely useful in identifying internal or external resorption, restorative materials, or bacterial stain from coronal percolation.

DIAGNOSTIC PROCEDURES

- If many teeth are affected, one tooth can be extracted and sent for histologic evaluation (see below).
- Transillumination with a strong fiber-optic light can benefit the clinician by distinguishing between a vital and necrotic pulp.
- Appropriate preoperative diagnostics when indicated prior to procedure.

PATHOLOGIC FINDINGS

- Tooth or teeth are discolored; enamel and/or dentin can be pitted or broken with staining.
- Extrinsic discoloration—all stain is in the enamel or exposed dentin, otherwise the tooth structure is normal.
- Intrinsic discoloration—hyperbilirubinemia; enamel

hypoplasia; lines of resolution on the tooth; all teeth affected.

- Localized red blood cell destruction—stain in dentinal tubules; pulpitis/liquefactive necrosis of the pulp.
- Internal resorption—well-circumscribed enlargement of an area of the endodontic system with granulation tissue containing many odontoclasts.
- External resorption—moth-eaten loss of tooth structure anywhere along the periodontal ligament; can extend into the endodontic system; areas of tooth resorption have granulation tissue with many osteoclasts.
- Fluorosis—enamel hypoplasia; enamel hypocalcification; medications; systemic (e.g., tetracycline has irregular matrix formation to the enamel and dentin), all teeth affected.
- Amelogenesis imperfecta—irregular formation of the enamel matrix, mineralization, or maturation.
- Dentinogenesis imperfecta—irregular formation of dentin; enamel may be separated from the dentin.

**TREATMENT****APPROPRIATE HEALTH CARE**

- Extrinsic stain removal—mainly cosmetic
- Intrinsic stain treatment—functional and pain relieving

NURSING CARE

- Extrinsic stain—remove inciting cause
- Intrinsic stain—soft food; remove chew toys

ACTIVITY

Curtail or treat specific behavioral abnormalities (cage biting).

DIET

Intrinsic stain—soft food

CLIENT EDUCATION

- To prevent it in future animals or litters.
- Intrinsic causes—if untreated the tooth or teeth are more likely to accumulate plaque and calculus, leading to subsequent periodontal disease; tooth fracture is more prevalent, which could result in tooth abscessation.

SURGICAL CONSIDERATIONS

- Extrinsic stain (cosmetic)—internal and/or external bleaching; veneers or crowns.
- Polishing the affected teeth with 3% hydrogen peroxide in pumice will help remove external stain. Also good home care with plaque control will check redevelopment of some stains (plaque/calculus/bacteria stain).
- Intrinsic stain (functional and pain relief)—possible endodontic treatment

(internal resorption and localized red blood cell destruction).

- Restorative procedures such as crowns or veneers to protect both tooth and pulp.
- Extraction of affected teeth may be required, especially with external resorption.

**MEDICATIONS****DRUG(S) OF CHOICE**

N/A

**FOLLOW-UP****PREVENTION/AVOIDANCE**

- See “Pathophysiology”
- Good oral care at home will help prevent the reoccurrence of certain specific stains.

POSSIBLE COMPLICATIONS

See “Client Education”

EXPECTED COURSE AND PROGNOSIS

Varies dependent upon the etiology but can vary from just aesthetics to significant pain.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Juvenile purpura

AGE-RELATED FACTORS

Most common in young dogs and cats

ZOONOTIC POTENTIAL

None

PREGNANCY/FERTILITY/BREEDING

- Tetracycline administration during pregnancy may result in permanent tooth discoloration in the offspring.
- See “Genetics.”

SYNONYMS

- Chlorhexidine staining
- Extrinsic staining
- Intrinsic staining
- Tetracycline staining

DISCOSPONDYLITIS

BASICS

DEFINITION

A bacterial or fungal infection of the intervertebral discs and adjacent vertebral bodies.

PATHOPHYSIOLOGY

- Hematogenous spread of bacterial or fungal organisms—most common cause.
- Neurologic dysfunction—may occur; usually the result of spinal cord compression caused by proliferation of bone and fibrous tissue; less commonly owing to luxation or pathologic fracture of the spine, epidural abscess, or extension of infection to the meninges and spinal cord.

SYSTEMS AFFECTED

- Musculoskeletal—infection and inflammation of the spine
- Nervous—compression of the spinal cord

GENETICS

- No definite predisposition identified.
- An inherited immunodeficiency has been detected in a few cases.

INCIDENCE/PREVALENCE

Approximately 0.1–0.8% of dog hospital admissions

GEOGRAPHIC DISTRIBUTION

- More common in the southeastern United States.
- Grass awn migration and coccidiomycosis—more common in certain regions.

SIGNALMENT

Species

Dog; rare in cat

Breed Predilections

Large and giant breeds, especially German shepherd and Great Dane.

Mean Age and Range

- Mean age—4–5 years
- Range—5 months–12 years

Predominant Sex

Males outnumber females by ~2:1

SIGNS

Historical Findings

- Onset usually relatively acute; some patients have mild signs for several months before examination.
- Pain—difficulty rising, reluctance to jump, and stilted gait are most common signs.
- Ataxia or paresis.
- Weight loss and anorexia.
- Lameness.
- Draining tracts.

Physical Examination Findings

- Focal or multifocal areas of spinal pain in >80% of patients.

- Any disc space may be affected; lumbosacral space is most commonly involved.
- Paresis or paralysis, especially in chronic, untreated cases.
- Fever in ~30% of patients.
- Lameness.

CAUSES

- Bacterial—*Staphylococcus pseudintermedius* is the most common. Others include *Streptococcus*, *Brucella canis*, and *E. coli*, but virtually any bacteria can be causative.
- Fungal—*Aspergillus*, *Paecilomyces*, *Scedosporium apiospermum*, and *Coccidioides immitis*.
- Grass awn migration is often associated with mixed infections, especially *Actinomyces*; tends to affect the L2–L4 disc spaces and vertebrae.
- Other causes—surgery, bite wounds.

RISK FACTORS

- Urinary tract infection; reproductive tract infection
- Periodontal disease
- Bacterial endocarditis
- Pyoderma
- Immunodeficiency

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Intervertebral disc protrusion—may cause similar clinical signs; differentiated on the basis of radiography and myelography.
- Vertebral fracture or luxation—detected on radiographs.
- Vertebral neoplasia—usually does not affect adjacent vertebral end plates.
- Spondylosis deformans—rarely causes clinical signs; has similar radiographic features, including sclerosis, ventral spur formation, and collapse of the disc space; rarely causes lysis of the vertebral end plates.
- Focal meningomyelitis—often identified by CSF analysis.

CBC/BIOCHEMISTRY/URINALYSIS

- Hemogram—often normal; may see leukocytosis.
- Urinalysis—may reveal pyuria and/or bacteriuria with concurrent urinary tract infections.

OTHER LABORATORY TESTS

- Aerobic, anaerobic, and fungal blood cultures identify the causative organism in about 35% of cases; obtain if available.
- Sensitivity testing—indicated if cultures are positive.
- Urine cultures—indicated; positive in about 30% of patients.
- Organisms other than *Staphylococcus* spp.—may not be the cause.
- Serologic testing for *Brucella canis*—indicated.

IMAGING

- Spinal radiography—usually reveals lysis of vertebral end plates adjacent to the affected disc, collapse of the disc space, and varying degrees of sclerosis of the end plates and ventral spur formation; may not see lesions until 3–4 weeks after infection.
- Myelography—indicated with substantial neurologic deficits; determine location and degree of spinal cord compression, especially if considering decompressive surgery; spinal cord compression caused by discospondylitis typically displays an extradural pattern.
- Computed tomography or magnetic resonance imaging—more sensitive than radiography; indicated when radiographs are normal or inconclusive.

DIAGNOSTIC PROCEDURES

- CSF analysis—occasionally indicated to rule out meningomyelitis; usually normal or reveals mildly high protein.
- Bone scintigraphy—occasionally useful for detecting early lesions; helps clarify if radiographic changes are infectious or degenerative (spondylosis deformans).
- Fluoroscopically guided fine-needle aspiration of the disc—valuable for obtaining tissue for culture when blood and urine cultures are negative and there is no improvement with empiric antibiotic therapy.

PATHOLOGIC FINDINGS

- Gross—loss of normal disc space; bony proliferation of adjacent vertebrae.
- Microscopic—fibrosing pyogranulomatous destruction of the disc and vertebral bodies.

TREATMENT

APPROPRIATE HEALTH CARE

- Outpatient—mild pain managed with medication.
- Inpatient—severe pain or progressive neurologic deficits require intensive care and monitoring.

NURSING CARE

Non-ambulatory patients—keep on a clean, dry, well-padded surface to prevent decubital ulceration.

ACTIVITY

Restricted

DIET

Normal

CLIENT EDUCATION

- Explain that observation of response to treatment is very important in determining the need for further diagnostic or therapeutic procedures.
- Instruct the client to immediately contact the veterinarian if clinical signs progress or recur or if neurologic deficits develop.

(CONTINUED)

SURGICAL CONSIDERATIONS

- Curettage of a single affected disc space—occasionally necessary for patients that are refractory to antibiotic therapy.
- Goals—remove infected tissue; obtain tissue for culture and histologic evaluation.
- Decompression of the spinal cord by hemilaminectomy or dorsal laminectomy—indicated for substantial neurologic deficits and spinal cord compression evident on myelography when there is no improvement with antibiotic therapy; also perform curettage of the infected disc space; it may be necessary to perform surgical stabilization if more than one articular facet is removed.

**MEDICATIONS****DRUG(S) OF CHOICE****Antibiotics**

- Selection based on results of blood cultures and serology.
- Negative culture and serology—assume causative organism is *Staphylococcus* spp.; treat with a cephalosporin (e.g., cefadroxil; dogs, 22 mg/kg PO q12h; cats, 22 mg/kg PO q24h) for 8–12 weeks.
- Acutely progressive signs or substantial neurologic deficits—initially treated with parenteral antibiotics (e.g., cefazolin; dogs and cats, 20–35 mg/kg IVq8h).
- Brucellosis—treated with tetracycline (dogs, 15 mg/kg PO q8h) and streptomycin (dogs, 3.4 mg/kg IM q24h) or enrofloxacin (dogs, 2.5–5 mg/kg PO q12h).

Analgesics

- Signs of severe pain—treated with an analgesic (e.g., oxymorphone; dogs, 0.05–0.2 mg/kg IV, IM, SC q4–6h).
- Taper dosage after 3–5 days to gauge effectiveness of antibiotic therapy.

CONTRAINDICATIONS

Glucocorticoids

PRECAUTIONS

Use NSAIDs and other analgesics cautiously—may cause a temporary resolution of clinical signs even when infection is progressing; when used, discontinue after 3–5 days to assess efficacy of antibiotic therapy.

POSSIBLE INTERACTIONS

None

ALTERNATIVE DRUG(S)

- Initial therapy—cephradine (dogs, 20 mg/kg PO q8h); cloxacillin (dogs, 10 mg/kg PO q8h).

- Refractory patients—clindamycin (dogs and cats, 10 mg/kg PO q12h), enrofloxacin (dogs, 5–20 mg/kg PO q24h; cats, 5 mg/kg PO q24h), orbifloxacin (dogs and cats, 2.5–7.5 mg/kg PO q24h).

**FOLLOW-UP****PATIENT MONITORING**

- Reevaluate after 5 days of therapy.
- No improvement in pain, fever, or appetite—reassess therapy; consider a different antibiotic, percutaneous aspiration of the affected disc space, or surgery.
- Improvement—evaluate clinically and radiographically every 4 weeks.

PREVENTION/AVOIDANCE

Early identification of predisposing causes and prompt diagnosis and treatment—help reduce progression of clinical symptoms and neurologic deterioration.

POSSIBLE COMPLICATIONS

- Spinal cord compression owing to proliferative bony and fibrous tissue.
- Vertebral fracture or luxation.
- Meningitis or meningomyelitis.
- Epidural abscess.

EXPECTED COURSE AND PROGNOSIS

- Recurrence is common if antibiotic therapy is stopped prematurely (before 8–12 weeks of treatment).
- Some patients require prolonged therapy (1 year or more).
- Prognosis—depends on causative organism and degree of spinal cord damage.
- Mild or no neurologic dysfunction (dogs)—usually respond within 5 days of starting antibiotic therapy.
- Substantial paresis or paralysis (dogs)—prognosis guarded; may note gradual resolution of neurologic dysfunction after several weeks of therapy; treatment warranted.
- *Brucella canis*—signs usually resolve with therapy; infection may not be eradicated; recurrence common.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

DISSEMINATED INTRAVASCULAR COAGULATION

BASICS

DEFINITION

DA complex hemostatic defect arising from a variety of inciting causes that leads to uncontrolled activation and consumption of clotting factors. It results in widespread formation of microthrombi with clinical manifestations of thrombosis and/or hemorrhage.

PATHOPHYSIOLOGY

- DIC represents a complication of a variety of primary conditions. It begins with a hypercoagulable state that leads to microthrombi in many small vessels.
- The primary conditions primarily act through increased exposure/production of TF (Factor III) which activates the extrinsic coagulation pathway.
- TF is normally restricted from intravascular exposure. It is usually exposed when endothelium is damaged revealing subendothelial tissue, which localizes coagulation. Increased exposure/production mainly occurs through widespread endothelial injury and/or increased production secondary to inflammation.
- Inflammation activates endothelial cells, platelets, and monocytes leading to membrane expression of TF. Inflammatory cytokines also induce vesiculation of these membranes releasing large quantities of microparticles into circulation that are enriched with both TF and PS and that facilitate extensive dissemination of coagulation. Some neoplastic cells constitutively produce membrane TF and also release microparticles.
- Microparticles provide a suitable membrane surface for amplifying intrinsic and common pathway coagulation, potentially leading to uncontrolled production of thrombin that overwhelms coagulation inhibitors (AT, APC, TFPI). Thrombin's conversion of fibrinogen to fibrin contributes to vascular occlusion.
- Widespread microthrombus formation consumes coagulation factors and platelets while initiating fibrinolysis. By-products of fibrinolysis (FDPs) have anticoagulant properties and inhibit platelet function. Hemorrhage at a variety of sites can follow.
- Uncontrolled progression leads to widespread tissue hypoxia, multi-organ dysfunction, and death.

SYSTEMS AFFECTED

Multisystemic syndrome

GENETICS

N/A

INCIDENCE/PREVALENCE

Associated with severe systemic disease, often in the terminal stages

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Dogs and cats; diagnosed more in dogs

Breed Predilections

None

Mean Age and Range

Depends on the primary disease

Predominant Sex

None

SIGNS

- Vary with the primary disease and with DIC-associated organ dysfunction
- Petechiae
- Bleeding from venipuncture sites, mucosa, or in body cavities
- Bleeding is infrequent in cats, possibly leading to under-diagnosis

CAUSES

- Gastric dilatation-volvulus
- Heart failure
- Heartworm disease
- Heat stroke
- Hemolysis, especially immune mediated
- Hemorrhagic gastroenteritis
- Infectious diseases, systemic (especially endotoxemia)
- Inflammation, severe—regardless of underlying cause
- Liver disease, if severe (e.g., ICH, xylitol toxicity in dogs; lipidosis in cats)
- Malignancies, especially hemangiosarcoma, mammary carcinoma, and pulmonary adenocarcinoma in dogs and lymphoma in cats
- Pancreatitis
- Protein-losing nephropathy (nephrotic syndrome)
- Shock, hypoxia, acidosis
- Thrombocytopenia, especially immune mediated
- Transfusion incompatibility
- Trauma
- Venom

RISK FACTORS

Vary with cause

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Key differentials: immune-mediated thrombocytopenia, anticoagulant toxicity, coagulation factor deficiency, paraproteinemia.
- Highly variable diagnostic pattern includes thrombocytopenia, prolonged clotting tests (PT, APTT), decreased fibrinogen, decreased AT, and increased fibrinolysis (FDPs, D-dimers). At least three abnormalities in animals affected by a predisposing condition (see "Causes") is considered diagnostic.
- Suspect DIC any time thrombocytopenia and prolonged clotting tests are seen together.

- Patients showing predisposing conditions should have laboratory monitoring every 24–48 hours. A sudden drop in platelet count and a 20–30% prolongation in APTT is very suspicious for DIC.

- Hepatic insufficiency may mimic DIC pattern. Decreased production of clotting factors is common. Decreased clearance of normal fibrin(ogen)olytic by-products may increase FDP values. Mild idiopathic thrombocytopenia may also be seen. Spontaneous bleeding is uncommon unless DIC is present.

CBC/BIOCHEMISTRY/URINALYSIS

- Inflammatory leukogram, often with a stress component.
- Thrombocytopenia; very consistent finding in dogs, less reliable in cats.
- Anemia is possible. RBC fragmentation (schistocytes) is a supportive finding.
- Biochemical changes reflect affected organs.

OTHER LABORATORY TESTS

- Prolonged clotting tests (PT, APTT); APTT is more sensitive.
- Hypofibrinogenemia, although inflammatory increase may mask consumption.
- Increased FDPs and D-dimers. D-dimers are very sensitive. DIC is unlikely if D-dimers are low/negative. Neither test is specific enough alone to diagnose DIC.
- Decreased AT; may be a positive acute phase reactant in cats, masking consumption.
- TEG reportedly identifies hypercoagulable and hypocoagulable states in DIC. Case fatality rate is significantly higher in the hypocoagulable state.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

None

PATHOLOGIC FINDINGS

- Usually related to the primary disease or DIC-affected organs
- Petechiae common

TREATMENT

APPROPRIATE HEALTH CARE

- Requires intensive inpatient treatment.
- Aggressive treatment of the primary disease is essential (e.g., antimicrobials for sepsis).

NURSING CARE

- Maintain tissue perfusion and oxygenation using fluids, transfusions, and oxygen therapy.
- Restore depleted factors by blood/plasma transfusions. Use fresh frozen plasma (6–20 mL/kg) to correct bleeding due to factor deficiency.

ACTIVITY

Limited by the disease severity

(CONTINUED)

DISSEMINATED INTRAVASCULAR COAGULATION

DIET

Maintain nutritional support as appropriate for the clinical condition of the patient.

CLIENT EDUCATION

Inform the owner that the condition is life-threatening with a guarded to poor prognosis.

SURGICAL CONSIDERATIONS

Related to primary disease. Plasma or whole blood transfusion to restore clotting factors is a presurgical consideration. Surgery may be contraindicated with uncontrolled bleeding.

MEDICATIONS

DRUG(S) OF CHOICE

- Successful drug protocols are mostly anecdotal and traditionally use heparin to effect (clinical improvement, test results).
- Heparin binds to and potentiates the action of AT. Plasma or blood transfusions are often needed to replenish AT for heparin to be effective.
- Heparin dosage depends on severity of signs and lab changes.
- Mild to moderate disease: heparin at 5–200 U/kg SC q8h or IV (q8h or continuous infusion)
- Severe disease: heparin at 300–1,000 U/kg SC q8h or IV (q8h or continuous infusion)

CONTRAINDICATIONS

Inhibitors of fibrinolysis should not be used. Fibrinolysis is important in the clearance of thrombi.

PRECAUTIONS

- High doses of heparin may cause fatal hemorrhage.
- Watch for overhydration in cases with renal or pulmonary compromise.
- Corticosteroids impair function of mononuclear phagocytes, possibly delaying removal of activated coagulation factors and FDPs. Avoid prolonged use.
- Use of antiplatelet medications (aspirin, clopidogrel) in thrombocytopenic patients warrants caution for hemorrhage even though platelet activation is a part of DIC pathogenesis.

POSSIBLE INTERACTIONS

None

ALTERNATIVE DRUG(S)

Low molecular weight heparin: many forms with variable activity are available. Fewer complications reported but very expensive. Most information is anecdotal.

FOLLOW-UP

PATIENT MONITORING

- Clinical improvement and the arrest of bleeding are key positive findings.
- Daily lab testing (e.g., coagulation tests, fibrinogen, platelet counts) is warranted in severe cases to identify positive or negative trends. Less frequent testing may suffice in milder cases.
- Coagulation times and fibrinogen often return to normal more rapidly than FDPs and platelet counts.

PREVENTION/AVOIDANCE

- Related to primary disease.

POSSIBLE COMPLICATIONS

Aside from the primary disease, DIC affected organs may have permanent dysfunction or marginal reserve capacity.

EXPECTED COURSE AND PROGNOSIS

Mortality rates for dogs range from 50% to 77%. For cats, rates may be > 90%.

DROWNING (NEAR DROWNING)

BASICS

OVERVIEW

- Defined as process of experiencing respiratory impairment from submersion or immersion in liquid; near-drowning defined as water submersion followed by survival for at least 24 hours. Recent changes in terminology prefer the use of “death, morbidity or no morbidity following a drowning episode.”
- Following submersion, elevations in carbon dioxide levels in the bloodstream stimulate respiration, and subsequent aspiration of water occurs.
- Fresh water aspiration dilutes pulmonary surfactant, leading to alveolar collapse ± infectious pneumonia. Hypertonic seawater aspiration leads to diffusion of interstitial water into alveoli. Large volumes of water are not typically aspirated, but any amount results in ventilation-perfusion mismatch, hypoxemia, and metabolic acidosis.
- Submersion time, temperature of the water, and type of water (fresh vs. salt vs. chemical water) significantly affect development of organ damage.

SIGNALMENT

Dogs and cats. Approximately half of the animals involved in immersion accidents are less than 4 months of age.

SIGNS

- Noted acutely after exposure to water
- Cyanosis, apnea, respiratory distress
- Coughing ± clear to frothy red sputum
- Vomiting
- Obtunded to comatose
- Crackles or wheezes auscultated over chest
- Tachycardia or bradycardia, asystole

CAUSES & RISK FACTORS

- Greater risk near bodies of water (including pools, buckets, bathtubs) or ice.
- Owner negligence or inadequate safety precautions versus purposeful harm.
- Animals in or near water at the time of a seizure, head trauma, hypoglycemic event, cardiac arrhythmia, or syncopal episode are at risk of drowning.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hypothermia, neck trauma, and meningitis.
- With drowning secondary to a seizure, head trauma, hypoglycemic event, cardiac arrhythmia, or syncopal episode, history at the time of presentation may be informative.

CBC/BIOCHEMISTRY/URINALYSIS

- Fresh water inhalation/ingestion—hemodilution, hemolysis, and decreases in sodium, chloride, and urine specific gravity.
- Hypertonic salt water ingestion/inhalation—hemoconcentration and increases in sodium, chloride, and urine specific gravity.

OTHER LABORATORY TESTS

Arterial blood gas reveals hypoxemia ($\text{PaO}_2 < 80 \text{ mmHg}$), hypoventilation ($\text{PaCO}_2 > 50 \text{ mmHg}$), and acid-base derangements.

IMAGING

- Radiographic changes may not be detectable for 24–48 hours.
- Focal or diffuse alveolar pattern due to aspiration pneumonia or non-cardiogenic pulmonary edema.
- Mixed patterns may be present, ± a radiopaque material filling the airways (“sand bronchogram”).
- Foreign body inhalation may produce segmental atelectasis.
- Progression of pulmonary injury to ARDS is possible and may appear as bilateral, diffuse, symmetrical alveolar infiltrates.

DIAGNOSTIC PROCEDURES

- Endotracheal or transtracheal wash with cytologic evaluation and culture with sensitivity indicated if animal is stable.
- Electrocardiographic monitoring.
- Cervical radiographs, CT or MRI of brain, and BAER assessment in select cases.

TREATMENT

- Initiate mouth-to-muzzle resuscitation on-site.
- Emergency inpatient care is required.
- Airway clearance, if obstructed, is first priority.
- Cardiopulmonary resuscitation, if necessary.
- Oxygen supplementation.
- Intubation and mechanical ventilation with positive end-expiratory pressure may be required in animals with severe hypoxemia, hypercapnia, or imminent respiratory fatigue.
- Fluid therapy and acid-base/electrolyte management are crucial.
- Gradually rewarm (over 2–3 hours) hypothermic animals.
- Gravitational drainage or abdominal thrusts (Heimlich maneuver) are not recommended in the absence of airway obstruction owing to high risk of regurgitation and subsequent aspiration of stomach contents.

MEDICATIONS

DRUG(S) OF CHOICE

- Mannitol, 0.5 g/kg IV over 30 minutes, may be beneficial in animals with suspected cerebral edema.
- Broad-spectrum antibiotics (e.g., ampicillin, 22 mg/kg IV q8h, and enrofloxacin, 10–20 mg/kg IV q24h in the dog or 5 mg/kg IV q24h in the cat) for aspiration pneumonia.
- Beta-2 agonists may help animals with suspected bronchospasm.
- Pentoxifylline decreased incidence of lung injury in dogs with experimental freshwater aspiration.

CONTRAINDICATIONS

- Corticosteroid therapy not indicated; use could be detrimental in animals with aspiration pneumonia.
- Use of enrofloxacin in young animals may result in cartilage erosion.

FOLLOW-UP

PATIENT MONITORING

- Continuous monitoring of heart rate and rhythm, respiratory rate, MM color and CRT, urine output, arterial blood pressure, rectal temperature, and neurologic status.
- Arterial blood gas, complete blood count, biochemical profile, coagulation profile, and acid-base status checked as needed.

PREVENTION/AVOIDANCE

Close monitoring of animals (especially young and old/debilitated animals) near bodies of water. Place barriers around bodies of water, life jackets on animals, train owners to perform CPR.

POSSIBLE COMPLICATIONS

Aspiration pneumonia, non-cardiogenic pulmonary edema, ARDS, gastrointestinal bleeding, diarrhea, vomiting, acute kidney injury, permanent neurologic derangements, DIC, central diabetes insipidus.

EXPECTED COURSE AND PROGNOSIS

Directly related to animal's status at time of admission: animals that present comatose, severely acidotic ($\text{pH} < 7.0$), or requiring cardiopulmonary resuscitation or mechanical ventilation have a poor prognosis. Animals that present conscious have a good prognosis if no complications ensue; 37.5% mortality rate in 15 dogs and 1 cat with freshwater aspiration.

MISCELLANEOUS

ABBREVIATIONS

- ARDS = acute respiratory distress syndrome
- BAER = brainstem auditory evoked response
- CPR = cardiopulmonary resuscitation
- CT = computed tomography
- DIC = disseminated intravascular coagulation
- MRI = magnetic resonance imaging

DUCTAL PLATE MALFORMATION (CONGENITAL HEPATIC FIBROSIS)

BASICS

DEFINITION

- Ductal plate malformations (DPMs) are noninflammatory hepatopathies recognized in juvenile and young adult dogs or cats reflecting developmental abnormalities of biliary structures.
- Diverse phenotypes defined by involved structures, coexistent hepatic fibrosis, portal hypertension, and acquired portosystemic shunts (APSS).
- Propensity for septic suppurative cholangitis, choledochitis, cholelithiasis, or extrahepatic bile duct obstruction (EHBDO) reflects structural malformations.
- Represent abnormal development, differentiation, and resorption of embryonic anlage of the ductal plate, the embryologic precursor of the portal tract and bile ducts.
- In humans (and knockout mouse models), DPMs represent gene mutations influencing structure or function of primary cilia.
- Primary cilia—solitary, non-motile organelles located on the apical surface of most mammalian cells. These function as mechano-, osmo-, and chemoreceptors and are involved in designation of planar cell polarity, in cell cycle control, and numerous additional signaling pathways. Pathomechanisms leading to DPM involves interrupted tubulogenesis.
- Polycystic kidney disease in Persian cats involves the polycystin-1 precursor gene; ~ 15% develop hepatic DPM.

Four Major DPM Phenotypes

- (1) *Choledochal cyst*—diverticulum protruding from the common bile duct (CBD) or cystic duct; has propensity for infection—similar to appendicitis in humans causing sepsis, EHBDO, and cranial abdominal mass effect.
- (2) *Caroli's malformation*—irregular sacculation and dilation of hepatic, interlobular and large intralobular bile ducts; ducts have variable morphology appearing elongate, irregular, lanceolate, or sacculated, usually with attenuated biliary epithelium and intraluminal debris; with chronicity may develop choleliths, dystrophic mineralization, and septic cholangitis.
- (3) *Diffuse intralobular bile duct malformation without OR with diffuse portal-to-portal bridging fibrosis; if fibrosis = congenital hepatic fibrosis (CHF)*—Abnormal tubulogenesis of small intralobular bile ducts reflect abnormal resorption of extraneous ductule anlage; results in retention of numerous small malformed proliferative ductules lacking luminal apertures, variously embedded in excessive extracellular matrix (ECM); amalgamation of proliferative ductules, numerous stout arterials, and ECM dimensionally expand portal tracts forming variable bridging partitions between portal regions; portal veins are often inconspicuous;

dense fibrosis may cause presinusoidal portal hypertension and formation of APSS in CHF phenotype.

(4) *von Meyenberg complexes*

(VMC)—isolated single microscopic DPM comprised of clusters of proliferative intralobular bile ductule profiles embedded in an expanded ECM profile; also called bile duct hamartoma; are inconsequential.

(5) Progressive presinusoidal fibrosis with aging can lead to gradual onset of portal hypertension, formation of APSS, ascites, and hepatic encephalopathy (HE).

PATHOPHYSIOLOGY

- DPMs are not associated with increased liver enzymes or jaundice until compromised by infection, choleliths, EHBDO, or choledochitis.
- As described, different phenotypes may involve different acquired disease manifestations.
- *Choledochal cysts*—not recognized until cystic luminal contents are contaminated by bacteria; ensuing infection, cyst expansion, choledochitis or EHBDO cause clinical signs; until compromised CBD, patient remains anicteric and asymptomatic.
- *Caroli's malformation*—serendipitously recognized on abdominal radiography (limy gallbladder, mineralized sacculated large bile ducts), or abdominal US, when obstructed by choleliths or infected (choledochitis).
- *Diffuse DPM without extensive bridging fibrosis or presinusoidal portal hypertension*—not typically associated with increased liver enzymes or jaundice and have normal total serum bile acids (TSBA); diagnosed when infection causing increase in liver enzymes leads to liver biopsy.
- *Diffuse DPM with bridging fibrosis (CHF) causes presinusoidal portal hypertension*—may present for ascites, increased TSBA, ± increased liver enzymes reflecting secondary cholangitis.

SYSTEMS AFFECTED

- Liver—microhepatia, normal, or large liver; gallbladder agenesis, maldevelopment of left liver lobes; rare concurrent congenital intrahepatic or extrahepatic congenital portosystemic vascular anomaly (shunt, PSVA); jaundice due to EHBDO from choledochal cyst, or cholelithiasis (Caroli's malformation, choledochal cyst), or increased liver enzymes from suppurative cholangitis.
- Gastrointestinal—anorexia; intermittent vomiting or diarrhea reflecting concurrent IBD or enteric hypertensive vasculopathy (splanchnic hypertension from presinusoidal ECM deposition).
- Nervous—episodic HE.
- Musculoskeletal—stunted growth and poor body condition; chronic disease, inappetence, enteric malassimilation. Urogenital—polyuria and polydipsia; possible polycystic renal phenotype; ammonium biurate urolithiasis reflects APSS or rare PSVA.
- Hemic/Lymphatic/Immune—RBC microcytosis due to APSS; neutrophilic leukocytosis with toxic neutrophils and left-shifted leukon in

suppurative cholangitis/choledochitis, choledochal cyst.

SIGNALMENT

- Dog and cat, no sex predilection.
- Juvenile and young adults; dogs: mean age 1.5–2.5 years (0.2–12) years.
- May affect multiple littermates.
- Boxer dogs may be predisposed.
- Persian cats with polycystic renal disease predisposed.

SIGNS

- May be asymptomatic.
- Stunted growth, poor body condition if APSS.
- GI signs: inappetence, emesis, diarrhea, enteric hemorrhage; especially if concurrent IBD.
- PU/PD if APSS or polycystic renal disease.
- ± Increased liver enzymes.
- ± Fever, leukocytosis, increased bilirubin: septic choledochitis, choledochal cyst, or cholelithiasis.
- ± Abdominal distention: ascites with APSS.
- ± Episodic CNS signs due to HE.
- ± Urolithiasis (ammonium urates) reflect hyperammonemia due to APSS or rare PSVA.

CAUSES & RISK FACTORS

- Congenital malformation; suspected gene mutations affecting structure or function of primary cilia have not been proven in dogs.
- Clinical signs usually caused by acquired complications, see previously.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Stunted growth, increased total serum bile acids—PSVA, portal atresia, splanchnic portal venous thromboembolism (TE).
- Increased liver enzymes with or without hyperbilirubinemia—chronic hepatitis, toxicity, cholangiohepatitis, choledochitis, cholecystitis.
- Jaundice—acute liver injury, toxic injury, chronic hepatitis, copper associated hepatopathy, cholelithiasis, ruptured gallbladder (if GB cannot be imaged), EHBDO, hemolysis—check RBC morphology for schistocytes, acanthocytes, spherocytes, Coombs' test.
- CNS signs—fungal disorders (distemper); toxicities (lead); hydrocephalus; epilepsy; metabolic disorders (hypoglycemia, hypokalemia, hyperkalemia, hypophosphatemia); Wernicke's encephalopathy (thiamine deficiency).
- Ascites—Pure Transudate, many causes (see Portal Hypertension).
- HE—APSS or PSVA or Portal TE.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC—RBC microcytosis: reflects APSS; target cells in dogs.
- Biochemistry—if APSS: ± low albumin, cholesterol, BUN, variable globulin; all DPM phenotypes: ± increased ALP and ALT activity; hyperbilirubinemia: if EHBDO due to choledochal cyst or cholelithiasis or if septic.
- Urinalysis—

DUCTAL PLATE MALFORMATION (CONGENITAL HEPATIC FIBROSIS)

ammonium biurate crystalluria if APSS in CHF phenotype.

OTHER LABORATORY TESTS

Routine Coagulation Tests

Variable abnormalities (see Coagulopathy of Liver Disease). Low protein C and antithrombin activity may reflect APSS in CHF phenotype.

TSBA

Increased with shunting pattern if APSS or rare PSVA.

Peritoneal Fluid Analysis

Pure transudate (protein < 2.5 g/dL); modified transudate if chronic—only in CHF phenotype.

IMAGING

Radiography

- Abdominal radiography: variable liver size (microhepatia to large liver, e.g., severe polycystic liver disease in cats). • Abdominal effusion: APSS in CHF phenotype.
- Ammonium biurate calculi—radiolucent unless radiodense mineral shell; implies APSS.
- Thoracic radiography—normal: rule out right-sided heart disease or pericardial tamponade.

Abdominal Ultrasonography

- Variable liver size: small to large. • GB may not be discovered: atresia possible. • May disclose parenchymal or biliary system changes due to malformations (sacculated or cystic ductal structures); variable liver texture; unremarkable vasculature to portal hypoperfusion. • Choledochal cyst—may be difficult to image owing to overlying enteric gas and confusion with CBD and cystic duct.
- Abdominal effusion: if APSS in CHF.
- APSS—confirm using color-flow Doppler; may confirm hepatofugal portal flow (away from the liver); tortuous APSS usually adjacent or caudal to left kidney, adjacent to splenic vasculature; rule out portal TE and hepatic AV malformations. • Uroliths: renal pelvis, urinary bladder; obstructive uropathy: urethral obstruction.

ADDITIONAL IMAGING

Colorectal (CRS) or Splenoportal (SPS) Scintigraphy

- Technetium-^{99m} pertechnetate; gamma camera imaging documents isotope appearance in heart before liver to confirm shunting; shunt fraction (time activity plot) is not quantitatively reliable; normal shunt fraction ≤ 15% CRS. Sensitive noninvasive test—confirms shunting; cannot differentiate PSVA from APSS or intrahepatic from extrahepatic PSVA. • SPS: requires splenic injection with contrast; same principle, can miss caudal PSVA.

Multisector CT

- Gold standard imaging to confirm APSS or PSVA; demonstrates arterial and portal circulations, may disclose asymmetric liver

development, GB atresia, choledochal cyst, sacculated interlobular and cystic ducts.

- Non-invasive test: IV contrast administration and short-term (20 minutes) general anesthesia.

DIAGNOSTIC PROCEDURES

- Fine-needle aspiration cytology—cannot diagnose DPM, can sometimes identify bacteria.
- Liver biopsy—open surgical wedge or laparoscopic cup samples from several liver lobes are best, record symmetry of liver lobes sampled, needle core samples can often diagnose DPM.

Echocardiography

Rule out right-sided heart disease and vena caval occlusion (see Portal Hypertension).

DIAGNOSTIC PROCEDURES

- Liver biopsy: as described above.
- Portal hypertension: > 13 cmH₂O attenuated by APSS; measurement may be hazardous and is not clinically useful.

PATHOLOGIC FINDINGS

- Gross—depends on phenotype.
 - (1) *Choledochal cyst*: variable size (as large as 10 cm); wall thick or thin; contents acholic and mucinous white bile; purulent, or bile laden; may be abscessed; may envelop CBD.
 - (2) *Caroli's malformation*: grossly distended hepatic, interlobular, and segmental bile ducts, thick walls if choledochitis, may be mineralized, may have pigment-calcium carbonate choleliths.
 - (3) *Diffuse DPM*: firm fibrotic parenchyma, fine nodular to smooth surface, may have splanchnic APSS if CHF phenotype.
 - (4) *von Meyenburg complexes*: inapparent or tiny pale foci. In phenotypes 2 and 3 above, possible GB atresia, PSVA, other vascular malformation, or left-sided liver agenesis.
- Microscopic—variable severity as previously described. Portal hypoperfusion with diffuse DPM and CHF phenotype; direct intersection of proliferative bile ductules and hepatocytes is a unique feature; islands of hepatocytes encircled by portal-to-portal bridging partitions of variable width in the CHF phenotype.

TREATMENT

APPROPRIATE HEALTH CARE

- Inpatient—for septic complications of choledochal cyst or DPM cholangitis or severe HE (see Hepatic Encephalopathy; Hepatitis, Suppurative and Hepatic Abscess; Cholangitis/Cholangiohepatitis Syndrome).
- Surgical intervention: choledochal cyst—best managed by resection; depends on anatomic malformation and location; may be marsupialized or anastomosed to intestine. Attempt to use alcohol ablation not advised.
- Outpatient—stable patients. • Avoid endoparasitism. • Treat infections promptly—DPM patients (except VMC)

predisposed to cholangitis, choledochitis due to blind ended non-contiguous ductal structures; in CHF portal venous hypoperfusion reduces Kupffer cell surveillance.

- In CHF: remain vigilant for ammonium biurate obstructive uropathies (all levels of urinary system); urethral obstruction (males) may require permanent urethrostomy.
- If APSS—avoid NSAIDs which may augment ascites (sodium and water retention) and gastrointestinal bleeding provoking HE.

NURSING CARE

Hepatic Encephalopathy

- Eliminate causal factors of HE; individualize diet, supplement water-soluble vitamins, vitamin E, and K depending on PT or PIVKA test; optimize HE management to individual response (see Hepatic Encephalopathy). Strive to maintain body condition and muscle mass—muscle mass attenuates ammonia toxicity as temporary storage site; provide multiple small feedings daily.
- Ascites (see Portal Hypertension).

MEDICATIONS

DRUG(S) OF CHOICE

Hepatic Encephalopathy

- Lactulose (0.5–1.0 mL/kg PO q8–12h)—goal to maintain several soft stools daily; may withdraw with optimal diet modifications.
- Oral antibiotics to modify encephalogenic enteric toxin production—first choices: metronidazole (7.5 mg/kg PO q12h) or amoxicillin (22 mg/kg PO q12h). Avoid neomycin (20 mg/kg PO q8–12h PO)—has potential for enteric absorption (esp. if concurrent IBD) causing ototoxicity (deafness) and nephrotoxicity [chronic neomycin: ~ 3% absorbed per dose].

Ascites (also see Portal Hypertension)

- *Dietary sodium restriction* (see Portal Hypertension; Portosystemic Shunting, Acquired)
- Diuretics: *Furosemide* (1–4 mg/kg PO, IM, or IV q12–24h)—potassium wasting effect modulated by *combination with spironolactone* (1–4 mg/kg PO q12h, loading dose then maintenance dose of 2–4 mg/kg; potassium sparing; less potent than furosemide (see Portal Hypertension; Portosystemic Shunting, Acquired).
- *Diuretic-resistant ascites*—consider therapeutic abdominocentesis, V₂ receptor antagonists, and angiotensin receptor blocker diuretic (see Portal Hypertension for details).
- *Antifibrotic*—in humans with DPM, traditional antifibrotics have no influence on age-related accrual of portal ECM causing presinusoidal portal hypertension. The only drug with some efficacy in rat model of adult polycystic renal disease (with CHF) is telmisartan.

DUCTAL PLATE MALFORMATION (CONGENITAL HEPATIC FIBROSIS)

D

- *Telmisartan* is an angiotensin receptor blocker (ARB) used widely in humans as an antihypertensive with partial PPAR- γ agonist activity; it also is nephroprotective (diabetes, other forms of renal injury), prevents certain forms of drug-induced hepatotoxicity, and reduces hepatic fibrosis. ARBs—selectively antagonize the angiotensin-1 receptor, bypassing intermediary activation steps within the RAAS cascade. Telmisartan administration PO to healthy dogs at 1.0 mg/kg/day significantly increased urine volume and sodium excretion and was safely used (single case report) for amelioration of pathologic proteinuria in a dog; effective, non-toxic at escalating doses of 0.43 mg/kg PO q24h to 0.9 mg/kg/day.

Antioxidant Medications

Indicated in dogs with chronic cholangitis, increased liver enzymes, or CHF (see Cirrhosis and Fibrosis of the Liver).

Bleeding Tendencies

See Coagulopathy of Liver Disease. Rare in CHF; may encounter in chronic EHBDO caused by choledochal cyst or cholelithiasis.

Gastrointestinal Hemorrhage

See Cirrhosis and Fibrosis of the Liver; Portal Hypertension. Hypertensive enteric vasculopathy may be encountered with CHF because of APSS.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Avoid or reduce dosage of drugs relying on hepatic biotransformation or first pass hepatic metabolism; avoid drugs reacting with GABA-benzodiazepine receptors; avoid drugs inhibiting biotransformation and metabolism of other drugs (e.g., cimetidine, chloramphenicol, quinidine, some calcium channel blockers). • Avoid metoclopramide if spironolactone used as a diuretic (augments aldosterone).

FOLLOW-UP

PATIENT MONITORING

- Biochemistry—initially, monitor q2–4 weeks until stable in animals presenting

with sepsis or EHBDO, then q4–6 months or if cyclically ill or febrile; monitor for recurrent septic cholangitis/choledochitis, development of septic effusion; HE decompensation. If colchicine used for fibrosis (NOTE: not recommended), monitor CBC for bone marrow suppression and observe for enteric toxicity and neurotoxicity.

POSSIBLE COMPLICATIONS

CHF associated with HE—requires indefinite nutritional and medical management.

EXPECTED COURSE AND PROGNOSIS

- Long-term survival (years) possible.
- Short-term or life-long treatments may be required—antibiotics, unknown long-term benefit from antifibrotics, necessary nutritional modifications if APSS in CHF, ancillary treatments for HE and hypertensive portal vasculopathy (enteric hemorrhage, inappetence), and ascites. • Occasional flare-ups of HE and ascites may require hospitalizations for adjustment of nutritional and medical interventions. Sodium restriction and diuretics may require titration to achieve optimal control of ascites.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Hepatic encephalopathy • Ascites
- Gastrointestinal bleeding • APSS

AGE-RELATED FACTORS

- Prognosis depends on: (1) degree of fibrosis and APSS in CHF, (2) severity of relapsing septic cholangitis or choledochal cyst infection, (3) intrahepatic infectious cholelithiasis, and (4) evidence of hepatic insufficiency at initial diagnosis. • Fibrosis likely progressive with aging.

DYSAUTONOMIA (KEY-GASKELL SYNDROME)

BASICS

OVERVIEW

- Failure of autonomic function in multiple organs with minimal motor or sensory involvement.
- Young adult, rural, Midwestern dogs at greatest risk.
- Treatment is symptomatic and the prognosis guarded.

SIGNALMENT

- Dog and less commonly cat.
- No breed or sex predilection.
- Median age is 18 months but any age animal may be affected.

SIGNS

- Acute to subacute onset (5–14 days).
- Various combinations of signs may be present but both sympathetic and parasympathetic signs in various organs are necessary to be confident of a diagnosis.
- Sensory or motor deficits are minimal.

Presenting Complaints

- Most commonly GI signs of vomiting or regurgitation, diarrhea, or occasionally constipation.
- Straining to urinate and dribbling urine.
- Photophobia and third-eyelid elevation.
- Dyspnea, coughing, and purulent nasal discharge.
- Depression, anorexia, and weight loss.

Examination Findings

- Variable combinations of autonomic dysfunction.
- Loss of anal sphincter tone.
- Dry nose and mucous membranes; lack of tear production.
- Distended, easily expressed bladder.
- Pupils midrange to maximally dilated with no pupillary light reflex but intact vision.
- Third-eyelid elevation, ptosis, and enophthalmos.
- Lack of gut sounds and occasional abdominal pain.
- Heart rate and blood pressure typically in the low end of normal range but do not rise in response to stress.
- Secondary aspiration pneumonia or rhinitis.
- Cachexia.
- Occasionally mild proprioceptive deficits or weakness.

CAUSES & RISK FACTORS

- Cause unknown.
- Highest incidence in Missouri, Oklahoma, and Kansas as well as Wyoming and northern Colorado, but occasional cases reported throughout United States.
- Free-roaming, rural dogs at greatest risk.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Anticholinergic toxicity.
- Other differential diagnoses depend upon the specific clinical

signs; e.g., urinary tract infection for dysuria, corneal ulcer for photophobia, dehydration for dry mucous membranes.

CBC/BIOCHEMISTRY/URINALYSIS

Unremarkable

IMAGING

- Megaeosophagus ± aspiration pneumonia
- Distended bowel loops with no peristalsis
- Distended urinary bladder
- Echocardiography may show systolic dysfunction as a reduced fractional shortening.

DIAGNOSTIC PROCEDURES

- If pupils affected, 0.05% pilocarpine drops in one eye will produce miosis within 60 minutes. Rules out anticholinergic toxicity.
- Atropine (0.03 mg/kg IV) may not produce a rise in heart rate; suggests loss of vagal tone.
- Intradermal histamine may produce no response or a wheal but no flare; demonstrates loss of sympathetic innervation of arterioles.

TREATMENT

- Symptomatic.
- IV fluids to prevent dehydration.
- High calorie food. Feeding tube to ensure adequate nutrition if megaesophagus is present. If GI motility is absent, parenteral nutrition may be necessary.
- Lubricating eye drops if tear production is insufficient.
- Humidification of the air may help with dry mucous membranes.
- Manual bladder expression.

MEDICATIONS

DRUG(S)

- Antibiotics as needed to treat secondary infections.
- Prokinetic drug such as metoclopramide if GI motility affected.
- Bethanechol to stimulate lacrimation and urination (start at 0.05 mg/kg q8–12h and adjust dose based on response); manual expression of bladder more reliable.
- Ocular pilocarpine to relieve photophobia.
- Pimobendan if poor cardiac contractility.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Animals with dysautonomia develop denervation supersensitivity to direct acting cholinergic or adrenergic drugs.
- Great care must be exercised in using such drugs, particularly adrenergic drugs that could

precipitate fatal tachyarrhythmias. It is best to start at < 10% of the low end of the dose range when using direct-acting drugs and escalate the dose as needed to produce the desired effect.

FOLLOW-UP

- Prognosis is guarded. Most animals die of aspiration pneumonia or euthanasia due to poor quality of life.
- Animals who survive often have some degree of permanent autonomic dysfunction that may require constant care.

MISCELLANEOUS

- Necropsy identification of neuronal loss in ganglia confirms the diagnosis.
- Clinical diagnosis based on autonomic failure in multiple organs without underlying cause or significant motor or sensory involvement and appropriate response to pharmacologic testing.

ABBREVIATION

- GI = gastrointestinal

DYSCHEZIA AND HEMATOCHEZIA

BASICS

DEFINITION

- Dyschezia—painful or difficult defecation
- Hematochezia—bright red blood in or on the feces

PATHOPHYSIOLOGY

Results from inflammatory, infectious, or neoplastic conditions affecting the colon, rectum, or anus.

SYSTEMS AFFECTED

Gastrointestinal

SIGNALMENT

- Dog and cat
- No breed or sex predilection

SIGNS

Historical Findings

- Vocalizing and whimpering during defecation.
- Tenesmus.
- Decreased frequency of defecation in association with severe dyschezia (animal resists defecating due to pain) resulting in constipation or obstipation.
- Mucoid, bloody diarrhea with a marked increase in frequency and scant fecal volume in patients with colitis.
- Scooting behavior in association with anal gland infection or impaction.

Physical Examination Findings

- Rectal examination may reveal hard feces (constipation or obstipation), diarrhea (colorectal disease), colorectal masses, anorectal thickening, rectal or colonic strictures, anal sac enlargement/pain, prostatomegaly, or perineal hernias.
- Fistulous tracts around anus occur with perianal fistulae.
- Anal occlusion with matted hair and feces occurs with pseudocoprostasis.

CAUSES

Rectal/Anal Disease

- Stricture or spasm
- Anal sacculitis or abscess
- Perianal fistulae
- Rectal or anal foreign body
- Pseudocoprostasis
- Rectal prolapse
- Trauma—bite wounds, etc.
- Neoplasia—adenocarcinoma, lymphoma, and anal sac tumors
- Rectal polyps
- Mucocutaneous lupus erythematosus

Colonic Disease

- Neoplasia—adenocarcinoma, lymphoma, other tumors
- Idiopathic megacolon—cats
- Inflammation—IBD, infectious parasitic agents, colitis secondary to dietary-responsive enteropathy (see Colitis and Proctitis)

- Constipation (see Constipation and Obstipation)

Extraintestinal Disease

- Fractured pelvis or pelvic limb
- Prostatic disease
- Perineal hernia
- Intrapelvic neoplasia

RISK FACTORS

- Ingestion of hair, bone, foreign material may contribute to constipation and subsequent dyschezia.
- Environmental factors such as a dirty litter pan, infrequent outside walks may contribute to constipation and subsequent dyschezia.

DIAGNOSIS

It is pivotal to recognize that hematochezia in animals can be seen with both diffuse colitis as well as with focal or discrete colorectal neoplasms. The fundamental differences in the clinical presentation between the two disorders can usually be recognized during the history and following a thorough physical examination, including a rectal examination. Dogs with colorectal neoplasms do not have diarrhea, and the most important and frequent clinical sign is hematochezia in the absence of an increase in defecation frequency or change in stool consistency. Pencil-thin or ribbon-like stools can be seen when the colorectal neoplasm is advanced, causing a change in the shape of the stool. *A rectal examination must be performed on every patient with a history of hematochezia or dyschezia.*

DIFFERENTIAL DIAGNOSIS

- Dysuria, stranguria, or hematuria—abnormal findings on urinalysis, such as pyuria, crystalluria, bacteriuria. The history and physical examination should differentiate whether the animal is having difficulty urinating or defecating.
- Dystocia—differentiate with history and imaging.

CBC/BIOCHEMISTRY/URINALYSIS

- Usually unremarkable, unless there is a history of chronic blood loss with secondary iron deficiency causing a microcytic and hypochromic non-regenerative anemia.
- Mild neutrophilia (with or without a left shift) with infection or inflammation.

OTHER LABORATORY TESTS

Centrifugation fecal flotation to help rule out parasitic causes of colitis

IMAGING

- Pelvic radiographs may reveal intrapelvic disease, foreign body, or fracture.
- Ultrasonography may demonstrate prostatic disease or caudal abdominal masses; however, a portion of the descending colon cannot be visualized because of the pelvis.

DIAGNOSTIC PROCEDURES

Colonoscopy/proctoscopy to evaluate for inflammatory or neoplastic disease

TREATMENT

- Depends on the underlying cause.
- Colonic strictures secondary to neoplasms can be managed via surgical excision or balloon catheter dilation.
- Consider laxatives (lactulose) to ease defecation and discomfort in animals with colorectal strictures or masses.
- Colorectal masses are best removed surgically or via endoscopy (snare and cauterization for polyps).

MEDICATIONS

DRUG(S) OF CHOICE

- Antibiotics—if bacterial infection (e.g., anal sac abscess); amoxicillin/clavulanic acid 15 mg/kg PO q12h for 7–10 days.
- Anti-inflammatory drugs—sulfasalazine or prednisone (dogs) and prednisolone (cats) if colitis is present (see Colitis chapters).
- Cyclosporine (5 mg/kg q12h for 3–4 months with gradual taper thereafter) for dogs with perianal fistulae.
- Laxatives—lactulose, 1 mL/4.5 kg PO q8–12h to effect; docusate sodium or docusate calcium—dogs, 50–100 mg PO q12–24h; cats, 50 mg PO q12–24h.
- Cisapride—prokinetic indicated for cats with moderate to severe megacolon (and no evidence of obstruction) in conjunction with lactulose and dietary therapy at a dose of 5 mg per cat q12h.

CONTRAINdications

Avoid agents that cause increased fecal bulk (insoluble fiber), unless specifically indicated (colitis).

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

N/A

FOLLOW-UP

- The need for follow-up depends on the underlying cause. Dogs and cats that are undergoing balloon dilation of colorectal strictures usually require multiple procedures to manage the stricture properly. Animals should always be rechecked at suture removal

DYSCHEZIA AND HEMATOchezIA

(CONTINUED)

or 10–14 days following surgical resection of colorectal masses.

- Animals with hematochezia secondary to colitis should have a marked improvement or resolution of their clinical signs within 5–7 days following implementation of elimination dietary therapy.

PATIENT MONITORING

D Daily monitoring by the owner with periodic phone calls to the clinician every 2–3 weeks during the beginning of treatment.

POSSIBLE COMPLICATIONS

- May see fecal incontinence following surgical resection of anal sacs or colorectal tumors if anal sphincter is compromised.
- Secondary megacolon may occur if obstipation is severe and long-term.

**MISCELLANEOUS ASSOCIATED CONDITIONS**

Consulting Editor Stanley L. Marks

BASICS

DEFINITION

- Dysphagia refers to abnormal swallowing and is far more commonly seen in dogs compared to cats.
- Dysphagia is divided into 3 main categories: oropharyngeal, esophageal, and gastroesophageal causes.
- Oropharyngeal causes of dysphagia can be further subcategorized into oral, pharyngeal, or cricopharyngeal causes.
- Any disorder causing difficulty with prehension or mastication can cause dysphagia.
- Odynophagia refers to painful swallowing and is most commonly seen in association with esophageal foreign bodies or to severe esophagitis.
- Esophageal dysphagia is discussed in the chapters on MegAESOPHAGUS and Regurgitation.

PATHOPHYSIOLOGY

- The *oral preparatory phase* is voluntary and begins as food or liquid enters the mouth. Mastication and lubrication of food are the hallmarks of this phase. Abnormalities of the oral preparatory phase usually are associated with dental disease, xerostomia, weakness of the lips (cranial nerves V and VII), tongue (cranial nerve XII), and cheeks (cranial nerves V and VII).
- The *oral phase* of swallowing consists of the muscular events responsible for movement of the bolus from the tongue to the pharynx and is facilitated by the tongue, jaw, and hyoid muscle movements.
- The *pharyngeal phase* begins as the bolus reaches the tonsils and is characterized by elevation of the soft palate to prevent the bolus from entering the nasopharynx, elevation and forward movement of the larynx and hyoid, retroflexion of the epiglottis and closure of the vocal folds to close the entrance into the larynx, contraction of the muscles of the pharynx, and relaxation of the cricopharyngeus muscle that makes up much of the proximal esophageal sphincter (PES) to allow passage of the bolus into the esophagus. Respiration is briefly halted (apneic moment) during the pharyngeal phase.
- Abnormalities of the pharyngeal phase of swallowing are associated with pharyngeal weakness secondary to neuropathies or myopathies, pharyngeal tumors or foreign bodies, cricopharyngeus muscle disorders.
- The *esophageal phase* is involuntary and begins with the relaxation of the PES and movement of the bolus into the esophagus.

SYSTEMS AFFECTED

- Gastrointestinal
- Nervous

- Neuromuscular
- Respiratory

GENETICS

Breeds that have a hereditary predisposition or a high incidence of dysphagia include the golden retriever (pharyngeal weakness), cocker and springer spaniels (cricopharyngeal dysphagia), Bouvier des Flandres and Cavalier King Charles spaniel (muscular dystrophy), and boxer (inflammatory myopathy). In addition, large and giant-breed dogs are predisposed to acquired megaesophagus.

INCIDENCE/PREVALENCE

Variable depending on underlying etiology. Megaesophagus is one of the most common causes of dysphagia in dogs.

GEOGRAPHIC DISTRIBUTION

None

SIGNALMENT

- Dog and cat.
- Congenital disorders that cause dysphagia (e.g., cricopharyngeal achalasia, cleft palate, hiatal hernia) are usually diagnosed in animals < 1 year old.
- Acquired esophageal dysmotility and pharyngeal weakness is more common in older patients.

SIGNS

Historical Findings

- Drooling (due to pain or inability to swallow saliva), gagging, ravenous appetite, repeated or exaggerated attempts at swallowing, swallowing with the head in an abnormal position, nasal discharge (due to nasal reflux of food and liquids into the nasopharynx), coughing (due to aspiration), regurgitation, painful swallowing, and occasionally anorexia and weight loss are all possible. If the tongue is not functioning normally, problems with prehension and mastication may be seen.
- Ascertain onset and progression. Foreign bodies cause acute dysphagia; pharyngeal dysphagia may be chronic and insidious in onset.

Physical Examination Findings

- Physical examination must include careful examination of the oropharynx using sedation or anesthesia if necessary to help rule out morphologic abnormalities such as dental disease, foreign bodies, cleft palate, glossal abnormalities, and oropharyngeal tumors.
- Evaluation of cranial nerves should be performed, including assessment of tongue and jaw tone, and assessment of laryngeal function.
- A complete physical and neurologic examination may identify clinical signs supporting a generalized neuromuscular disorder, including muscle atrophy, stiffness, or decreased or absent spinal reflexes.
- Evaluate the gag reflex by placing a finger in the pharynx; however, the presence or absence

of a gag reflex does not correlate with the efficacy of the pharyngeal swallow nor the adequacy of deglutitive airway protection.

- The importance of the clinician's carefully observing the dysphagic animal while it is eating (kibble and canned food) and drinking in the hospital is pivotal, and such observation helps to localize the problem to the oral cavity, pharynx, or esophagus.

ORAL DYSPHAGIA

- Modified eating behavior (e.g., eating with head tilted to one side or having difficulty prehending the bolus or opening the mouth).
- Tongue paralysis or dystrophy, dental disease, masticatory muscle myositis, temporal muscle atrophy, or pain, and food packed in the buccal folds suggest oral dysphagia.

PHARYNGEAL DYSPHAGIA

- Prehension of food is normal.
- Repeated attempts at swallowing with food falling out of the mouth, and excessive gagging suggest pharyngeal dysphagia.
- Saliva-coated food retained in the buccal folds, a diminished gag reflex, and nasal discharge may also exist.

CRICOPHARYNGEAL DYSPHAGIA

- Patients make repeated, nonproductive efforts to swallow, gag, and cough, then forcibly regurgitate immediately after swallowing.
- Gag reflex and prehension are normal.
- Nasal reflux is commonly observed when food hits the closed PES.

ESOPHAGEAL DYSPHAGIA

- Most common causes include megaesophagus, esophagitis, esophageal stricture, esophageal foreign bodies, and esophageal dysmotility.
- Diagnosis made with survey radiographs of the thorax and neck followed by videofluoroscopy.

GASTROESOPHAGEAL DYSPHAGIA

Most common cause is a sliding hiatal hernia that is often associated with gastroesophageal reflux and subsequent esophagitis.

CAUSES

- Anatomic or mechanical lesions include pharyngeal inflammation (e.g., abscess, inflammatory polyps, and oral eosinophilic granuloma), neoplasia, pharyngeal and retropharyngeal foreign body, sialocele, temporomandibular joint disorders (e.g., luxation, fracture, and craniomandibular osteopathy), mandibular fracture, cleft or congenitally short palate, cricopharyngeal achalasia, lingual frenulum disorder, and pharyngeal trauma.
- Pain as a result of dental disease (e.g., tooth fractures and abscess), mandibular trauma, stomatitis, glossitis, and pharyngeal inflammation may disrupt normal prehension, bolus formation, and swallowing. Stomatitis, glossitis, and pharyngitis may be

DYSPHAGIA

(CONTINUED)

D

- secondary to feline viral rhinotracheitis, FeLV/FIV, pemphigus, SLE, uremia, and ingestion of caustic agents or foreign bodies.
- Neuromuscular disorders that impair prehension and bolus formation include cranial nerve deficits (e.g., idiopathic trigeminal neuropathy CN V, lingual paralysis CN XII) and masticatory muscle myositis.
- Pharyngeal weakness, paresis, or paralysis can be caused by infectious polymyositis (e.g., toxoplasmosis and neosporosis), immune-mediated polymyositis, muscular dystrophy, polyneuropathies, and myoneuron junction disorders (e.g., myasthenia gravis, tick bite paralysis, and botulism).
- Other CNS disorders, especially those involving the brainstem.
- Rabies can cause dysphagia by affecting both the brainstem and peripheral nerves.

RISK FACTORS

Many of the causative neuromuscular conditions have breed predispositions.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Differentiate vomiting from regurgitation.
- Vomiting is associated with abdominal contractions; dysphagia is not.

CBC/BIOCHEMISTRY/URINALYSIS

- Inflammatory conditions often cause a leukocytosis, sometimes with a left shift.
- High serum creatine kinase activity is usually suggestive of a myopathy.
- May find evidence of renal disease (e.g., azotemia and low urine concentration) in patients with oral and lingual ulcers secondary to uremia.

OTHER LABORATORY TESTS

- Type 2M muscle antibody serology (masticatory muscle myositis).
- Acetylcholinesterase receptor antibody serology (acquired myasthenia gravis).
- Antinuclear antibody serology (immune-mediated diseases).
- T_4 , free T_4 , TSH, anti-thyroglobulin antibodies to rule out hypothyroidism.
- Resting cortisol and/or ACTH stimulation test to rule out Addison's disease.

IMAGING

- Obtain survey radiographs of the thorax and neck in all dysphagic animals for which an oral cause of dysphagia has been ruled out.
- Ultrasonography of the pharynx may be useful in patients with mass lesions and for obtaining ultrasound-guided biopsy specimens.
- Fluoroscopy with barium is useful in evaluating pharyngeal and esophageal motility as well as proper coordination of the upper and lower esophageal sphincters.

- CT and/or MRI for a suspected intracranial mass.
- Esophagram (liquid barium administered orally followed by immediate survey radiographs of the thorax) is helpful for diagnosing radiolucent esophageal foreign bodies and esophageal strictures, but is insensitive for diagnosing eosophageal functional disorders.

OTHER DIAGNOSTIC PROCEDURES

- Endoscopy of the nasopharynx—retroflexion of the endoscope over the soft palate to look for foreign bodies and evaluate the esophagus and lower esophageal sphincter.
- Electromyography of skeletal musculature to confirm the presence of a myopathy.
- Repetitive nerve stimulation and edrophonium chloride (0.1–0.2 mg/kg IV) test for suspected myasthenia gravis.
- Cerebrospinal fluid analysis in patients with a CNS disorder.

PATHOLOGIC FINDINGS

Variable depending on underlying etiology. Myopathies can be inflammatory or dystrophic.

TREATMENT

APPROPRIATE HEALTH CARE

- Determine the underlying cause to optimize therapy and outcome.
- Most patients can be managed on an outpatient basis unless there are other complicating factors such as aspiration pneumonia, dehydration or weakness.

NURSING CARE

- Supportive care may be necessary if the patient is dehydrated (IV fluids).
- Other supportive modalities may be necessary in the case of aspiration pneumonia (oxygen, coupage, etc.).
- For patients with generalized weakness due to myopathies, good nursing care is required, such as rotating position, good padding, and physical therapy.

ACTIVITY

Alterations in activity should be based on the underlying etiology.

DIET

- Nutritional support is important for all dysphagic patients.
- Elevating the head and neck during feeding and for 10–15 minutes after feeding may help patients with esophageal disease. Consider altering the consistency of the diet. Dogs with cricopharyngeal dysphagia are able to handle kibble better than canned food or water.
- If nutritional requirements cannot be met orally, a gastrostomy tube may be necessary.

CLIENT EDUCATION

- Variable dependent on the underlying cause.
- Educate the client that not all diseases can be cured, but managed.
- Changes in feeding (see above section) may be long-term.
- Clients should be taught to monitor for signs of possible aspiration pneumonia (mucopurulent nasal discharge, respiratory rate, coughing, dyspnea, tachypnea).

SURGICAL CONSIDERATIONS

- Cricopharyngeal myectomy may benefit patients with cricopharyngeal dysphagia; a correct diagnosis is essential using videofluoroscopy before surgery.
- Hiatal hernia surgery generally involves a left-sided gastropexy with esophageal hiatal plication and esophagopexy.

MEDICATIONS

DRUG(S) OF CHOICE

Dysphagia is not immediately life-threatening; direct drug therapy at the underlying cause.

PRECAUTIONS

- Use barium sulfate with caution in patients with evidence of aspiration.
- Use corticosteroids with caution or not at all in patients with evidence of, or at risk for, aspiration.

FOLLOW-UP

PATIENT MONITORING

- Daily for signs of aspiration pneumonia (e.g., lethargy, fever, mucopurulent nasal discharge, coughing, and dyspnea).
- Body condition and hydration status daily; if oral nutrition does not meet requirements, use gastrostomy tube feeding.

POSSIBLE COMPLICATIONS

Aspiration pneumonia and malnutrition.

EXPECTED COURSE AND PROGNOSIS

Variable dependent on the cause

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Aspiration pneumonia
- Megaesophagus
- Malnutrition

AGE-RELATED FACTORS

- Puppies are more likely to have congenital abnormalities such as cricopharyngeal achalasia, congenital megaesophagus, vascular ring anomalies, and cleft palates.

(CONTINUED)

- Puppies with vascular ring anomalies will typically present with signs of regurgitation shortly after being weaned onto solid food at 6–8 weeks of age.
- Puppies with cleft palates usually have milk or food refluxing from the nasal passage during mastication and swallowing.
- Puppies with cricopharyngeal achalasia typically present with repeated bouts of swallowing, gagging, and retching during swallowing with nasal reflux of water or food.
- Puppies are more likely to ingest foreign objects that can lodge in the esophagus and cause esophagitis and stricture formation.
- Older dogs, in particular Labrador retrievers, are more likely to have esophageal dysmotility secondary to a polyneuropathy.

ZOONOTIC POTENTIAL

- Consider rabies in any patient with oropharyngeal dysphagia, especially if the

animal's rabies vaccination status is unknown or questionable or it has been exposed to a potentially rabid animal.

- If a dysphagic animal dies of rapidly progressive neurologic disease, submit the head to a qualified laboratory designated by the local or state health department for rabies examination.

D

DYSPNEA AND RESPIRATORY DISTRESS

BASICS

DEFINITION

Dyspnea—a subjective term that in human medicine means “an uncomfortable sensation in breathing” or a sensation of air hunger; in veterinary medicine, it is used to indicate difficulty breathing or respiratory distress.

PATHOPHYSIOLOGY

Dyspnea and respiratory distress are believed to occur when the central nervous system notes a difference between the afferent feedback from a given efferent motor drive signal (ventilation demanded) and what the brain had anticipated would be the appropriate afferent response (ventilation achieved).

SYSTEMS AFFECTED

Respiratory

SIGNALMENT

Dogs and cats; age, breed, and sex predisposition vary with inciting cause.

SIGNS

Historical Findings

- Acute or chronic onset.
- Often associated with coughing, tachypnea, exercise intolerance.

Physical Examination Findings

- General signs of respiratory distress—increased abdominal effort, nasal flaring, open-mouth breathing, cyanosis, orthopnea (neck extension, elbow abduction); other signs depend on underlying cause.
- Nasal disease—stertor, nasal discharge, lack of airflow through nostrils; dyspnea improves with open-mouth breathing.
- Upper airway disease—stridor, cough, hyperthermia, respiratory effort and noise on inspiration.
- Tracheal collapse—honking cough, tracheal sensitivity.
- Lower airway disease—cough, expiratory wheezes on auscultation,
- Pulmonary parenchymal disease—may have crackles, harsh or moist lung sounds on auscultation; may be normal.
- Pneumonia—fever, may have tracheal sensitivity.
- Cardiogenic pulmonary edema—heart murmur, arrhythmia, hypothermia, pale mucous membranes, prolonged capillary refill time.
- Pleural space disease—diminished breath sounds: ventrally—fluid; dorsally—air; unilaterally—space-occupying lesions or pyothorax/chylothorax. Often paradoxical respiratory pattern (inward movement of the abdominal wall during inspiration).
- Thoracic wall disease—can have paradoxical respiratory pattern, visible or palpable trauma.
- PTE—may have clinical signs of the underlying disease predisposing to thrombosis, e.g., hyperadrenocorticism, IMHA, neoplasia.
- Other signs will pertain to the underlying disease, e.g., shock, trauma.

CAUSES & RISK FACTORS

Upper Airway Disease

- Nasal obstruction—stenotic nares, nasopharyngeal polyp or stenosis, infection, inflammation, neoplasia, trauma, foreign body, coagulopathy.
- Pharynx—elongated soft palate, foreign body, neoplasia, granuloma.
- Larynx—laryngeal paralysis, everted laryngeal saccules, edema, collapse, foreign body, neoplasia, trauma, webbing.
- Trachea—collapse, stenosis, trauma, foreign body, neoplasia, parasites, extraluminal compression (lymphadenopathy, enlarged left atrium, heart-base tumors).

Lower Airway Disease

Inflammatory, infectious (*Mycoplasma*), parasitic, neoplastic (bronchogenic carcinoma).

Pulmonary Parenchymal Disease

- Edema—cardiogenic or non-cardiogenic.
- Pneumonia—infectious; parasitic; aspiration; eosinophilic; interstitial.
- Neoplasia (primary or metastatic).
- Inflammatory—ARDS; uremic pneumonitis; smoke inhalation.
- Hemorrhage—trauma; coagulopathy.
- PTE—IMHA; PLN or PLE; heartworm disease; hyperadrenocorticism; neoplasia.
- Others—lung lobe torsion, atelectasis.

Pleural Space Disease

- Pneumothorax—traumatic; iatrogenic; secondary to pulmonary parenchymal disease; ruptured bulla; migrating foreign body; primary spontaneous (no underlying cause).
- Pleural effusion—transudates, exudates; hemothorax; chylothorax.
- Soft tissue—neoplasia; diaphragmatic hernia.
- Fibrosing pleuritis.

Thoracic Wall Disease

- Open pneumothorax—trauma; flail segment—trauma; neoplasia; paralysis due to cervical spinal disease, botulism, polyradiculoneuritis, tick bite paralysis, myasthenia gravis, elapid snake envenomation.

Diaphragmatic Disease

- Trauma—rupture; hernia
- Phrenic nerve disease
- Neoplasia
- Fibrosis

Abdominal Distention

- Organomegaly—hyperplasia; neoplasia, pregnancy; obesity; ascites; gastric dilatation, torsion

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Inspiratory dyspnea—suggests extrathoracic upper airway disease.
- Expiratory dyspnea—suggests intrathoracic airway disease.
- Dyspnea on inspiration and expiration can occur with fixed upper airway obstructions and severe intrathoracic disease.
- Congestive

heart failure—murmur, arrhythmia, tachycardia, poor pulse quality, jugular pulses, hypothermia, crackles on auscultation, fluid dripping from nose.

CBC/BIOCHEMISTRY/URINALYSIS

- Anemia—can cause non-respiratory dyspnea.
- Polycythemia—chronic hypoxia.
- Inflammatory leukogram—pneumonia, pyothorax.
- Eosinophilia—hypersensitivity or parasitic airway disease.
- Thrombocytosis—hyperadrenocorticism predisposes to PTE.
- Sodium:potassium ratio < 27—can be seen with pleural or abdominal effusions.
- Azotemia—if severe may lead to uremic pneumonitis.
- Proteinuria—can predispose to PTE.
- Multiple organ dysfunction—ARDS.
- Hypoproteinemia—may suggest protein-losing disease that can predispose to PTE or hydrothorax.

OTHER LABORATORY TESTS

- Pleural fluid analysis.
- Fecal examination for parasites
- Serum antigen or antibody titers—heartworm, toxoplasmosis, distemper, FeLV, FIV.
- Increased urine protein:creatinine ratio with PLN could indicate loss of antithrombin and hypercoagulability resulting in PTE.
- PaO_2 —partial pressure of oxygen dissolved in arterial blood; normoxemia: PaO_2 80–120 mmHg (room air, sea level); hypoxemia: PaO_2 < 80 mmHg; $F_1\text{O}_2$ —fraction of inspired oxygen ranges from 0.21 (room air) to 1.0; $\text{PaO}_2/F_1\text{O}_2$ ratio—measure of lung efficiency; $\text{PaO}_2/F_1\text{O}_2 \geq 500$ —normal lung efficiency; 300–500—mild insufficiency; 200–300—moderate insufficiency; < 200—severe insufficiency. Reduction in lung efficiency is most commonly due to pulmonary parenchymal disease.
- PaCO_2 or PvCO_2 —partial pressure of CO_2 dissolved in arterial or venous blood; measure of ventilation; normal 30 mmHg < PCO_2 < 40 mmHg. Hypercapnia = hypoventilation = decreased alveolar minute ventilation (MV).
- Coagulation testing—if suspect hemothorax and/or pulmonary hemorrhage.
- Plasma NT-proANP, BNP, ET-1, and cTNI concentrations may aid in differentiation of cardiac and non-cardiac causes of dyspnea.

IMAGING

- Cervical and thoracic radiography: upper airway disease—soft palate elongation, large airway narrowing, lymphadenopathy, intraluminal abnormalities. Lower airway disease—bronchial thickening, middle lung lobe consolidation (cats), atelectasis, hyperinflation and diaphragmatic flattening (primarily cats). Pneumonia—alveolar infiltrates; lobar sign—lung lobe torsion, foreign body pneumonia, neoplasia; cardiogenic pulmonary edema—enlarged cardiac silhouette, pulmonary venous distention, enlarged left atrium with perihilar pulmonary infiltrates in dogs; infiltrates can

(CONTINUED)

DYSPNEA AND RESPIRATORY DISTRESS

be of any distribution in cats. Non-cardiogenic pulmonary edema—caudodorsal distribution. ARDS—diffuse, symmetrical alveolar infiltrates. Pulmonary vascular abnormalities—PTE, heartworm disease. Pleural space disease—pneumothorax, pleural effusion, mass lesions, diaphragmatic hernias. Thoracic wall disease—rib fractures, neoplasia. • Thoracic ultrasonography: evaluation of distribution of pleural effusion, pneumothorax (absence of “glide sign”), and parenchymal disease (presence of “comet tail” artifact). Pulmonary mass identification—guide fine-needle aspiration; mediastinal evaluation. • Echocardiography: evaluate cardiac function if cardiogenic pulmonary edema or pleural effusion suspected; elevated pulmonary artery pressure and right ventricular overload can support diagnosis of PTE; visualize heart-based masses.

- Abdominal radiography or ultrasound: evaluation of abdominal distention.
- Fluoroscopy: evaluate tracheal and bronchial collapse; evaluate diaphragmatic function.
- Computed tomography: airway, pulmonary parenchymal, and pleural space disease can be evaluated; can detect lesions not clearly defined on radiographs.
- Pulmonary vascular angiography: gold standard for diagnosis of PTE.
- Ventilation perfusion scintigraphy: abnormal perfusion scan is considered supportive of PTE.

DIAGNOSTIC PROCEDURES

- Pulse oximetry—SpO₂ of hemoglobin saturated with oxygen. The relationship between PaO₂ and SpO₂ is defined by the oxygen hemoglobin dissociation curve; PaO₂ of 60 mmHg = SpO₂ of 90%; PaO₂ of 80 mmHg = SpO₂ of 95%; PaO₂ of > 100 mmHg = SpO₂ of 100%. Below 95%, small changes in SpO₂ signify large changes in PaO₂. SpO₂ measurements in animals on high inspired oxygen lack sensitivity.
- Thoracocentesis—fluid analysis and culture.
- Laryngoscopy/nasopharyngoscopy/tracheoscopy—visualize foreign bodies and masses.
- Bronchoscopy—evaluate upper and lower airways; perform bronchoalveolar lavage for cytology and culture. Requires anesthesia, perform only when stabilized.

**TREATMENT****APPROPRIATE HEALTH CARE**

- Inpatient care until the cause is identified and treated or determined not to be life-threatening; therapy dependent on underlying cause.
- ALWAYS administer oxygen and keep patient in sternal recumbency until ability to oxygenate is determined.
- Lower airway disease—bronchodilators; oxygen therapy until stable;

systemic corticosteroids may be required to stabilize cats with acute bronchoconstriction.

- Pulmonary parenchymal disease—oxygen therapy, antibiotics if pneumonia; treat coagulation disorders; cardiogenic edema requires furosemide ± vasodilators.
- Non-cardiogenic edema requires oxygen therapy, may require positive-pressure ventilation.
- Pleural space disease—thoracocentesis for air and fluid. Place a chest tube if repeated thoracocentesis is necessary to keep patient stable.
- Thoracic wall disease—surgery as indicated, particularly if open chest wound is present; flail chest may require surgery if medical management fails or there is a severe displacement of fractures.
- Thoracic wall paralysis/muscle fatigue—positive-pressure ventilation if severely hypercapnic.
- Abdominal distention—drain ascites as needed; relieve gastric distention.

NURSING CARE

- Oxygen therapy via cage, nasal cannula, E-collar covered in plastic wrap, mask, or flow-by. Humidify oxygen source if giving oxygen therapy for more than a few hours.
- Maintain in sternal recumbency and turn hips every 3–4 hours if patient cannot tolerate lateral recumbency.
- Monitor temperature regularly, as excess work of breathing results in hyperthermia, which augments respiratory distress.

DIET

Weight-reducing diet if obesity is a contributing cause.

SURGICAL CONSIDERATIONS

- Anesthesia must be carefully tailored to the patient. Securing an airway is essential and rapid intravenous induction is important. The ability to positive-pressure ventilate patients is often required.
- Animals with upper airway obstruction are fragile and can rapidly decompensate. Have multiple-sized endotracheal tubes available.
- Dyspnea associated with a laryngeal mass can respond to debulking surgery but edema and hemorrhage can lead to worsened obstruction. Warn owners of increased likelihood of aspiration pneumonia complications in animals with laryngeal disease.
- Avoid positive-pressure ventilation in patients with a closed pneumothorax. Must monitor oxygenation status of anesthetized patients with pulse oximetry and when possible arterial blood gases.

**MEDICATIONS****DRUG(S)**

Varies with underlying cause (see “Appropriate Health Care”).

**FOLLOW-UP****PATIENT MONITORING**

- Patients receiving oxygen therapy can be monitored by assessing the degree of respiratory effort. As the animal stabilizes, perform a room air trial and reevaluate the level of respiratory difficulty. Arterial and venous blood gases can be a useful assessment.
- Pulse oximetry is an effective and noninvasive tool for monitoring patients on room air.
- Repeat radiographs are often indicated in assessing pulmonary parenchymal disease and pleural space disease.

DYSTOCIA

BASICS

DEFINITION

Difficult birth

PATHOPHYSIOLOGY

- Dystocia may occur as a result of maternal or fetal factors and may occur during any stage of labor.
- Abnormal presentation, posture, and position; may be causal. Normal: anterior or posterior longitudinal, dorsosacral, and head and feet extended.
- Three stages of labor:

Stage 1

- Early onset of uterine contractions and relaxation of the cervix; ends with rupture of first chorioallantoic sac—averages 6–12 h (up to 36 h in nervous, primiparous bitch).
- Bitch—may be restless, nervous, shiver, pant, pace, and nest.
- Queen—tend to vocalize initially; purr and socialize as Stage 1 progresses.

Stage 2

- Delivery of the fetuses.
- Bitch—obvious abdominal contractions; from beginning of stage 2 to delivery of first offspring usually <4 h; time between delivery of subsequent fetus usually 20–60 min (may be as long as 2–3 h).
- Queen—average length of parturition is 16 h, with a range of 4–42 h (up to 3 d in some cases may be normal); important to consider this variability when intervening.
- Number of fetuses present may significantly affect the length of stages 2 and 3.

Stage 3

- Delivery of the fetal membranes.
- May alternate between stage 2 and 3 with multiple fetuses.

INCIDENCE/PREVALENCE

- Dog: incidence unknown; difficult to estimate due to breed variability and breeder intervention.
- Cat: reported average ranges from 3.3–5.8%; mixed-breed cats 0.4%; increased with pedigree cats, to a high of 18.2% in the Devon rex.

SIGNALMENT

Breed Predilections

Dogs

- Higher incidence with miniature and small breeds due to small litter size with concurrent large fetal size; may occur in large breeds with large or singleton litters.
- Brachycephalic—broad head and narrow pelvis—Bulldog, Boston terrier, pug.
- Large fetal head: maternal pelvis ratio—Sealyham terrier, Scottish terrier.
- Uterine inertia—Scottish terrier, dachshund, border terrier, Aberdeen terrier, Labrador retriever (see Uterine Inertia).
- Miscellaneous breeds with overall increased incidence of dystocia—Chihuahua, dachshund, Pekingese, Yorkshire terrier, miniature poodle, Pomeranian.

Cats

- Brachycephalic—Persian, Himalayan
- Dolichocephalic—Devon rex

SIGNS

Historical Findings

- Indicators of dystocia include:
 - More than 30 min of persistent, strong, abdominal contractions without fetal delivery.
 - More than 4 h from the onset of stage 2 to delivery of first fetus (bitches).
 - More than 2 h between delivery of fetuses (bitch).
 - Failure to commence labor within 24 h of the drop in rectal temperature below 37.2°C (99°F) or within 36 h of serum progesterone < 2 ng/mL (bitch).
 - Female cries, displays signs of pain, and constantly licks the vulvar area when contracting.
 - Prolonged gestation—more than 72 d from day of first mating (bitch); more than 59 d from the first day of cytologic diestrus (bitch); more than 66 d from LH peak (bitch); more than 68 d from the day of mating (queen).

Physical Examination Findings

- Presence of greenish-black discharge (uteroverdin) preceding the birth of first fetus by more than 2 h.
- Presence of bloody discharge prior to delivery of first fetus.
- Diminished or absent Ferguson's reflex (stimulation or pressure to dorsal vaginal wall to elicit abdominal straining: "feathering") indicates uterine inertia.

CAUSES

Fetal

- Oversize; fetal monsters, fetal anasarca; fetal hydrocephalus; prolonged gestation due to inability of a singleton fetus to initiate labor.
- Abnormal presentation, position, or posture of fetus in the birth canal.
- Fetal death.

Maternal

- Inadequate uterine contractions (primary or secondary uterine inertia)—myometrial defect; biochemical imbalance; psychogenic disturbance; exhaustion.
- Ineffective abdominal press—pain; fear; debility (exhaustion); diaphragmatic hernia; age.
- Placentitis, metritis, endometritis.
- Pregnancy toxemia, gestational diabetes.
- Abnormal pelvic canal—previous pelvic injury; abnormal conformation; pelvic immaturity.
- Congenitally small pelvis—Welsh corgis; brachycephalic breeds.
- Inguinal hernia.
- Abnormality of the vaginal vault—stricture; septae; vaginal hyperplasia; hypoplastic vagina; intraluminal or extraluminal cysts; neoplasia.
- Abnormality of the vulvar opening—stricture; small vulva; fibrosis from trauma; neoplasia.
- Insufficient cervical dilation.
- Lack of adequate lubrication.
- Uterine torsion.
- Uterine rupture.
- Uterine neoplasia, cysts, or adhesions.

RISK FACTORS

- Age
- Brachycephalic and toy breeds
- Persian, Himalayan, and Devon rex breeds

- Obesity
- Abrupt changes in environment peripartum
- Previous history of dystocia

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Uterine inertia—hypocalcemia versus hypoglycemia

PHYSICAL EXAMINATION

- Complete physical examination—determine concurrent or contributing problems (e.g., hypoglycemia, hypocalcemia, dehydration, fever); perform careful abdominal palpation to confirm the existence of fetuses.
- Digital vaginal examination—presence of a fetus or fetal membranes in the vaginal canal; abnormalities of the maternal pelvic canal; assess Ferguson's reflex.
- Bitches unresponsive to oxytocin or lacking Ferguson's reflex—uterine inertia more likely than obstructive dystocia, except if obstructed for several hours.

CBC/BIOCHEMISTRY/URINALYSIS

Minimum database—PCV, total protein, BUN, serum glucose, and calcium concentrations (ionized preferable to total serum calcium).

OTHER LABORATORY TESTS

Progesterone concentration

IMAGING

- Radiography—determine pelvic conformation, number and position of fetuses, evidence of fetal obstruction, fetal oversize, and fetal death; may require two views.
- Radiographic evidence of fetal death—collapse of fetal skeletons, abnormal association of fetal bones to the axial skeleton, presence of air/gas surrounding a fetus, fetal balling.
- Ultrasonography—recommended for monitoring fetal viability; fetal stress (e.g., fetal heart rate sustained at < 180 bpm) or death; sustained tachycardia (> 260 bpm) indicates need for more frequent monitoring; placental separation, and character of fetal fluids (presence of meconium or blood in amniotic fluid); fetal heart rate is normally two to three times that of the dam in bitches.

TREATMENT

APPROPRIATE HEALTH CARE

- Inpatient—until delivery of all fetuses and the dam is stabilized.
- Uterine inertia—initiate medical treatment if no evidence of fetal stress.
- Ecbolic agents contraindicated in the face of possible obstructive dystocia—may accelerate placental separation and fetal death, or cause uterine rupture.
- Hypocalcemia—bitch: administer 10% calcium gluconate at 0.2 mL/kg slowly IV (over 5–10 minutes; monitor for arrhythmia);

(CONTINUED)

may be repeated q4-6h as needed; queen: 0.5–1.0 mL calcium gluconate IV slowly—use with caution in cats as risk of uterine rupture is increased due to strong uterine contractions following calcium administration. • Hypoglycemia—administration of balanced electrolyte solution with 5–10% dextrose at a rate of 60–80 mL/kg/day IV. • Oxytocin—once calcium and glucose deficits are treated, microdoses of oxytocin (0.5–4.0 IU IM, SC depending on the size of the bitch and response to treatment); may be repeated at 30-minute intervals as long as delivery progresses. Consider C-section if more than three doses of oxytocin per fetus are required or more than four fetuses remain. If the bitch is not contracting adequately on her own, allow a minimum of 30 min between delivery of a fetus and the next dose of oxytocin.

- WhelpWise™ system monitors fetal heart rates and uterine contraction patterns; extremely useful for bitches with a history of uterine inertia or with large litters to determine the need for, and response to, medical treatment.

Manual Delivery

- To deliver a fetus lodged in vaginal vault:
 - Apply lubrication liberally.
 - Digital manipulation—least amount of damage to fetus and dam. Apply traction in a postero-ventral direction.
 - Instrument delivery not recommended due to inadequate space—undesirable sequelae include fetal mutilation and laceration of the dam.
 - Never apply traction to the distal extremities of a live fetus.
 - Failure to deliver a fetus located in the vaginal canal within 30 minutes—C-section indicated.

SURGICAL CONSIDERATIONS

- Indications for C-section—uterine inertia unresponsive to oxytocin or a uterine inertia with more than four fetuses remaining *in utero* (maximizes fetal survivability); pelvic or vaginal obstruction; inability to correct fetal malposition; fetal oversize; fetal stress; *in utero* fetal death.
- Elective C-section—breeds prone to dystocia; bitches with a history of dystocia; bitches with singleton or large litter size; often performed to maximize fetal survivability.

General Comments

- Provide fluid therapy with a balanced electrolyte solution before, during, and after surgery.
- The gravid uterus can compress great vessels, compromise venous return, and place pressure on diaphragm, resulting in decreased tidal volume.
- Pregnant bitches have lower systolic BP, PO₂, PCV; and higher PCO₂, respiratory rates, and incidence of

acidosis.

- Pre-oxygenation of patients improves maternal and neonatal outcome.
- Premedication with glycopyrrolate if fetal heart rates are normal (bitches: 0.01 mg/kg IV, IM; queens: 0.005–0.01 mg/kg IV, IM); or if fetal bradycardia exists with atropine (bitches: 0.02–0.04 mg/kg IM; queens: 0.04 mg/kg IM); induction with propofol (4–6 mg/kg IV), intubate and maintain with sevoflurane (or isoflurane) preferred; propofol CRI until fetuses delivered, then switch to sevoflurane/isoflurane.
- If propofol is unavailable, premedication with diazepam (0.1–0.4 mg/kg IV, IM) and butorphanol (0.2–0.4 mg/kg IM) followed by masking with sevoflurane (or isoflurane).
- Ketamine—not recommended in the bitch due to fetal depression; may be used in the queen where ketamine affects the fetus in a dose-dependent manner. With appropriate premedication a low-dose induction (1 mg/kg IV or 5 mg/kg IM) may be adequate.
- Epidural—bitch: (0.2 mg/kg 0.5% bupivacaine and 0.1 mg/kg preservative-free morphine or 0.1–0.3 mL/kg 2% lidocaine without epinephrine given to desired effect but not to exceed 10 mg/kg total lidocaine dose; queen: 2% lidocaine (0.2 mL/kg) given to desired effect plus butorphanol (0.2–0.4 mg/kg IV, IM); local anesthesia may also be utilized. Disadvantages of local/regional anesthesia are the inability to oxygenate adequately without an endotracheal tube and increased regional blood flow making hemostasis more difficult. Severely depressed or exhausted queen—premedication with diazepam (0.2–0.4 mg/kg IV, IM) or midazolam (0.066–0.22 mg/kg IV, IM) and either butorphanol (0.2–0.4 mg/kg IV, IM) or oxymorphone (0.1–0.4 mg/kg IV, IM); followed by propofol induction and maintenance with sevoflurane or isoflurane.
- Butorphanol (0.1–0.4 mg/kg IV, IM) or buprenorphine (0.005–0.01 mg/kg IV/IM) for postoperative analgesia.
- Premedications—if using diazepam, reverse neonates with flumazenil (0.01 mg/kg IV); if using opiates, reverse neonates with naloxone (0.04 mg/kg IV, IM, SC); repeat dosing until medications are fully metabolized in the neonate. Avoid premedication if fetal stress exists.

MEDICATIONS

CONTRAINDICATIONS

Oxytocin—contraindicated with obstructive dystocia, fetal stress, long-standing *in utero* fetal death, uterine rupture, uterine torsion.

FOLLOW-UP

PREVENTION/AVOIDANCE

- Schedule elective C-section for bitches with abnormal pelvic canal; small pelvis; vaginal vault abnormalities; breeds predisposed to dystocia; dams with previous history of uterine inertia.
- Scheduling of surgery—extremely important that D1 diestrus, LH peak, or ovulation is identified during breeding to ensure acceptable fetal survivability (see Breeding, Timing). If ovulation timing is not available, gestational aging and maturation assessment via ultrasonography is necessary.

EXPECTED COURSE AND PROGNOSIS

- If dystocia is identified promptly and intervention is successful—good to fair for life of the dam; fair for survival of fetuses.
- If dystocia unrecognized or untreated for 24–48 h—poor to guarded for life of the dam; unlikely that any fetuses will survive.

MISCELLANEOUS

PREGNANCY/FERTILITY/BREEDING

History of dystocia may or may not impact future fertility. Dystocia may recur depending on cause (anatomic abnormalities, primary uterine inertia). Resolution of dystocia by C-section does not preclude natural whelping during future deliveries.

DYSURIA AND POLLAKIURIA

BASICS

DEFINITION

- Dysuria—difficult or painful urination.
- Pollakiuria—voiding small quantities of urine with increased frequency of micturition.

PATHOPHYSIOLOGY

The urinary bladder and urethra normally serve as a reservoir for storage and periodic release of urine. Inflammatory and non-inflammatory disorders of the lower urinary tract may decrease bladder compliance and storage capacity by damaging structural components of the bladder wall or by stimulating sensory nerve endings located in the bladder or urethra. Sensations of bladder fullness, urgency, and pain stimulate premature micturition and reduce functional bladder capacity. Dysuria and pollakiuria are caused by lesions of the urinary bladder and/or urethra and provide unequivocal evidence of lower urinary tract disease; these clinical signs do not exclude concurrent involvement of the upper urinary tract or disorders of other body systems.

SYSTEMS AFFECTED

Renal/Urologic—bladder, urethra, and prostate gland

SIGNALMENT

Dog and cat

SIGNS

N/A

CAUSES

Urinary Bladder

- Urinary tract infection—bacterial, viral, fungal, parasitic, or mycoplasmal.
- Urocystolithiasis.
- Neoplasia—e.g., transitional cell carcinoma.
- Trauma.
- Anatomic abnormalities—e.g., ureterocele, persistent uterus masculinus, perineal hernias containing the urinary bladder, and spay granulomas.
- Detrusor atony—e.g., chronic partial obstruction and dysautonomia.
- Chemicals/drugs—e.g., cyclophosphamide.
- Iatrogenic—e.g., catheterization, palpation, reverse flushing, overdistension of the bladder during contrast radiography, urohydropropulsion, urethrocystoscopy, and surgery.
- Idiopathic—e.g., idiopathic feline lower urinary tract disease.

Urethra

- Urinary tract infection—see previous section.
- Urethrolithiasis—see previous section.
- Urethral plugs—e.g., matrix and matrix-crystalline.
- Neoplasia—see previous section; local invasion by malignant neoplasms of adjacent structures.

- Trauma.
- Anatomic anomalies—e.g., congenital or acquired strictures, urethrorectal fistulas, and pseudohermaphrodites.
- Urethral sphincter hypertonicity—e.g., upper motor neuron spinal cord lesions, reflex dyssynergia, and urethral spasm.
- Iatrogenic—see previous section.
- Idiopathic—see previous section.

Prostate Gland

- Prostatitis or prostatic abscess
- Neoplasia—adenocarcinoma and transitional cell carcinoma
- Cystic hyperplasia
- Paraprostatic cysts

RISK FACTORS

- Diseases, diagnostic procedures, or treatments that (1) alter normal host urinary tract defenses and predispose to infection, (2) predispose to formation of uroliths, or (3) damage the urothelium or other tissues of the lower urinary tract.
- Mural or extramural diseases that compress the bladder or urethral lumen.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Differentiating from Other Abnormal Patterns of Micturition

- Rule out polyuria—increased frequency and volume of urine $> 50 \text{ mL/kg/day}$.
- Rule out urethral obstruction—stranguria, anuria, overdistended urinary bladder, signs of post-renal uremia.
- Rule out urinary incontinence—involuntary urination, urine dribbling, enuresis, incomplete bladder emptying.
- Rule out urine spraying or marking—voiding small amounts of urine on vertical surfaces or other socially significant places.

Differentiate Causes of Dysuria and Pollakiuria

- Rule out urinary tract infection—hematuria; malodorous or cloudy urine; small, painful, thickened bladder.
- Rule out urolithiasis—hematuria; palpable uroliths in urethra or bladder.
- Rule out neoplasia—hematuria; palpable masses in urethra or bladder.
- Rule out neurogenic disorders—flaccid bladder wall; residual urine in bladder lumen after micturition; other neurologic deficits to hind legs, tail, perineum, and anal sphincter.
- Rule out prostatic diseases—urethral discharge, prostatomegaly, pyrexia, depression, tenesmus, caudal abdominal pain, stiff gait.
- Rule out cyclophosphamide cystitis—history.
- Rule out iatrogenic disorders—history of catheterization, reverse flushing, contrast

radiography, urohydropropulsion, urethrocystoscopy, or surgery.

CBC/BIOCHEMISTRY/URINALYSIS

- Results of CBC and biochemistries are often normal. Lower urinary tract disease complicated by urethral obstruction may be associated with azotemia, hyperphosphatemia, acidosis, and hyperkalemia. Patients with concurrent pyelonephritis may have impaired urine-concentrating capacity, leukocytosis, and azotemia. Patients with acute prostatitis or prostatic abscesses may have leukocytosis. Dehydrated patients may have elevated total plasma protein.
- Disorders of the urinary bladder are best evaluated with a urine specimen collected by cystocentesis. Urethral disorders are best evaluated with a voided urine sample or by comparison of results of analysis of voided and cystocentesis samples. (Caution: cystocentesis may induce hematuria.)
- Pyuria, hematuria, and proteinuria indicate urinary tract inflammation, but these are non-specific findings that may result from infectious and non-infectious causes of lower urinary tract disease.
- Identification of bacteria, fungi, or parasite ova in urine sediment suggests, but does not prove, that urinary tract infection is causing or complicating lower urinary tract disease. Consider contamination of urine during collection and storage when interpreting urinalysis results.
- Identification of neoplastic cells in urine sediment indicates urinary tract neoplasia. Use caution in establishing a diagnosis of neoplasia based on urine sediment examination. Urinary tract inflammation or extremes in urine pH or osmolality can cause epithelial cell atypia that is difficult to differentiate from neoplasia.
- Crystalluria occurs in normal patients, patients with urolithiasis, or patients with lower urinary tract disease unassociated with uroliths. Interpret the significance of crystalluria cautiously.
- Hematuria, proteinuria, and variable crystalluria occur in cats with non-obstructive idiopathic lower urinary tract disease. Significant pyuria is rare in these patients.

OTHER LABORATORY TESTS

- Quantitative urine culture—the most definitive means of identifying and characterizing bacterial urinary tract infection; negative urine culture results suggest a non-infectious cause (e.g., uroliths and neoplasia) or inflammation associated with urinary tract infection caused by fastidious organisms (e.g., mycoplasmas or viruses).
- Cytologic evaluation of urine sediment, prostatic fluid, urethral or vaginal discharges or biopsy specimens obtained by catheter or needle aspiration—may help in evaluating patients with localized urinary tract disease; may establish a definitive diagnosis of urinary tract neoplasia, but cannot rule it out.

(CONTINUED)

IMAGING

Survey abdominal radiography, contrast urethrocytography and cystography, urinary tract ultrasonography, and excretory urography are important means of identifying and localizing causes of dysuria and pollakiuria.

DIAGNOSTIC PROCEDURES

- Use urethrocytscopy in patients with persistent lesions of the lower urinary tract for which no definitive diagnosis has been established by other, less-invasive, means.
- Use light microscopic evaluation of tissue biopsy specimens from patients with persistent lesions of the urinary tract for which no definitive diagnosis has been established by other, less-invasive, means. Tissue specimens may be obtained by catheter biopsy, urethrocytscopy and forceps biopsy, or surgery.

**TREATMENT**

- Patients with non-obstructive lower urinary tract diseases are typically managed as outpatients; diagnostic evaluation may require brief hospitalization.
- Dysuria and pollakiuria associated with systemic signs of illness (e.g., pyrexia, depression, anorexia, vomiting, and dehydration) or laboratory findings of azotemia or leukocytosis warrant aggressive diagnostic evaluation and initiation of supportive and symptomatic treatment.
- Treatment depends on the underlying cause and specific sites involved. See specific chapters describing diseases listed in section on causes.
- Clinical signs of dysuria and pollakiuria often resolve rapidly following specific treatment of the underlying cause(s).

**MEDICATIONS****DRUG(S) OF CHOICE**

- Patients with urge incontinence, severe or persistent signs, or untreatable lower urinary tract disease may benefit from symptomatic therapy with propantheline, oxybutynin, or dicyclomine anticholinergic agents that may reduce the force and frequency of uncontrolled detrusor contractions.
- Propantheline—dogs: 0.2 mg/kg PO q6–8h; cats: 0.25–0.5 mg/kg PO q12–24h.

Oxybutynin—dogs: 0.2 mg/kg PO q8–12h; cats: 0.5–1.25 mg/cat PO q8–12h.
Dicyclomine—dogs: 5–10 mg/dog PO q8h.

- Patients with transitional cell carcinoma of the urinary bladder or urethra may be symptomatically managed with the nonsteroidal anti-inflammatory drug piroxicam (0.3 mg/kg PO q24h), which reduces the severity of clinical signs, improves quality of life, and in some cases, induces tumor remission.

CONTRAINdications

- Glucocorticoids or other immunosuppressive agents in patients suspected of having urinary or genital tract infection.
- Potentially nephrotoxic drugs (e.g., gentamicin) in patients that are febrile, dehydrated, or azotemic or that are suspected of having pyelonephritis, septicemia, or preexisting renal disease.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

N/A

**FOLLOW-UP****PATIENT MONITORING**

- Monitor response to treatment by status of clinical signs, serial physical examinations, laboratory testing, and radiographic and ultrasonic evaluations appropriate for each specific cause.
- Refer to specific chapters describing diseases listed, under "Causes."

POSSIBLE COMPLICATIONS

- Dysuria and pollakiuria may be associated with formation of macroscopic vesicourachal diverticula.
- Refer to specific chapters describing diseases listed, under "Causes."

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- Hematuria, pyuria, and proteinuria
- Disorders predisposing to urinary tract infection

- Disorders predisposing to formation of uroliths

D

EAR MITES

BASICS

OVERVIEW

Otodectes cynotis mites infest primarily the external ear canal and cause variable degrees of otic discharge and pruritus.

E

SIGNALMENT

- Common in young dogs and cats, although it may occur at any age.
- No breed or sex predilection.

SIGNS

- Pruritus is usually present, but can be minimal.
- Pruritus primarily located around the ears, head, and neck; occasionally generalized.
- Thick, red-brown or black otic exudate ("coffee grounds" appearance)—usually seen in the outer ear.
- Otic exudate and pruritus demonstrate individual variability.
- Crusting and scales may occur on the neck, rump, and tail (dogs).
- Excoriations on the convex surface of the pinnae often occur, owing to the intense pruritus.

CAUSES & RISK FACTORS

Otodectes cynotis

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Pediculosis
- *Pelodera* dermatitis
- Sarcoptic mange
- Notoedric mange
- Chiggers
- Otitis externa secondary to allergy/hypersensitivity
- Flea bite hypersensitivity

CBC/BIOCHEMISTRY/URINALYSIS

Normal

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Ear swabs placed in mineral oil—usually effective means of identification.
- Skin scrapings—may identify mites if signs are generalized.
- Mites may be visualized in external ear canal.
- Diagnosis may be made by response to treatment.

TREATMENT

- Outpatient.
- Diet and activity—no alteration necessary.
- Very contagious—all animals in contact with the affected animal must be treated.
- Thoroughly clean and treat the environment.

MEDICATIONS

DRUG(S)

- Ears should be thoroughly cleaned with a commercial ear cleaner.
- Otic parasiticides should be used for 7–10 days to eradicate mites and eggs; effective topical commercial products contain pyrethrins, thiabendazole, ivermectin, amitraz and milbemycin; treat during alternative weeks for two to three treatment cycles recommended to prevent reinfection from eggs.
- Selamectin : per label instructions or repeated at 2 weeks.
- Imidacloprid/moxidectin (Advantage Multi/Advocate): per label instructions.
- Ivermectin 200–300 µg/kg PO (three treatments) or SC (two treatments) at 14-day intervals: non-FDA-approved usage.

- Flea treatments should be applied to animal for elimination of ectopic mites.

- Mites may persist in the environment; environmental treatment may be helpful.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Ivermectin and moxidectin—do not use orally or by injection in collies, shelties, their crosses, or other herding breeds; use only if absolutely necessary in animals <6 months of age; an increasing number of toxic reactions have been reported in kittens.
- Ivermectin and milbemycin—cause elevated levels of monoamine neurotransmitter metabolites, which could result in adverse drug interactions with amitraz and benzodiazepines.

FOLLOW-UP

- Ear swab and physical examination should be done 1 month after therapy commences.
- Prognosis is good.
- If signs persist after treatment, an additional, underlying cause may be present.
- Repeat infestation indicates an uncontrolled source of mites.

EBSTEIN'S ANOMALY

BASICS

OVERVIEW

- Atrialization of the right ventricle—an apical displacement of the tricuspid valve complex into the right ventricle.
- Accompanied by various degrees of tricuspid insufficiency or stenosis.
- Major pathophysiology related to the degree of tricuspid insufficiency or stenosis.
- An abnormal accessory pathway may lead to supraventricular tachycardias.

SIGNALMENT

- Very rare—occasionally encountered in dogs and cats.
- No breed or sex predilection.
- Murmur auscultated at a young age, though can be very difficult to auscult with stenosis.

SIGNS

- Animals with mild tricuspid insufficiency or stenosis are asymptomatic.
- Animals with moderate insufficiency or stenosis are often exercise intolerant.
- Animals with severe insufficiency or stenosis have R-CHF with pleural effusion and/or ascites.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Tricuspid dysplasia

CBC/BIOCHEMISTRY/URINALYSIS

Results usually normal

OTHER LABORATORY TESTS

N/A

IMAGING

Thoracic Radiography

- Right atrial and ventricular enlargement
- Hepatomegaly

Echocardiography

- Two-dimensional echocardiography reveals an apically displaced tricuspid valve with an enlarged right atrium and small right ventricle.
- Color Doppler shows tricuspid insufficiency and/or tricuspid stenosis.
- Spectral Doppler confirms tricuspid stenosis and estimates right ventricular pressure.

OTHER DIAGNOSTIC PROCEDURES

Electrocardiography

- Simultaneous intracardiac pressure and ECG tracings may be needed to verify the diagnosis.
- Accessory conduction pathway (ventricular preexcitation) or supraventricular tachycardia.

TREATMENT

- Medical management currently the only practical approach.
- Surgical replacement of the tricuspid valve can be successfully performed at a few institutions.
- Restrict sodium intake only if right heart failure develops.

MEDICATIONS

DRUG(S)

- Patients with R-CHF—start furosemide (2–4 mg/kg q6–12h) and enalapril (0.5 mg/kg q12h).
- Patients with tricuspid stenosis—gradually increase atenolol dose (0.1–1 mg/kg q12h) to obtain low normal heart rate to facilitate ventricular filling.
- Patients with supraventricular tachycardia (WPW syndrome)—start procainamide (15 mg/kg q8h).

- If WPW syndrome persists, consider a calcium channel blocker (i.e., verapamil or diltiazem) or a beta-blocker (e.g., propranolol or atenolol).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Do not use calcium channel blockers and beta-blockers concurrently

E

FOLLOW-UP

Monitor with serial echocardiography

ECLAMPSIA

BASICS

OVERVIEW

- Post-parturient hypocalcemia.
- Usually develops 1–4 weeks postpartum; may occur at term, prepartum, or during late lactation.
- Alters cell membrane potentials, causing spontaneous discharge of nerve fibers and tonic-clonic contraction of skeletal muscles.
- Life-threatening tetany and convulsions, leading to hyperthermia.
- Cerebral edema possible.

SIGNALMENT

- Dog—postpartum bitch; most common in toy breeds; higher incidence with first litter.
- Most common prior to day 40 postpartum; occasionally occurs prepartum.
- Breeds at increased risk: Chihuahua, miniature pinscher, Shih Tzu, miniature poodle, Mexican hairless, Pomeranian.
- Cat—rare.

SIGNS

Historical Findings

- Poor mothering
- Restlessness, nervousness
- Panting, whining
- Vomiting, diarrhea
- Ataxia, stiff gait, limb pain
- Facial pruritis
- Muscle tremors, tetany, convulsions
- Recumbency, extensor rigidity—usually seen 8–12 hours after onset of signs.

Physical Examination Findings

- Hyperthermia
- Rapid respiratory rate
- Dilated pupils, sluggish pupillary light responses
- Muscle tremors, muscular rigidity, convulsions

CAUSES & RISK FACTORS

- Calcium supplementation during gestation, including dairy products
- Inappropriate Ca:P ratio in gestational diet
- Low body weight:litter size ratio
- Poor prenatal nutrition
- First litter
- Large litter size

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hypoglycemia—may be concurrent; hypoglycemia alone does not cause muscular rigidity.

- Toxicosis—distinguished by signalment and history.

- Epilepsy or other neurologic disorder—differentiated by signalment; calcium concentration diagnostic.

CBC/BIOCHEMISTRY/URINALYSIS

- Total serum calcium < 9 mg/dL in bitches; < 8 mg/dL in queens.
- Although ionized calcium (< 2.4–3.2 mg/dL) is the form important for normal neuromuscular function, measurement of total serum calcium is usually sufficient for diagnosis.
- Hypoglycemia—may be concurrent.
- Hypomagnesemia has been reported in 44% of affected bitches; may promote tetany.
- Serum potassium elevated in 56% of cases, due to metabolic acidosis or respiratory alkalosis.

IMAGING

N/A

OTHER LABORATORY TESTS

N/A

DIAGNOSTIC PROCEDURES

ECG shows prolonged QT interval, bradycardia, tachycardia, or ventricular premature complexes.

TREATMENT

- Emergency inpatient.
- Hyperthermia—cool with cool water soak and fans; use caution with cool water enemas.
- Puppies—remove from dam onto a foster dam or hand-raise; if not possible or undesirable due to behavioral need for contact with dam, remove pups from dam for 24 hours, or until serum calcium is stabilized, and provide supplementation for remainder of lactation; continue to monitor serum calcium level.

MEDICATIONS

DRUG(S)

- Calcium gluconate—10% solution 0.22–0.44 mL/kg IV given slowly to effect over 5 minutes; monitor heart rate or ECG during administration.
- Correct hypoglycemia.
- Diazepam 5 mg IV; for unresponsive seizures.
- Cerebral edema—treat, if indicated.
- Send home on calcium carbonate, or gluconate 10–30 mg/kg PO q8h until lactation ends (calcium carbonate (TUMS) 500 mg tablets supply 200 mg calcium).

- Magnesium supplementation may be helpful in hypomagnesemic bitches.
- Start puppies/kittens on solid food at 3–4 weeks of age.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Corticosteroids—avoid; cause decreased intestinal absorption and increased renal excretion of calcium.

FOLLOW-UP

PATIENT MONITORING

- Serum calcium concentration—monitor until it is stabilized in the normal range.
- Avoid calcium supplementation during gestation.
- Diet—maternal: ensure a calcium:phosphorus ratio of 1:1 or 1.2:1; avoid high-phytate foods (e.g., soybeans); puppies: supplement feeding for large litters.

POSSIBLE COMPLICATIONS

- Cerebral edema
- Death
- Hand-raising of puppies

EXPECTED COURSE AND PROGNOSIS

- Probably will recur with subsequent litters; calcium supplementation can be started after parturition for bitches with history of eclampsia in prior litters.
- Prognosis—good with immediate treatment; poor with delayed treatment.

ECTOPIC URETER

BASICS

OVERVIEW

- Congenital anomaly of the urinary system. The ureteral orifice(s) is/are inappropriately positioned caudal to the bladder trigone (i.e., trigone, urethra, vagina, vestibule, uterus, or prostate), resulting in urinary incontinence.
- A common cause of urinary incontinence in juvenile female dogs. Also seen in adult dogs.
- Anomalous differentiation of the mesonephric and metanephric ducts resulting in inappropriate ureteral termination.
- Dogs—> 95% tunnel intramurally, traversing the urethra in the submucosa.
- Male dogs—most commonly associated with severe hydronephrosis and hydroureter due to ureteral opening stenosis.
- Commonly associated with multiple anomalies of the urinary tract: > 75% have concurrent USMI, > 90% have PPMR, chronic UTIs (~ 80%), hydroureter (35–50%), hydronephrosis (25–50%), short urethral/intrapelvic bladders (~ 20%).

SIGNALMENT

- Dog and cat. • Juvenile incontinent dogs (commonly). • Infrequently reported in cats and male dogs; 20:1 ratio of female:male dogs. • Dog breeds may be predisposed: retrievers, Siberian huskies, Newfoundlands, poodles, terriers.

SIGNS

- Constant or intermittent incontinence since birth. • Normal voiding in some. • Chronic UTIs. • May be asymptomatic (male dogs) and can have moderate to severe hydroureter/hydronephrosis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- USMI—urethral pressure profilometry.
- Inappropriate urination—urge incontinence, “overactive bladder,” behavioral (conscious urination).
- UTI—pollakiuria and urge incontinence.
- Vaginal pooling—leakage after urination when patient stands up from recumbent position.
- Congenital hydroureter/hydronephrosis—male dogs with EU often continent.
- Short urethra/intrapelvic bladder syndrome.

CBC/BIOCHEMISTRY/URINALYSIS

Urine specific gravity and serum creatinine or urea nitrogen concentration often normal. Abnormal with concurrent anomalies (e.g., renal dysplasia, pyelonephritis).

OTHER LABORATORY TESTS

Urine bacterial culture and sensitivity—via cystocentesis.

IMAGING

- Cystoscopy (96% sensitivity): diagnostic method of choice.
- Helical computed tomography (91% sensitivity): more accurate than standard radiography.
- Urinary tract ultrasonography (60–91% sensitivity) can provide accurate diagnosis and anatomical information of the upper urinary tract.
- Excretory urography (50–75% sensitivity) with positive contrast cystogram or a pneumocystogram, followed by a vaginourethrogram (female) or urethrogram (male); may diagnose associated hydroureter/hydronephrosis, ureterocele, and/or absent or abnormal kidneys.
- Retrograde urethrography (47% sensitivity).

DIAGNOSTIC PROCEDURES

- Cystourethrogastroscopy—definitive diagnosis of EU, short urethral syndrome, location of ectopic orifice in the genitourinary tract; identifies multiple fenestrations, troughs.
- UPP—may detect concurrent USMI, but intramural ectopic ureter may confound results and therefore should not guide treatment of concurrent EU.

TREATMENT

- Cystoscopic-guided laser ablation (CLA): performed for intramural EU only; simultaneous diagnosis and treatment; opens ureteral tract in a minimally invasive manner; addresses concurrent vaginal defects (~ 95%).
- Surgical: neoureterostomy (with or without distal tract dissection/reconstruction), reimplantation, or ureteronephrectomy; complication rates range between 14% and 25% including ureteral strictures, leakage, and infection.
- Never consider ureteronephrectomy if ipsilateral renal function remains.
- Warn owners that incontinence may continue in ~ 45–70% of patients after surgery. Many patients become continent with the addition of medications, bulking agent augmentation, and/or placement of an artificial urethral sphincter.

MEDICATIONS

DRUG(S)

- Use if incontinence persists after surgery.
- Phenylpropanolamine: an α -blocker (1–1.5 mg/kg PO q8h) will improve continence after surgery/laser therapy in 10–20% of dogs, improving continence levels to 50–60%.
- Diethylstilbestrol: initially 0.1–0.3 mg/kg q24h for 7 days, then once weekly; 0.1–1 mg PO for 3–5 days, then 1 mg per week thereafter. Gradually titrate to the lowest effective dose. DES is potentially toxic to the

bone marrow and can cause blood dyscrasias. Estriol tablets: 2 mg once daily and then titrated to lowest effective dose. Combination of estrogen and PPA therapy may be more effective.

- Testosterone propionate (2.2 mg/kg IM q2–3 days) or methyltestosterone (0.5 mg/kg/day) is administered to male dogs initially to see if replacement therapy will be effective. For longer action, testosterone cypionate (2.2 mg/kg IM q30 days) can be used.
- Not advised in immature animals.
- Estriol: can be used for estrogen-responsive urinary incontinence. The dose is 2 mg once daily per dog (regardless of body weight) for 14 days, followed by the lowest effective daily dose tapered every 7 days.

OTHER

After surgery/laser ablation (1) transurethral submucosal bulking agent injections: can improve continence to ~60–65%; (2) placement of an artificial urethral sphincter (called a hydraulic occluder) can improve continence to ~80–90%.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

- Dogs—with surgery (25–50%) or laser ablation (40–55%) alone, continence rates range from 25% to 55%, which improves to 60% with medications, 65% with bulking-agent injection, and ~80–90% with the placement of a hydraulic occluder.
- Care should be taken in evaluation of hydroureter/hydronephrosis after surgery as ureteral strictures have been reported, which can result in permanent loss of the ipsilateral kidney.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Hydronephrosis, hydroureter, ureterocele, pelvic bladder, persistent paramesonephric remnant, vaginal septum, renal dysplasia, renal agenesis, USMI, short urethra/intrapelvic bladder.

Consulting Editor Carl A. Osborne

ECTROPION

BASICS

OVERVIEW

- Eversion or rolling out of the eyelid margin, resulting in exposure of the palpebral conjunctiva.
- Ophthalmic system (exposure and poor tear retention/distribution)—may predispose patient to irritation, recurrent infections, and sight-threatening corneal disease).

SIGNALMENT

- Dogs, seldom cats.
- Breeds with higher than average prevalence—sporting breeds (e.g., spaniels, hounds, and retrievers); giant breeds (e.g., Saint Bernards and mastiffs); any breed with loose facial skin (especially bloodhounds).
- Developmental—genetic predisposition in listed breeds; may occur in dogs < 1 year old.
- Acquired—noted in other breeds; occurs late in life secondary to age-related loss of facial muscle tone and developing skin laxity.
- Intermittent—caused by fatigue; may be observed after strenuous exercise or when drowsy.

SIGNS

- Eversion of the lower eyelid with lack of contact of the lower lid to the globe and exposure of the palpebral conjunctiva and third eyelid—usually obvious.
- Facial staining caused by poor tear drainage—tears spill over onto the face instead of passing from the eye to the nose via the nasolacrimal ducts.
- History of mucoid to mucopurulent discharge owing to conjunctival exposure.
- Recurrent foreign body irritation due to debris localizing between lid and globe in inferior cul-de-sac.
- History of bacterial conjunctivitis.

CAUSES & RISK FACTORS

- Usually secondary to breed-associated alterations in facial conformation and eyelid support.
- Marked weight loss or muscle mass loss about the head and orbits—may result in acquired disease.
- Tragic facial expression in hypothyroid dogs.
- Scarring of the eyelids secondary to injury or after overcorrection of entropion—may result in cicatricial disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Usually clinically obvious.
- Look for any underlying disorder in non-predisposed breeds and patients with late-age onset.
- Loss of orbital or periorbital mass—may cause condition in patients with masticatory myositis.
- Palpebral nerve paralysis—condition associated with lack of muscle tone of the orbicularis oculi muscles.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

- Possible masticatory myositis—test for auto-antibodies against type 2M muscle fibers.
- Palpebral nerve paralysis or tragic facial expression—consider testing for hypothyroidism.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Palpebral nerve paralysis—full neurologic evaluation; potential for hypothyroidism.
- Secondary conjunctivitis—consider bacterial culture or cytologic examination to help select an appropriate topical antibiotic.
- Fluorescein or rose bengal staining of the cornea and conjunctiva—may document corneal ulcerations; may reveal severity of the exposure problem.

TREATMENT

- Supportive care (topical lubricant or antibiotic-containing ointments) and good ocular and facial hygiene—sufficient for most mild disease.
- Surgical treatment—eyelid shortening or radical facelift; necessary for severely affected patients that have chronic ocular irritation.
- Intermittent, fatigue-induced condition—do not treat surgically.

MEDICATIONS

DRUG(S)

- Topical broad-spectrum ophthalmic antibiotics—bacterial conjunctivitis or corneal ulceration. Neomycin/polymyxin B/bacitracin (or others based on bacterial culture and sensitivity) q6–8h.
- Lubricant eye drops and ointments—reduce conjunctival and corneal desiccation secondary to exposure.
- Hypothyroid and masticatory myositis-induced conditions—may respond well to appropriate medical treatment of the underlying disease.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

- May become more severe as patient ages.
- Non-surgically treated patient—monitor for signs of infectious conjunctivitis, exposure keratopathy, corneal ulceration, and facial dermatitis.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Hypothyroidism
- Myopathy, focal Inflammatory—masticatory myositis and extraocular myositis

AGE-RELATED FACTORS

Old animals more likely to have ectropion secondary to loss of facial muscle tone.

SEE ALSO

- Hypothyroidism
- Myopathy, Inflammatory—Masticatory Myositis and Extraocular Myositis

Consulting Editor Paul E. Miller

EHRLICHIOSIS (ANAPLASMA)

BASICS

DEFINITION

Caused by *Ehrlichia* spp.—tick-borne rickettsial disease

Dogs

- Within the family Anaplasmataceae—three pathogenic genera: *Ehrlichia*, *Anaplasma*, and *Neorickettsia*.
- *Ehrlichia* spp.—divided into three groups: (1) *E. canis*: ehrlichiosis found intracytoplasmically in circulating leukocytes; (2) *E. ewingii*: canine granulocytic ehrlichiosis; like *A. phagocytophilum*, infects granulocytic cells in dogs, but differs in geographic distribution (mainly found in southeastern and south-central United States); (3) *E. chaffeensis*: like *E. canis*, tropism for mononuclear cells; mainly a human pathogen but causes disease in dogs; disease distribution based on vector (mainly *Amblyomma americanum*) range.
- *Anaplasma* spp.—two organisms of importance: (1) *A. phagocytophilum*: infects mainly horses but also the granulocytic cells of dogs; mainly found in northeastern and upper midwestern states and California based on distribution of vectors (hard ticks *Ixodes* spp.); (2) *A. platys*: tropism for platelets; shares serologic cross-reactivity with *A. phagocytophilum*.
- Although usually found in defined ranges, serologic evidence suggests *E. canis* and *A. phagocytophilum* occur in all 48 contiguous states.
- *Neorickettsia* spp.—two organisms of importance: (1) *N. risticii*: causes Potomac horse fever in horses but also infects dogs and cats; infections acquired by ingesting infected snails, free nematode life stages, or aquatic insects with encysted metacercaria; grazing or drinking from standing water explains why horses become infected more often than dogs; infected dogs have negative *E. canis* titers; (2) *N. helminthoeca*: causes salmon poisoning disease in dogs.

Cats

- Feline mononuclear ehrlichiosis (and *E. risticii* extremely rarely) can cause clinical disease.
- Serologic evidence for *A. phagocytophilum* infection but no disease.
- Serologic evidence—suggests a species that cross-reacts with *E. canis* can cause illness.

PATHOPHYSIOLOGY

- *E. canis* • *Rhipicephalus sanguineus*—brown dog tick; transmits disease to dogs in saliva; 1- to 3-week incubation period; three stages of disease:
 - Acute—spreads from bite site to the spleen, liver, and lymph nodes (causes organomegaly); then subclinical with mild thrombocytopenia; mainly endothelial cells affected; vasculitis; antiplatelet antibodies may exacerbate thrombocytopenia; variable leukopenia; mild anemia; severity depends on organism.
 - Subclinical—organism persists; antibody response increases

(hyperglobulinemia); thrombocytopenia persists.

- Chronic—impaired bone marrow production (platelets, erythroid suppression); marrow hypercellular with plasma cells.

SYSTEMS AFFECTED

- Bleeding tendencies—thrombocytopenia and vasculitis.
- CNS, eyes (anterior uveitis), and lungs—rarely affected by vasculitis.
- Lymphadenopathy.
- Multisystemic.
- Splenomegaly.

INCIDENCE/PREVALENCE

- Occurs throughout the year; insidious.
- Average duration from onset to presentation—usually > 2 months.
- Prevalence depends on geographic locality.

GEOGRAPHIC DISTRIBUTION

- Worldwide.
- North America—mainly Gulf Coast and eastern seaboard; also the Midwest and California.

SIGNALMENT

Species

- Dogs—can be infected with a number of species; *E. canis*, *A. platys*, *A. phagocytophilum*, *E. ewingii*, and *E. chaffeensis* produce main disease entities.
- Cats—*E. risticii*; serology suggests a species like *E. canis*, and *A. phagocytophilum*.

Breed Predilections

Chronic (*E. canis*)—seems more severe in Doberman pinschers and German shepherds.

Mean Age and Range

- Average age—5.22 years
- Range 2 months–14 years

SIGNS

General Comments

Duration of clinical signs from initial acute illness to presentation—usually > 2 months.

Historical Findings

- Lethargy, depression, anorexia, and weight loss
- Fever
- Spontaneous bleeding—sneezing, epistaxis
- Respiratory distress
- Ataxia, head tilt
- Ocular pain (uveitis)

Physical Examination Findings

Acute

- Bleeding diathesis (petechiation of mucous membranes as a result of thrombocytopenia) associated with fever (with depression, anorexia, weight loss) and generalized lymphadenopathy should raise suspicions.
- Ticks—found in 40% of cases.
- Respiratory—dyspnea (even cyanosis); increased bronchovesicular sound.
- Diffuse CNS disease (meningitis).
- Ataxia with upper motor neuron dysfunction.
- Vestibular dysfunction.
- Generalized or local hyperesthesia.
- Most dogs recover without treatment and enter a subclinical state.

Chronic

- In non-endemic areas.
- Spontaneous bleeding.
- Anemia.
- Generalized lymphadenopathy.
- Scrotal and limb edema.
- Splenomegaly.
- Hepatomegaly.
- Uveitis, usually bilateral (75%), can sometimes be the

only presenting sign.

- HypHEMA.
- Retinal hemorrhages and detachment with blindness.
- Corneal edema.
- Arthritis (rare).
- Seizures (rare).

RISK FACTORS

Concurrent infection with *Babesia*, *Haemobartonella*, *A. platys*, and *Hepatozoon canis*—worsens clinical syndrome.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Rocky Mountain spotted fever (*Rickettsia rickettsii*)—usually seasonal between March and October; serologic testing for diagnosis; responds to same treatment as ehrlichiosis.
- Immune-mediated thrombocytopenia—not usually associated with fever or lymphadenopathy; serologic testing best distinguishes; may treat for both until results are known.
- Systemic lupus erythematosus—ANA test usually negative with ehrlichiosis; serologic testing for diagnosis.
- Multiple myeloma—serologic testing to differentiate and determine cause of hyperglobulinemia.
- Chronic lymphocytic leukemia—differentiate by lymphocytosis and cytology of bone marrow.
- Brucellosis—serologic testing for diagnosis.

CBC/BIOCHEMISTRY/URINALYSIS

Acute

- Thrombocytopenia—before onset of clinical signs.
- Anemia.
- Leukopenia—from lymphopenia and eosinopenia.
- Leukocytosis and monocytosis—as disease becomes more chronic.
- Morulae—intracytoplasmic inclusions in leukocytes rare; buffy coat smear increases the sensitivity of finding morulae.
- Nonspecific changes—mild increases in ALT, ALP, BUN, creatinine, and total bilirubin (rare).
- Hyperglobulinemia—progressively increases 1–3 weeks post-infection.
- Hypoalbuminemia—usually from renal loss.
- Proteinuria—with or without azotemia; about half of patients.

Chronic

- Pancytopenia—typical; monocytosis and lymphocytosis may be present.
- Hyperglobulinemia—magnitude of globulin increase correlates with duration of infection; usually polyclonal gammopathy, but monoclonal (IgG) gammopathies occur.
- Hypoalbuminemia.
- High BUN and creatinine from primary renal disease.

OTHER LABORATORY TESTS

Serologic Testing

- Most clinically useful and reliable method.
- IFA highly sensitive; poor specificity with cross-reactivity between *E. canis* and *A. phagocytophila*, but not between *E. canis* and *A. platys*.
- More specific tests being developed.
- Titers—reliable 3 weeks after infection; > 1:10 diagnostic.
- Coombs’

EHRlichiosis (ANAPLASMA)

(CONTINUED)

positive anemia—may be seen; may confuse the diagnosis. • Test for other accompanying pathogens—*Babesia*, *Mycoplasma haemofelis*, *A. platys*, and *Hepatozoon canis*. • Point-of-care screening serology testing for single or multiple agents are both practical, sensitive, and specific for IFA titers greater than 320. Positive tests should be confirmed with IFA and other testing (CBC) before treatment is initiated as false-positive results frequently occur. Immunoblotting can be used to distinguish cross-reactions (especially between *E. canis* and *E. ewingii*). • PCR—more reliable than finding circulating morulae. • PCR of blood for *E. canis* provides a species-specific diagnosis and is positive by day 7 post-infection, usually before the development of clinical disease (9–12 days post-infection) in experimental settings. It is less reliable in natural infections and should not be used as the only screening method of diagnosis. Real-time PCR techniques are proving to be more sensitive and may hold a place in initial diagnostic testing as more data on accuracy becomes available.

DIAGNOSTIC PROCEDURES

Bone Marrow Aspirate

- Acute—hypercellularity of megakaryocytic and myeloid series.
- Chronic—often erythroid hypoplasia with increased M:E ratios and plasmacytosis.
- Increased numbers of mast cells seen on marrow smears.

PATHOLOGIC FINDINGS

- Acute—petechial hemorrhages on serosal and mucosal surfaces of most organs; generalized lymphadenopathy (brownish discoloration), splenomegaly, hepatomegaly, and red bone marrow (hypercellularity).
- Chronic—pale marrow (hypoplastic); subcutaneous edema; histologically, perivascular plasma cell infiltrate in numerous organs most characteristic; multifocal non-suppurative meningoencephalitis with lymphoplasmacytic cell infiltrate into the meninges common.

TREATMENT

APPROPRIATE HEALTH CARE

- Inpatient—initial medical stabilization for anemia and/or hemorrhagic tendency resulting from thrombocytopenia.
- Outpatient—stable patients; monitor blood and response to medication frequently.

NURSING CARE

- Balanced electrolyte solution is indicated for dehydration.
- Blood transfusion is indicated for anemia.
- Platelet-rich plasma or a blood transfusion is indicated for hemorrhage resulting from thrombocytopenia.

CLIENT EDUCATION

- Acute—prognosis excellent with appropriate therapy.
- Chronic—response

may take 1 month; prognosis poor if the bone marrow is severely hypoplastic. • Progression from acute to chronic can be easily prevented by early, effective treatment; but many dogs remain seropositive and may relapse (even years later). • German shepherds and Doberman pinschers—more chronic and severe form of disease.

MEDICATIONS

DRUG(S) OF CHOICE

- Doxycycline (treatment of choice)—5 mg/kg PO q12h for 4 weeks; give IV for 5 days if the dog is vomiting.
- Glucocorticoids—prednisolone or prednisone; 1–2 mg/kg PO q12h for 5 days; may be indicated when thrombocytopenia is life-threatening (thought to be a result of immune-mediated mechanisms); because immune-mediated thrombocytopenia is a principal differential diagnosis, may be indicated until results of serologic tests are available.
- Androgenic steroids—to stimulate bone marrow production in chronically affected dogs with hypoplastic marrows; oxymetholone (2 mg/kg q24h PO until response) or nandrolone decanoate (1.5 mg/kg IM weekly).

CONTRAINdications

- Tetracycline (and derivatives)—do not use in dogs < 6 months old (permanent yellowing of teeth occurs); do not use with renal insufficiency (try doxycycline because it can be excreted via the gastrointestinal tract).
- Enrofloxacin not effective against *Ehrlichia* spp. but is against *Anaplasma* spp.

PRECAUTIONS

Glucocorticoids—prolonged use at immunosuppressive levels may interfere with the clearance and elimination of *E. canis* after use of tetracycline.

ALTERNATIVE DRUG(S)

- Oxytetracycline and tetracycline—22 mg/kg PO q8h for 21 days; effective and less expensive; minocycline (10 mg/kg PO q12h for 4 weeks) is effective if doxycycline is difficult to obtain.
- Chloramphenicol—20 mg/kg PO q8h for 14 days; for puppies < 6 months of age; avoids yellow discoloration of erupting teeth caused by tetracyclines; warn client of public health risks; avoid in dogs with thrombocytopenia, pancytopenia, or anemia.

FOLLOW-UP

PATIENT MONITORING

- Platelet count—every 3 days after initiating antirickettsial agent until normal;

improvement is rapid in acute cases.

- Serologic testing—repeat in 9 months; most dogs will become seronegative; positive titer suggests reinfection or ineffective treatment (reinstitute treatment regimen).

PREVENTION/AVOIDANCE

- Control tick infestation—dips or sprays containing dichlorvos, chlорfenvinphos, dioxathion, propoxur, or carbaryl; flea and tick collars may reduce reinfestation but reliability unproven; avoid tick-infested areas.
- Removing ticks by hand—use gloves (see “Zoonotic Potential”); ensure mouth parts are removed to avoid a foreign body reaction.

EXPECTED COURSE AND PROGNOSIS

- Acute—excellent prognosis with appropriate and early treatment.
- Chronic—may take 4 weeks for a clinical response; prognosis poor with hypoplastic marrow.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- *Babesia* • *Haemobartonella* • *A. platys*

ZOONOTIC POTENTIAL

- Serologic evidence indicates that *E. canis* (or possibly a related species) occurs in people; probably not directly infected from dogs; tick exposure thought to be necessary; *R. sanguineus* probably not the vector in humans.
- Most cases in the southern and south-central United States.

SYNOMYS

- Canine hemorrhagic fever • Canine rickettsiosis • Canine typhus • Lahore canine fever • Nairobi bleeding disease • Tracker dog disease • Tropical canine pancytopenia

ABBREVIATIONS

- ALP = alkaline phosphatase
- ALT = alanine transaminase
- ANA = antinuclear antibody
- CNS = central nervous system
- IFA = indirect fluorescent antibody
- PCR = polymerase chain reaction

ELBOW DYSPLASIA

BASICS

DEFINITION

A series of four developmental abnormalities that lead to malformation and degeneration of the elbow joint.

PATHOPHYSIOLOGY

- Four abnormalities—UAP, OCD, FMCP, and incongruity; alone or in combination; may be seen in one or both elbows; bilateral disease common (50% of cases).
- UAP—delayed closure of the growth plate between the anconeal process and the proximal ulnar metaphysis (olecranon) by 5 months of age; may be the result of abnormal mechanical stress on the anconeal process.
- OCD—affects the medial aspect of the humeral condyle; a disturbance in endochondral ossification causes retention of articular cartilage and subsequent mechanical stress leads to a cartilage flap lesion.
- FMCP—chondral or osteochondral fragmentation or fissure of the medial coronoid process of the ulna; likely a manifestation of osteochondrosis of the coronoid process; the coronoid does not have a separate ossification center; may be the result of abnormal mechanical stress on the medial coronoid process.
- Incongruity—asynchronous proximal growth between the radius and ulna may lead to abnormal loading, wearing, and erosion of cartilage in the humeroulnar compartment; possible malformation of the trochlear notch of the ulna; a slightly elliptical trochlear notch with a decreased arc of curvature is too small to articulate with the humeral trochlea, which results in major points of contact in areas of the anconeal process, coronoid process, and medial humeral condyle and little or no contact in other areas of the trochlea.

SYSTEMS AFFECTED

Musculoskeletal

GENETICS

- Inherited disease.
- High heritability—heritability index ranges between 0.25 and 0.45.

INCIDENCE/PREVALENCE

- Most common cause for elbow pain and lameness.
- One of the most common causes for forelimb lameness in large-breed dogs.

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Dog

Breed Predilections

Large and giant breeds—Labrador retrievers; rottweilers; golden retrievers; German

shepherds; Bernese mountain dogs; chow chows; bearded collies; Newfoundlands.

Mean Age and Range

- Age at onset of clinical signs—typically 4–10 months
- Age at diagnosis—generally 4–18 months.
- Onset of symptoms related to DJD—any age.

Predominant Sex

- FMCP—males predisposed
- UAP, OCD, incongruity—none established

SIGNS

General Comments

- Lameness—if no distinct abnormalities noted on physical examination or radiographs, early intervention may demand advanced imaging.
- Not all patients are symptomatic when young.
- Intermittent episodes of elbow lameness due to advanced DJD changes in a mature patient—common.

Historical Findings

Intermittent or persistent forelimb lameness—exacerbated by exercise; progressed from a stiffness seen only after rest.

Physical Examination Findings

- Pain—elicited on elbow hyperflexion or extension; elicited when holding the elbow and carpus at 90° while pronating and supinating the carpus.
- Affected limb—tendency to be held in abduction and supination.
- Joint effusion and capsular distension—especially noted between the lateral epicondyle and olecranon.
- Crepitus—may be palpated with advanced DJD.
- Diminished range of motion.

CAUSES

- Genetic
- Developmental
- Nutritional

RISK FACTORS

- Rapid growth and weight gain
- High-calorie diet

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Trauma
- Septic arthritis
- Panosteitis
- Avulsion or calcification of the flexor muscles
- Synovial sarcoma

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

Radiography

- Image both elbows—high incidence of bilateral disease.
- Elbow DJD recognized by osteophytes on the cranial margin of the radial head and epicondyles (medial and lateral), and medial coronoid process; also commonly see sclerosis of the ulna caudal to the coronoid process and trochlear notch and a staircase between the joint surface of the radius and lateral coronoid; may see these changes with UAP, OCD, FMCP, and incongruity.
- UAP—best diagnosed from the mediolateral hyperflexed view; may easily see lack of bony union. Comparison to the contralateral elbow may be helpful although the high incidence of bilateral disease should be kept in mind.
- OCD—best diagnosed from the craniocaudal and craniocaudal-lateromedial oblique views; reveals a radiolucent defect or flattening of the medial aspect of the humeral condyle.
- FMCP—may not be visualized in some cases; diagnosis is then presumptive based on DJD and the lack of UAP or OCD lesions; commonly see early osteophyte formation on the proximal caudal surface of the anconeal process with FMCP.

Other

CT, MRI, and linear tomography—can provide more definitive evidence for fissures and non-displaced fragments. CT is necessary in many cases of FMCP as survey radiographs have low sensitivity.

DIAGNOSTIC PROCEDURES

- Joint tap and analysis of synovial fluid—confirm involvement of joint.
- Synovial fluid—should be straw-colored with normal to decreased viscosity; cytology reveals < 5,000 nucleated cells/ μL (> 90% are mononuclear cells); normal results do not necessarily rule out the diagnosis.
- Arthroscopy—may help diagnose UAP, FMCP, and OCD.

PATHOLOGIC FINDINGS

- UAP—fibrous union between anconeal process and proximal ulnar metaphysis; fibrous tissue invasion and degeneration of the anconeal process; DJD.
- OCD—chondral flap on medial humeral condyle; sclerosis of underlying subchondral bone with fibrous tissue invasion; erosive lesion on apposing coronoid cartilage; DJD.
- FMCP—chondral or osteochondral fragmentation of the cranial tip or lateral margin of the medial coronoid; erosive lesion on cartilage of the apposing medial aspect of the humeral condyle; DJD.
- Incongruity—erosive lesions involving part or all of medial coronoid process and the apposing articular cartilage of the medial aspect of the humeral condyle; DJD; linear striations in the articular cartilage.

E

ELBOW DYSPLASIA

(CONTINUED)

TREATMENT

APPROPRIATE HEALTH CARE

Surgery—controversial but recommended for most patients

E

NURSING CARE

- Cold packing the elbow joint—perform immediately post-surgery to help decrease swelling and control pain; perform at least 5–10 minutes q8h for 3–5 days.
- Range-of-motion exercises—beneficial until the patient can bear weight on the limb(s).

ACTIVITY

Restricted for all patients postoperatively

DIET

- Weight control—important for decreasing the load and stress on the affected joint(s).
- Restricted weight gain and growth in young dogs—may decrease incidence and severity.

CLIENT EDUCATION

- Discuss the heritability of the disease.
- Discuss the likelihood of DJD progression regardless of intervention.
- Discuss the influence of excessive intake of nutrients that promote rapid growth.

SURGICAL CONSIDERATIONS

- Severity of DJD and advanced age of patient—negatively influence outcome. Generally DJD progresses faster without treatment.
- UAP—four options: removal, lag screw fixation, dynamic proximal ulnar osteotomy, and lag screw fixation plus dynamic proximal osteotomy; base decision on degree of DJD, patient's age, and surgical expertise.
- OCD and FMCP—medial approach to elbow (diagnostic differentiation not necessary); removal of loose fragment(s).
- Incongruity—controversial; four options: no surgery, coronoidectomy, dynamic proximal ulnar osteotomy, intra-articular osteotomy; base decision on type of incongruity, degree of DJD, patient's age, and surgical expertise.
- Arthroscopic diagnosis and treatment—excellent option for FMCP, OCD, and incongruity; benefits: superior visualization, minimally invasive.

MEDICATIONS

DRUG(S) OF CHOICE

- None that promotes healing of osteochondral or chondral fragments.
- NSAIDs—minimize pain, decrease inflammation, symptomatically treat associated DJD.
- Deracoxib (3–4 mg/kg PO q24h, chewable).
- Carprofen (2.2 mg/kg PO q12h or q24h).

- Etodolac (10–15 mg/kg PO q24h).
- Meloxicam (load 0.2 mg/kg PO, then 0.1 mg/kg PO q24h—liquid).
- Tepoxalin (load 20 mg/kg, then 10 mg/kg PO q24h).

CONTRAINDICATIONS

Avoid corticosteroids—potential side effects; articular cartilage damage associated with long-term use.

PRECAUTIONS

NSAIDs—gastrointestinal irritation may preclude use in some patients.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

Chondroprotective drugs (e.g., polysulfated glycosaminoglycans, glucosamine, and chondroitin sulfate)—may help limit cartilage damage and degeneration; may help alleviate pain and inflammation.

FOLLOW-UP

PATIENT MONITORING

- Post-surgery—limit activity for a minimum of 4 weeks; encourage early, active movement of the affected joint(s).
- Yearly examinations—recommended to evaluate progression of DJD.

PREVENTION/AVOIDANCE

- Discourage breeding of affected animals.
- Do not repeat dam-sire breedings that result in affected offspring.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Progression of DJD—expected
- Prognosis—fair to good for all forms

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

Middle-aged to old dogs with advanced DJD are not candidates for surgical intervention.

ZOONOTIC POTENTIAL

N/A

PREGNANCY/FERTILITY/BREEDING

ELECTRIC CORD INJURY

BASICS

OVERVIEW

- Electric cord injury is an uncommon event that occurs when an animal bites an electric cord.
- Other causes of electrocution are uncommon in dogs and cats but can occur.
- Household electrical currents are alternating (60 Hz) or 120 volts and dangerous.
- Injury can be caused due to thermal injury or due to disruption of normal electrophysiologic activity of excitable tissue.
- Pulmonary edema can be a sequelae to electrocution and the pathophysiology is thought to be neurogenic and centrally mediated, leading to pulmonary hypertension.
- Cataract formation is reported following electrocution.

SIGNALMENT

- Seen in dogs and cats.
- Most commonly seen in dogs.
- Most commonly seen in young animals. In published report age ranged from 5 months to 1.5 years.
- No breed or sex predilections.
- No genetic basis.

SIGNS

- Burns associated with gingiva, tongue, palate
- Singed hair or whiskers
- The most common clinical signs are related to acute dyspnea
- Coughing
- Tachypnea
- Orthopnea
- Increased respiratory effort
- Cyanosis
- Crackles during pulmonary auscultation
- Tachycardia
- Muscle tremors
- Tonic-clonic activity
- Collapse

CAUSES & RISK FACTORS

- Chewing electrical cord
- Young animals
- Primarily dogs but also reported in cats

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Left-sided congestive heart failure—may be due to congenital or acquired heart disease. The presence of cardiac murmur or dysrhythmia may help differentiate; however, dysrhythmias may be seen with electric cord injury.
- Vitamin K antagonist, rodenticide intoxication history (pulmonary hemorrhage).
- Thoracic trauma (pulmonary contusions)—history, thoracic radiographs.
- Other causes of non-cardiogenic pulmonary edema.
- Pleural space disease—muffled lung sounds during auscultation, thoracic radiographs.
- Thermal or chemical injuries—history, physical examination, thoracic radiographs.
- Exposure to fire and smoke inhalation—history, physical examination.
- Atypical pneumonia—history, physical examination, thoracic radiographs.

CBC/BIOCHEMISTRY/URINALYSIS

May help rule out other systemic causes of non-cardiogenic pulmonary edema.

OTHER LABORATORY TESTS

Arterial blood gas analysis may be useful to document hypoxemia. This may be difficult to perform in unstable patients.

IMAGING

• Thoracic radiographs may help distinguish between cardiogenic and non-cardiogenic causes of pulmonary edema.

• The radiographic pattern is usually a generalized, mixed alveolar bronchial pattern. The edema is often most notable in the caudal dorsal lung fields.

• Pulmonary venous congestion is absent with non-cardiogenic pulmonary edema.

Echocardiography may help identify or rule out underlying cardiac disease.

DIAGNOSTIC PROCEDURES

- Electrocardiogram—may help distinguish cardiogenic disease from non-cardiogenic disease; however, dysrhythmias may be seen with electrocution and other causes of non-cardiogenic pulmonary edema.
- Echocardiography should help identify heart failure as a cause.

PATHOLOGIC FINDINGS

- Pink, frothy fluid in airways
- Fluid-filled, congested lungs
- Subendocardial and subepicardial petechia
- Circumscribed, pale gray or tan oral lesions

TREATMENT

- If patient is close to live wire, turn off electricity and/or remove patient to safe area.
- Establish patent airway if patient is unconscious.
- Oxygen supplementation.
- Mechanical ventilation may be required.
- Establish venous access.

MEDICATIONS

DRUG(S)

- If in shock—treat with intravenous crystalloids (90 mL/kg/h in dog, 45–60 mL/kg/h in cat) or colloids (20 mL/kg in dogs, 5–10 mL/kg in cats).
- If pulmonary edema is present—furosemide I/V (2–4 mg/kg); this is controversial as this is a form of non-cardiogenic pulmonary edema.
- Anxiolytic therapy if dyspneic—butorphanol 0.1–0.2 mg/kg IV.
- Corticosteroids have been employed but are controversial and of unknown value.
- Inotropic support if required.

- Antiarrhythmic therapy if required.
- Oral and cutaneous burns—treated symptomatically.

FOLLOW-UP

PATIENT MONITORING

- Patient should be monitored until stable.
- Physical examination.
- Oral lesion should be monitored and may prevent the animal from eating.
- Electrocardiography.
- Central venous pressure.
- Blood pressure.
- Arterial blood gas.
- Thoracic radiographs.

PREVENTION/AVOIDANCE

- Damaged electric cords should be discarded.
- Avoid animal exposure to electric cords.
- Follow child safety rules for a safe home.

POSSIBLE COMPLICATIONS

- Infected burn wounds can occur but are uncommon.
- Oral-nasal fistula due to severe burns.

EXPECTED COURSE AND PROGNOSIS

- The prognosis is based on the response to therapy.
- Pulmonary edema can develop as soon 1 hour and as late as 36 hours after incident.
- Pulmonary edema associated with electrocution is associated with high mortality (38.5%).
- If patient survives first 24 hours the prognosis improves.
- Resolution of pulmonary edema may take 3–5 days.
- Most oral lesions resolve.
- Inappetence related to oral lesions resolves.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Cataracts have been reported in one dog 18 months after electrocution.

Suggested Reading

ENAMEL HYPOPLASIA/HYPOCALCIFICATION

BASICS

OVERVIEW

- Enamel hypoplasia refers to inadequate deposition of enamel matrix. This can affect one or several teeth and may be focal or multifocal. The crowns of the affected teeth can have areas of normal enamel next to areas of hypoplastic or missing enamel.
- Apparent defect in enamel surfaces, often pitted and discolored; focal or generalized.
- Defects due to disruption of normal enamel formation.
- Systemic influences during enamel formation (e.g., distemper, fever) over an extended time may cause generalized changes; local or focal influences (e.g., trauma, even from deciduous tooth extraction) over a short time may cause specific patterns or bands.
- Most cases are primarily aesthetic; some patients can have extensive structural damage, even root involvement.
- Enamel hypocalcification is a more correct description, since the amount of enamel is adequate (not hypoplastic), but defects in calcification lead to enamel defect.
 - Enamel hypocalcification refers to the inadequate mineralization of enamel matrix. This often affects several or all teeth. The crowns of affected teeth are covered by soft enamel that may be worn easily away.
- Teeth may be more sensitive with exposed dentin, and occasionally fractures of severely compromised teeth occur; usually they remain fully functional.

SIGNALMENT

- Dogs and less commonly cats.
- Often apparent at time of tooth eruption (after 6 months of age) or shortly thereafter (with signs of wear).

SIGNS

Historical Findings

Discolored teeth

Physical Examination Findings

- Irregular, pitted enamel surface with discoloration of diseased enamel and potential exposure of underlying dentin (light brown).
- Early or rapid accumulation of plaque and calculus on roughened tooth surface; possible gingivitis and/or accelerated periodontal disease.

CAUSES & RISK FACTORS

- Insult during enamel formation.
- Canine distemper virus, fever, trauma (e.g., accidents, excessive force during deciduous tooth extraction).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Enamel staining—discolored but smooth surface (tetracycline).
- Carious lesions—cavities with decay.
- Amelogenesis imperfecta—genetic and/or developmental formation and maturation abnormalities other than hypomineralization.
- Tooth resorption—similar to those found in cats.

CBC/BIOCHEMISTRY/URINALYSIS

- Usually normal.
- Appropriate preanesthetic diagnostic when indicated.

OTHER LABORATORY TESTS

N/A

IMAGING

- Intraoral radiographs are necessary to determine the structure and viability of roots.
- Cases reported of abnormal root formation, no root formation, or separated crown and root.

DIAGNOSTIC PROCEDURES

None

TREATMENT

- Treatment depends upon extent of lesions and equipment and materials available.
- Goal is to provide the smoothest surface possible.
- Appropriate preoperative antimicrobial and pain management therapy when indicated.

Optimal treatment

- Ideal treatment is to gently remove diseased enamel (enamel scrub) with white stone burs or finishing disks on high-speed handpiece (adequate water coolant)—handle with care!
- Take care not to damage the tooth—excess enamel/dentin removal; hyperthermic damage to pulp.
- Focal defects may be amenable to composite restoration, but long-term success is poor; metallic crown restoration is preferred; many restorative materials (bonding agents, composites) require use of light-curing units and appropriate skill levels.
- Bonding agent recommended to seal exposed dentinal tubules and protect surfaces.

Alternative treatment

- Without a high-speed handpiece and appropriate attachments, treatment can be more challenging.

- The soft, diseased enamel can sometimes be removed with ultrasonic scalers, but take care to avoid damage and hyperthermia.

- A strong fluoride treatment (in-hospital, on a dry tooth surface; varnish or strong sodium fluoride paste) can be used to decrease sensitivity and enhance enamel strength.

MEDICATIONS

DRUG(S)

N/A

CONTRAINdications/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

PATIENT MONITORING

Inform the owner that further degeneration of remaining enamel may occur, necessitating additional therapy in the future.

PREVENTION/AVOIDANCE

- Recommend regular professional dental cleaning and a routine homecare program (brushing); may include weekly application of stannous fluoride at home (minimize ingestion because of toxicity).
- Avoid excessive chewing on hard objects.

ENCEPHALITIS

BASICS

DEFINITION

Inflammation of the brain that may be accompanied by spinal cord and/or meningeal involvement.

PATHOPHYSIOLOGY

- Inflammation—caused by an infectious agent or by the patient's own immune system.
- Immune-mediated—immune system derangement generally of unknown cause.

SYSTEMS AFFECTED

- Nervous • Multisystemic signs—may be noted in patients with infectious diseases

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

Varies with the cause or agent implicated

SIGNALMENT

Species

Dog and cat

Breed Predilections

- Granulomatous meningoencephalitis—mostly small-breed dogs, especially terriers and miniature poodles; large-breed dogs also affected. • Pug encephalitis—pugs.
- Pyogranulomatous meningoencephalitis—German shorthaired pointers. • Maltese encephalitis—Maltese. • Yorkshire terrier necrotizing encephalitis—Yorkshire terriers.

SIGNS

Historical Findings

Acute onset of clinical signs that rapidly progress.

Physical Examination Findings

With mycotic, rickettsial, viral, and protothecal organisms—fundic lesions frequent.

Neurologic Examination Findings

- Rostral fossa—seizures; circling; pacing; personality change; decreasing level of responsiveness. • Caudal fossa—abnormalities related to the brainstem (e.g., somnolence, head tilt, facial paresis/paralysis, incoordination). • Progression (e.g., anisocoria, pinpoint pupils, decreasing level of consciousness, poor physiologic nystagmus)—suggests tentorial herniation.

CAUSES

Dogs

- Idiopathic, immune-mediated—GME; pug encephalitis; Maltese encephalitis; YNE; eosinophilic meningoencephalitis. • Viral—canine distemper virus; rabies; herpes; parvovirus; adenovirus; pseudorabies; West Nile virus; Eastern and Venezuelan equine encephalomyelitis virus. • Post-vaccinal encephalomyelitis—canine distemper virus; rabies; canine coronavirus-parvovirus.
- Rickettsial—Rocky Mountain spotted fever;

ehrlichiosis. • Mycotic—cryptococcosis; blastomycosis; histoplasmosis; coccidioidomycosis; aspergillosis; phaeohyphomycosis. • Bacterial—anaerobic and aerobic. • Protozoal—toxoplasmosis; neosporosis; encephalitozoonosis

- Spirochetes—borreliosis. • Parasite migration—*Dirofilaria immitis*; *Toxocara canis*; *Ancylostoma caninum*; *Cuterebra*; cysticercosis. • Migrating foreign body—plant awn; others. • Protothecosis. • PME.

Cats

- Idiopathic, immune-mediated—GME; EME. • Idiopathic polioencephalomyelitis.
- Viral—FIP; rabies; FIV; pseudorabies; panleukopenia; rhinotracheitis. • Mycotic—cryptococcosis; blastomycosis; phaeohyphomycoses. • Bacterial—anaerobic and aerobic. • Protozoal—toxoplasmosis.
- Parasite migration—*Dirofilaria immitis*; *Cuterebra*.

RISK FACTORS

- Immunosuppressive drugs and FIV or FeLV infection—infectious encephalitides. • Tick-infected areas—rickettsial and *Borrelia* infections. • Travel history—mycotic infections.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Fungal encephalitides—frequently accompanied by systemic signs. • Protozoal diseases—systemic; may have a chronic history. • Rickettsial diseases—CBC abnormalities common. • FIP—patients usually < 3 years of age; protracted course; characteristic CSF results. • Canine distemper virus—commonly seen as acute encephalitis with systemic signs in patients < 1 year old; can be difficult to confirm antemortem.
- Primary CNS neoplasia—signs may be similar to encephalitis. • Degenerative disorders—usually slow, insidiously progressive onset. • Metabolic or toxic encephalopathy—bilateral, symmetrical neurologic abnormalities that relate to the cerebrum; confirm toxins by laboratory tests or serum assay.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC—frequently normal; leukocytosis may be seen in diseases that produce systemic signs; may see lymphopenia in early stages of canine distemper virus and rickettsial infection; rickettsial encephalitis may be accompanied by thrombocytopenia and anemia. • Biochemistry—frequently normal; hyperproteinemia with polyclonal gammopathy often with FIP and chronic systemic infections; creatine kinase may be moderately high with *Neospora* infection.

OTHER LABORATORY TESTS

- Serology—available for fungal, protozoal, rickettsial, and viral diseases; helpful but must

be interpreted with caution because a positive titer does not always indicate active disease (e.g., toxoplasma in cats) and a negative titer does not always rule out active disease (e.g., FIP). • Indirect fluorescent antibody—a single positive titer of 1:10 or greater confirms ehrlichiosis. • ELISA—a four-fold rise between acute and convalescent IgG titers when the first titer is > 1:128 confirms Rocky Mountain spotted fever; an IgM titer of > 1:256 suggests infection within the previous 16 weeks by *Toxoplasma gondii* and may indicate exacerbation of chronic infection.

- Latex agglutination antigen—a single positive titer from serum or CSF confirms Cryptococcus. • Agar-gel immunodiffusion—diagnose blastomycosis with a high degree of accuracy. • Local production of canine distemper virus-specific antibody (IgG and IgM)—in CSF after virus infects the CNS.
- Positive *Neospora caninum* titer—correlates well with active disease. • Positive FIP titer—indicates only infection with a coronavirus; may not be pathogenic. • Positive *Borrelia burgdorferi* titer—indicates exposure to the organism, not necessarily active disease.

IMAGING

- Thoracic radiographs—may confirm lung abnormalities. • Skull radiographs—may confirm sinusitis/rhinitis in some cats with cryptococcosis. • CT or MRI of the brain—may detect multifocal or single mass lesions.

DIAGNOSTIC PROCEDURES

- CSF—perform on all animals with clinical signs that suggest encephalitis; results almost always abnormal; normal results do not rule out acute viral encephalitis that is limited to the parenchyma; with pleocytosis, culture for bacteria (aerobic and anaerobic). • CSF—neutrophils indicate acute active inflammatory process; small lymphocytes indicate an antigenic response; eosinophils indicate an allergic response or a reaction to foreign material (tumor, parasite).

PATHOLOGIC FINDINGS

The lesions are a function of the brain response to the infectious agent or other cause.

TREATMENT

APPROPRIATE HEALTH CARE

Inpatient—diagnosis and initial therapy

NURSING CARE

- Symptomatic treatment—control brain edema and seizure activity as necessary.
- Cerebral edema—20% mannitol (2.2 g/kg IV over 30–45 minutes); may repeat within 1–2 hours to achieve maximum response; limit parenteral fluids to prevent rebound cerebral edema; short-term (72-hour) corticosteroid treatment can be added for further control (dexamethasone sodium

ENCEPHALITIS

(CONTINUED)

phosphate at 0.5 mg/kg IV q12h for 24 hours; then reduce to 0.25 mg/kg q12h for 48 hours). • Seizures—treat with antiepileptic drugs; with boluses or constant-rate infusion.

ACTIVITY

As tolerated

DIET

If severe depression or vomiting—nothing oral until condition improves to prevent aspiration.

CLIENT EDUCATION

Inform client that relapse is possible with idiopathic or immune-mediated encephalitis when therapy is discontinued.

SURGICAL CONSIDERATIONS

Brain biopsy—may be needed in specific cases.

MEDICATIONS

DRUG(S) OF CHOICE

- Apply specific therapy once diagnosis is reached or highly suspected.
- Idiopathic and immune-mediated—2 mg/kg prednisone q12h initially; tapered over 6 months.
- Rickettsial and borreliosis—doxycycline.
- Protozoal—clindamycin.
- Mycotic—requires treatment for 1–2 years; itraconazole (5 mg/kg PO q12h with food) or fluconazole (6.25–12.5 mg/kg PO or IV q12h); corticosteroids often needed during the first 4–6 weeks to control cerebral edema.
- Viral and post-vaccinal—none definitive; treat symptomatically.
- Bacterial—broad-spectrum antibiotics that penetrate the blood-brain barrier; if agent is unknown, try a combination of enrofloxacin (5–10 mg/kg PO or IV q12h) and ticarcillin-clavulanate (50 mg/kg IV q8h) or amoxicillin-clavulanate (13.75 mg/kg PO q8h).

CONTRAINDICATIONS

- Bacterial and Rocky Mountain spotted fever—corticosteroids contraindicated.
- Puppies < 6 months of age with a rickettsial disease—use chloramphenicol (doxycycline-induced tooth discoloration). • Puppies < 8 months of age—enrofloxacin contraindicated (cartilage damage); use amoxicillin-clavulanate or ticarcillin-clavulanate alone.
- CNS infections—do not use aminoglycosides and first-generation cephalosporins because CNS penetration is poor.

PRECAUTIONS

- Administer mannitol intravenously 10 minutes prior to anesthesia for CSF collection to decrease intracranial pressure.
- Corticosteroids—observe closely for worsening signs that suggest an infectious cause.

POSSIBLE INTERACTIONS

- Chloramphenicol and cimetidine—do not use concurrently with phenobarbital to avoid toxic serum phenobarbital levels due to interference with liver metabolism.
- Corticosteroids alter CSF results if used for 12 hours or more.

ALTERNATIVE DRUG(S)

- Leflunomide 1.5–4 mg/kg PO q24h individualized based on its active metabolite, teriflunomide, blood level done 24h post-medication 7 days after therapy initiated due to long half-life. Safe therapeutic range is 20–40 µg/mL. Often effective for immune-mediated encephalitis unresponsive to conventional therapy. Leukopenia, thrombocytopenia, and hemorrhagic colitis are possible adverse effects. CBCs done monthly; treatment is for 1.5 years.
- Mycophenolate mofetil 10–16 mg/kg PO or IV q12h can be used in addition to leflunomide and prednisone in dogs with immune-mediated encephalitis to achieve further immune suppression. Adverse effects are similar to leflunomide. A CBC should be done 2 weeks after onset of therapy and then monthly.

FOLLOW-UP

PATIENT MONITORING

- Frequent neurologic evaluations in the first 48–72 hours to monitor progress. • Relapse as medication is withdrawn—repeat CSF analysis. • Measure serum titer of cryptococcus capsular antigen every 3 months until negative.

PREVENTION/AVOIDANCE

- A method of effective tick control should be used on animals that live in endemic areas.
- Avoid vaccination of dogs that have had GME.

POSSIBLE COMPLICATIONS

- Long-term corticosteroid therapy—signs of iatrogenic hyperadrenocorticism. • CSF collection or natural course of the disease—tentorial herniation and death.

EXPECTED COURSE AND PROGNOSIS

- Resolution of signs—generally gradual (2–8 weeks). • Protozoal—almost always progresses to death. • Immune-mediated—fair to good prognosis for complete remission with aggressive immunosuppression.
- Rickettsial, mycotic, bacterial, protozoal, and spirochete infections—fair chance of survival. • Parasite migration, migrating foreign bodies, PME, YNE, and polioencephalomyelitis—usually fatal. • Pug and Maltese encephalitis—may be fatal; course varies greatly; some patients respond to steroid treatment for long periods.
- Post-vaccinal encephalomyelitis—may resolve on its own; often permanent damage and death.

MISCELLANEOUS

AGE-RELATED FACTORS

- Young (< 2 years) and old (> 8 years) animals—more risk for infectious diseases.
- Dogs < 6 years of age—immune-mediated and idiopathic encephalitides.

ZOONOTIC POTENTIAL

- Rabies—consider in endemic areas if the patient is an outdoor animal that has rapidly progressive encephalitis.
- Humans may be infected by the same vector tick that affected the patient.
- Exudates from animals with mycosis can revert to the spore-forming, infectious mycelial stage.
- Cultures are highly contagious and should be handled with great care.

ENCEPHALITIS SECONDARY TO PARASITIC MIGRATION

BASICS

OVERVIEW

- Aberrant parasitic migration into the CNS.
- Parasites usually affect another organ system of the same host (e.g., *Dirofilaria immitis*, *Taenia*, *Ancylostoma caninum*, *Angiostrongylus*, or *Toxocara canis*), or a different host species (e.g., raccoon roundworm, *Baylisascaris procyonis*; skunk roundworm, *B. columellaris*; *Coenurus* spp.; or *Cysticercus cellulosae*).
- Access to CNS—hematogenously (dirofilariasis) or through adjacent tissues, including the middle ear, skull foramina, cribriform plate through nasal cavities, or open fontanelles (cuterebraiasis).

SIGNALMENT

- Dirofilariasis—adult animals only.
- Other parasites—young dogs and cats with access to outdoors—rare and sporadic occurrence.

SIGNS

- Vary with the portion of CNS affected.
- Likely asymmetrical.
- May suggest a focal mass lesion or a multifocal disease process.
- Cuterebraiasis—seasonal (July–October) acute or peracute onset of behavior changes, seizures, visual deficits, etc. A previous history of respiratory disease is common.
- Rat parasite, *Angiostrongylus cantonensis* (Australia)—lumbosacral syndrome (hind limbs, tail, and bladder paralysis/paresis) in puppies that may ascend to thoracic limbs and cranial nerves.

CAUSES & RISK FACTORS

Housing in a cage previously occupied by wildlife (raccoons, skunks).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Rule out other causes of focal encephalopathy—infectious diseases (viral, bacterial, protozoan, or fungal); granulomatous meningoencephalomyelitis; brain tumor.
- Diagnosis often made on necropsy.

CBC/BIOCHEMISTRY/URINALYSIS

Normal unless the parasite also affects non-neural tissues.

OTHER LABORATORY TESTS

CSF—may show an eosinophilic, neutrophilic, or mononuclear pleocytosis (also found in protozoal, fungal, and

protozoa encephalitides); may be normal (strictly parenchymal lesions).

IMAGING

CT or MRI—brain; focal lesion and/or cerebral infarction from occlusion of cerebral vessels. Non-specific and often inconclusive but could lead to surgical exploration and removal of migrating parasite.

PATHOLOGIC FINDINGS

- The parasite or its tracts may or may not be identified.
- Infarction, vascular rupture and hemorrhage or vascular emboli may cause local to extensive necrosis and malacia. There may be granulomatous proliferation or/and obstructive hydrocephalus.
- *Dirofilaria immitis*—intravascular or extravascular.
- Worms produce focal inflammation.
- Cuterebraiasis is the suspected cause of feline ischemic encephalopathy.

TREATMENT

- Surgical removal of intracranial Cuterebra.
- Parasiticides (see below) could potentiate illness.
- Supportive and nursing care.

MEDICATIONS

DRUG(S)

- Dirofilariasis and neural angiostrongylosis—ananthelmintic treatment may cause worsening of signs and sometimes death.
- Mild neural angiostrongylosis—puppies may recover with supportive care and corticosteroid therapy.
- A single dose of ivermectin (400 mg/kg SC) may kill cuterebra larvae in cats with suspected cuterebraiasis. Pretreatment with diphenhydramine (4 mg/kg) and intravenous dexamethasone (0.1 mg/kg) may mitigate allergic/anaphylactic reactions to dead or dying larvae.
- Treat inflammation and secondary infections: corticosteroids/NSAIDs, antibiotics.

FOLLOW-UP

PATIENT MONITORING

As necessary

PREVENTION/AVOIDANCE

- Keep pets indoors or/and segregated from wildlife.
- Use preventive anthelmintics and dirofilaricides.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

Acute or insidious onset, then usually progressive.

Consulting Editor Joane M. Parent

ENDOCARDITIS, INFECTIVE

BASICS

DEFINITION

The invasion of the cardiac endocardium, usually the valves, by infectious agents. Usually Gram-positive bacteria, especially staphylococci or streptococci. Occasionally *Rickettsia* or *Bartonella* in dogs. Rarely fungi in dogs. Culture-negative cases may be due to *Bartonella* or fungi (e.g., *Aspergillus*). Less likely due to *Brucella*, *Coxiella*, and *Chlamydia*.

PATHOPHYSIOLOGY

- Bacteremia develops from various portals of entry; bacteria invade and colonize the heart valves—usually the aortic, occasionally the mitral, and rarely the tricuspid and pulmonic valves.
- Endocardial ulceration exposes collagen causing platelet aggregation, activation of the coagulation cascade, and formation of vegetations.
- Vegetations on heart valves are composed of an inner layer of platelets, fibrin, RBCs, and bacteria; a middle layer of bacteria; and an outer layer of fibrin.
- Valvular insufficiency develops in virtually all patients; aortic insufficiency almost invariably leads to intractable LS-CHF within weeks to several months.
- CHF is less frequent and latent when only the mitral valve is affected.
- Vegetative lesions may dislodge causing infarction or metastatic infection to any organ; organs commonly infected include the spleen, kidneys, brain, and skeletal muscles.

SYSTEMS AFFECTED

- Cardiovascular—valvular insufficiency; arrhythmias, myocarditis.
- CNS—para/tetraparesis; cranial nerve deficits; abnormal mentation.
- Hemic/Lymphatic/Immune—hypercoagulation; DIC.
- Musculoskeletal—septic or immune-mediated polyarthropathy; hypertrophic osteopathy; discospondylitis.
- Renal/Urologic—renal infarction; immune-mediated glomerulonephritis; urinary tract infections.
- Respiratory—pulmonary edema and/or emboli.

SIGNALMENT

Species

Dogs; rarely cats

Breed Predilections

- Middle-sized to large breeds
- Breeds predisposed to subaortic stenosis

Mean Age and Range

Most affected dogs are 4–8 years of age; infection can occur at any age.

Predominant Sex

Most studies report male predominance—may be as great as 2:1.

SIGNS

General Comments

- Gram-negative bacteremia results in

peracute or acute clinical signs; Gram-positive bacteremia results in subacute or chronic clinical signs.

- Systemic signs are secondary to infarction, infection (inflammation), toxemia, or immune-mediated damage; usually override cardiac signs.

Historical Findings

- Infectious disease involving the skin, oral, GI, and genital tract (e.g., prostatitis).
- History of predisposing factors—immunosuppressive drug therapy, aortic stenosis, recent surgery, infected wounds, abscesses, or pyoderma.
- Common reasons for presentation include lethargy, paresis, fever, anorexia, GI disturbances, and lameness.

Physical Examination Findings

- Usually diverse and misleading—"the great imitator."
- Pyrexia and general malaise.
- Dyspnea caused by CHF.
- Arrhythmias (usually ventricular, supraventricular, or heart block).
- Single or shifting leg lameness.
- Systolic heart murmur.
- "To-and-fro" murmur—associated with aortic valve vegetation causing systolic turbulence and diastolic regurgitation.
- Diastolic murmur component with hyperdynamic femoral pulses are a strong indication of advanced aortic valve endocarditis.

CAUSES

- Bacterial infection associated with the oral cavity, bone, prostate, skin, and other sites.
- Invasive diagnostic or surgical procedures forcing bacteria into the bloodstream.

RISK FACTORS

- Congenital subaortic stenosis.
- Immunosuppression from long-term or high-dose corticosteroids, neoplasia, or cytotoxic drug administration.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Bacteremia of any cause.
- Polysystemic, immune-mediated disorders.
- Left-sided CHF caused by dilated cardiomyopathy or congenital subaortic stenosis.

CBC/BIOCHEMISTRY/URINALYSIS

- Active, severe infection associated with an inflammatory leukogram (i.e., neutrophilia, left shift, and monocytosis)—patients with chronic, relatively inactive, or walled-off infection may have normal or nearly normal leukogram; those with chronic infection may have mature neutrophilia with monocytosis.
- Nonregenerative anemia.
- Thrombocytopenia—variable severity.
- Low-normal or low albumin, low-normal or low glucose, and high SAP/bilirubin activity are inconsistently associated with sepsis (septic triad).
- Renal azotemia—secondary to renal embolization, pyelonephritis, and/or hypovolemia-induced renal failure.

- Proteinuria caused by septic embolization, immune-mediated glomerulonephritis, or infarction of the kidneys; hematuria, pyuria, and granular casts associated with pyelonephritis.

OTHER LABORATORY TESTS

- Blood culturing—three samples taken at least 1 hour apart over 24 hours; at least two should yield the same microbe; both aerobic and anaerobic cultures recommended; antibiotic removal systems available for diagnosis of patients given antibiotics.
- PCR with bacterial 16S primers, in combination with blood culturing, increases the likelihood of identification of bacteria in blood.
- Culture-negative bacteremia often due to prior antibiotic administration or fastidious microbes, especially *Bartonella*.
- Catheter tips—culture.
- Urine cultures (not a substitute for blood cultures)—easy; often yield positive results; do not necessarily incriminate the urinary tract as the source of infection.
- Tests for prostate, kidney, and bone infection may be warranted.
- Positive antinuclear antibody, lupus erythematosus, rheumatoid factor, and Coombs' test results occasionally found—non-specific; tend to confound the diagnosis.
- Bartonella* alpha-Proteobacteria growth medium (BAPGM) and PCR—for *Bartonella*.

IMAGING

Radiographic Findings

Left heart enlargement; rarely, calcification of one or more heart valves.

Echocardiography

Best test—vegetative endocarditis of the aortic valve is easily discerned; mitral valve infection may be difficult to differentiate from myxomatous degeneration. Hyperechoic with chronicity.

DIAGNOSTIC PROCEDURES

Joint taps for cytologic examination and culture—cytologic examination usually does not differentiate septic from immune-mediated arthritis; either, usually not septic, can exist with infective endocarditis. Neutrophils are usually non-degenerate regardless of cause.

Electrocardiographic Findings

- ECG—may be normal; occasionally reflects left heart enlargement; often detects ventricular tachyarrhythmias; occasionally heart block of variable severity or supraventricular tachyarrhythmias.
- Heart block suggests aortic valve involvement with infection or infarction of the adjacent septum.

PATHOLOGIC FINDINGS

- Cardiomegaly, almost always left sided when present.
- Vegetative lesions and blood clots on one or more valves.
- Infection, hemorrhage, and infarction of adjacent myocardium.
- Renal infarcts are always present and lead to proteinuria and possibly renal failure.
- Primary or secondary sites of

(CONTINUED)

infection, especially kidneys and spleen.
• Pulmonary hemorrhage or edema.

TREATMENT

Early index of suspicion with aggressive, rapid diagnostic testing, followed by appropriate treatment are imperative for cure. Cure is a reasonable expectation when mitral valve (alone) IE is identified early in its course and treatment is aggressive.

NURSING CARE

- Aggressive fluid therapy—overt or impending CHF limits fluid volumes that can be administered; this problem is virtually insurmountable in patients with concomitant renal failure.
- Imminent CHF—provide no more than maintenance volumes of fluid; alternate D5W with LRS (or 2.5% dextrose in half-strength LRS); potassium supplementation usually required.

CLIENT EDUCATION

Guarded prognosis if only mitral valve involved. The prognosis is grave if the aortic valve is involved.

MEDICATIONS

DRUG(S) OF CHOICE

Treatment variable—depends on severity of sepsis and presence or absence of CHF.

Antibiotics

- Backbone of treatment but usually do not eradicate infection before irreversible aortic valve damage occurs; more than minimal damage to the aortic valve is life-threatening because aortic insufficiency tends to be a lethal complication.
- High-dose IV administration of bactericidal antibiotics is imperative and recommended for as long as feasible (at least 1 week), followed by SC administration for 1 or more weeks.
- Oral administration—recommended only after at least 4 weeks of injectable therapy and at least 1 week after hematologic and clinical signs of infection and inflammation have disappeared; long-term (> 4 months) treatment required to eradicate the infection from the vegetations.
- Selection determined by both the urgency of septic complications and results of bacterial culture; coagulase-positive staphylococci and streptococci are most often incriminated, so choices can be logically made before culture results are obtained.
- Coagulase-positive staphylococci—usually resistant to penicillin, hetacillin, amoxicillin, and ampicillin.
- Streptococci—often resistant to aminoglycosides and fluoroquinolones.

- Gram-negative bacteria—often sensitive to third-generation cephalosporins, fluoroquinolones, and aminoglycosides.
- Bartonella*—only aminoglycosides appear cidal; can try doxycycline, fluoroquinolone, rifampin, or azithromycin.
- First-generation cephalosporins—reasonable choice for stable patients until culture results are obtained.
- Treat life-threatening sepsis immediately with drug combinations. Pending culture results, one of three regimens is recommended: (1) Penicillin, ampicillin, ticarcillin, or a first-generation cephalosporin is combined with an aminoglycoside. Aminoglycosides are not good choices for animals with overt or impending CHF or those with renal azotemia. Gentamicin (2 mg/kg q8h) is recommended for only 5–10 days because of renal toxicity. A fluoroquinolone may be substituted for an aminoglycoside. (2) Clindamycin (2–10 mg/kg IV q8h) plus enrofloxacin (10 mg/kg q24h given diluted 1:1 in sterile water and injected slowly over 15–20 minutes). (3) Advanced-generation cephalosporins or ticarcillin-clavulanic acid (Timentin)—high dosages, but only normal dosages if patient has renal failure.

Treatment of CHF

- Pimobendan, ACE inhibitor, spironolactone, amlodipine, and furosemide indicated for patients with overt or impending CHF.
- Oxygen, nitroglycerin, high-dose furosemide (2–8 mg/kg IV), and hydralazine (1–2 mg/kg q12h) for patients with acute, severe pulmonary edema.

CONTRAINDICATIONS

- Avoid antibiotics that cannot penetrate fibrin (e.g., sulfonamides).
- Corticosteroids.

OTHER DRUGS

- Anticoagulant therapy—controversial in the prevention of embolization. Heparin not recommended in human medicine as it increases risk of hemorrhage.
- Aspirin (5–7 mg/kg PO q24h) and/or dalteparin (100 U/kg SC q8h) and/or clopidogrel (2–4 mg/kg PO q24h)—may reduce bacterial dissemination and embolization.

FOLLOW-UP

PATIENT MONITORING

- Emergence of antibiotic resistance—relapsing fever and inflammatory leukogram; imperative to adjust treatment on the basis of culture results.
- Frequent examination and CBC after discharge.
- Repeat blood cultures 1 week after antibiotics are discontinued or if fever recurs.

ENDOCARDITIS, INFECTIVE

PREVENTION/AVOIDANCE

- Indwelling catheters—restrict to appropriate indications; aseptic placement; replace within 3–5 days.
- Administer antibiotics to dog with moderate to severe subaortic stenosis during dentistry or “dirty” procedures.
- Avoid careless use of corticosteroids.

POSSIBLE COMPLICATIONS

- CHF
- Renal failure
- Septic embolization of many tissues and organs
- Persistent or latent immune-mediated polyarthropathy

EXPECTED COURSE AND PROGNOSIS

- Best prognosis associated with short history of bacteremia, rapid diagnosis, and aggressive treatment.
- Mortality relatively higher in animals recently given corticosteroids.
- Grave prognosis for patients with aortic valve endocarditis.
- Patients with mitral valve endocarditis can be saved with appropriate treatment.
- Latent CHF can occur with advance, late diagnosis or inadequate treatment for mitral valve endocarditis.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Congenital heart defects (usually subaortic stenosis) in some animals.

ENDOMYOCARDIAL DISEASES—CATS

BASICS

OVERVIEW

- Endomyocarditis—acute cardiopulmonary disease that typically develops following a stressful event; characterized by interstitial pneumonia and endomyocardial inflammation; pneumonia is usually severe and commonly causes death; one report recorded the incidence of endomyocarditis at post-mortem to be equivalent to that of hypertrophic cardiomyopathy.
- Endocardial fibroelastosis—congenital heart disease in which severe fibrous endocardial thickening leads to heart failure secondary to diastolic and systolic failure.
- Excessive moderator bands (EMBs)—a rare and unique pathologic disease. Moderator bands are normal muscular bands in the right ventricle, but they can sometimes occur in the left ventricle.

SIGNALMENT

- Cats.
- Endomyocarditis—predominantly males (62%) age 1–4 years.
- Endocardial fibroelastosis—early development of biventricular or left heart failure, usually prior to 6 months of age.
- EMBs—can be seen in any age cat.

SIGNS

Historical Findings

Endomyocarditis

- Dyspnea following a stressful event in a young, healthy cat.
- Respiratory signs usually occur 5–21 days after the stressor.
- In one report, 73% of cases presented between August and September.

Endocardial Fibroelastosis and EMBs

- Lethargy, weakness, collapse, syncope
- Poor appetite and weight loss
- Dyspnea
- Tachypnea
- Cyanosis
- Abdominal distention
- Paresis or paralysis; signs of thromboembolic disease.

Physical Examination Findings

Endomyocarditis

- Severe dyspnea
- Occasional crackles
- May be murmur or gallop; murmur may vary in intensity
- May be evidence of thromboembolic disease
- Typically no significant abnormalities prior to the stressful event.

Endocardial Fibroelastosis and EMB

- Gallop
- Systolic murmur, possible mitral regurgitation
- Dyspnea and increased lung sounds or crackles

- Paresis or paralysis with weak or absent femoral pulses.
- Arrhythmias possible.

CAUSES & RISK FACTORS

- Cause unknown for all three diseases.
- Risk factors for endomyocarditis include stressful incidents such as anesthesia (commonly associated with neutering or declawing), vaccination, relocation, or bathing.
- Endocardial fibroelastosis may be familial in Burmese and Siamese cats.
- The appearance of EMBs in a young cat would suggest a congenital malformation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other Causes of Cardiac Disease

Hypertrophic cardiomyopathy, unclassified cardiomyopathy, restrictive cardiomyopathy, dilated cardiomyopathy, congenital heart malformations.

Other Causes of Dyspnea

- Other forms of cardiac disease, hypertrophic cardiomyopathy, unclassified cardiomyopathy, restrictive cardiomyopathy, dilated cardiomyopathy, congenital malformations
- Primary respiratory disease
- Pleural space disease
- Mediastinal disorders, infection, trauma, neoplasia
- Hemoglobin disorders, anemia, methemoglobinemia, causes of central cyanosis.

Other Causes of Collapse, Weakness, or Syncope

- Arrhythmias
- Neurologic or musculoskeletal disease
- Metabolic disease or electrolyte disorders
- Other forms of paresis or paralysis
- Arterial thromboembolism secondary to any form of cardiac disease or neoplasia
- Neurologic or musculoskeletal disease
- Neoplasia.

CBC/BIOCHEMISTRY/URINALYSIS

Not diagnostic

OTHER LABORATORY TESTS

N/A

IMAGING

Thoracic Radiographic Findings for All Three Diseases

- Cardiomegaly
- Interstitial or alveolar infiltrates or pleural effusion if congestion has developed.

Echocardiographic Findings

Endomyocarditis

- Normal to mildly large left atrium
- Left ventricular wall thickness can be normal to mildly thick (0.6–0.7 cm)

- Hyperechoic endomyocardium reported—incidence seems to vary and is subjective; in one report it was as high as 86%.

Endocardial Fibroelastosis

- Limited data available
- Reduced left ventricular function and enlarged left atrium.

Excessive Moderator Bands

- Many findings can overlap restrictive cardiomyopathy. A network of false tendons can sometimes be imaged with two-dimensional echocardiography.

DIAGNOSTIC PROCEDURES

Electrocardiographic Findings

- Endomyocarditis—sinus tachycardia common; ventricular premature complexes, atrial premature complexes, bundle branch block, and complete AV block reported.
- Endocardial fibroelastosis—evidence for left-sided enlargement; sinus rhythm typically present, but various arrhythmias possible.
- EMBs—various electrocardiographic findings have been reported: AV block, sinus bradycardia, right bundle branch block, and left axis deviation.

PATHOLOGIC FINDINGS

Endomyocarditis

- Interstitial pneumonia.
- Left heart enlargement and opacity of the left ventricular endomyocardium with foci of hemorrhage; fibroplasia of the endocardium is striking.
- Varying degrees of endomyocardial inflammation with infiltrates of neutrophils, lymphocytes, plasma cells, histiocytes, and macrophages seen histologically.

Endocardial Fibroelastosis

- Left ventricular and atrial dilation with severe diffuse white opaque thickening of the endocardium.
- Diffuse hypocellular, fibroelastic thickening of the endomyocardium; prominent endomyocardial edema with dilation of lymphatics.

Excessive Moderator Bands

- Changes typically include an irregular left ventricular endocardial contour with a rounded apex and numerous irregular left ventricular false tendons. Heart weights can be greater than normal. The moderator bands are composed of central Purkinje fibers and collagen.

TREATMENT

ENDOMYOCARDITIS

- No single therapy protocol to date.
- Small percentage of cats have survived; these cats are not on long-term therapy.
- Supportive care with oxygen and possibly ventilation.

(CONTINUED)

ENDOMYOCARDIAL DISEASES—CATS**ENDOCARDIAL FIBROELASTOSIS AND EMBS**

- Oxygen therapy via cage delivery is least stressful.
- Thoracocentesis if pleural effusion.

**MEDICATIONS****DRUG(S) OF CHOICE***Endomyocarditis*

Steroids, furosemide, and vasodilators have been tried, but efficacy is still unknown.

*Endocardial Fibroelastosis and EMB**Acute CHF*

- Parenteral administration of furosemide, 0.5–1 mg/kg IV or IM, q1–6h.
- Dermal application of 2% nitroglycerin ointment, one-eighth to one-fourth inch q4–6h.
- Arrhythmias may resolve with stabilization. If there is rapid atrial fibrillation (heart rate > 200), a calcium channel blocker or beta-blocker can be given to help control the ventricular response. If there is dilated cardiomyopathy, digoxin may be a better choice for controlling the atrial fibrillation rate. For other supraventricular arrhythmias and ventricular arrhythmias, waiting for a response to heart failure therapy may be wise before starting antiarrhythmic therapy.
- Intractable edema—nitroprusside, 1–5 µg/kg/minute, may be helpful.

Chronic CHF

- Treat as other CHF, with furosemide and enalapril.
- Digoxin can be added when patient is stable and eating.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

**FOLLOW-UP****EXPECTED COURSE AND PROGNOSIS**

- Endomyocarditis—poor, although some animals survive; animals that survive respiratory phase may progress to left ventricular endocardial fibrosis.
- Endocardial fibroelastosis and EMBS—medical treatment of CHF may prolong life, but recovery is unlikely.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- Aortic thromboembolism.
- Relationship possible between endomyocarditis and left ventricular endocardial fibrosis.

SEE ALSO

- Aortic Thromboembolism
- Congestive Heart Failure, Left-Sided
- Congestive Heart Failure, Right-Sided
- Myocarditis

ABBREVIATIONS

- AV = atrioventricular
- CHF = congestive heart failure
- EMB = excessive moderator band

ENTROPION

BASICS

OVERVIEW

- Inversion of part or all of one or more eyelid margins.
- Frictional irritation of the cornea, because of contact by the eyelashes or eyelid hair, may result in corneal ulceration or perforation or pigmentary keratitis.
- Ophthalmic system (vision may be threatened).

SIGNALMENT

- Common in dogs; occasionally seen in cats.
- Cats—usually seen in brachycephalic breeds (e.g., Persian and Himalayan).
- Dogs—seen in chow chow, shar-pei, Norwegian elkhound, sporting breeds (e.g., spaniel, retriever), brachycephalic breeds (e.g., English bulldog, pug, Pekingese), toy breeds (e.g., poodle, Yorkshire terrier), and giant breeds (e.g., mastiff, Saint Bernard, Newfoundland).
- Age—seen in puppies as early as 2–6 weeks old (especially chow chow and shar-pei); usually identified in dogs < 1 year old; may be seen in any age cat.

SIGNS

- Depends on type and degree of condition.
- Mild, medial—chronic epiphora and medial pigmentary keratitis (toy dogs and brachycephalic dogs and cats).
- Mild, lateral—chronic mucoid to mucopurulent ocular discharge (giant-breed dogs).
- Upper lid, lower lid, or lateral canthal—severe blepharospasm, purulent discharge, pigmentary or ulcerative keratitis, and potential cornea rupture (chow chows, shar-peis, bloodhounds, and sporting breeds).

CAUSES & RISK FACTORS

- Primarily genetic predisposition based on facial conformation and eyelid support.
- Brachycephalic breeds (dogs and cats)—excessive tension on the ligamentous structures of the medial canthus coupled with nasal folds and facial conformation defects results in rolling inward of the medial aspects of the upper and lower eyelids at the medial canthus.
- Giant breeds and breeds with heavy/loose facial skin (bloodhounds) or excessive facial folds (chow chows, shar-peis)—laxity of the lateral canthal ligamentous structures allows for entropion of the upper and lower eyelids and the lateral canthus.
- Chronic infectious conjunctivitis or keratitis (cats)—may lead to functional entropion caused by chronic blepharospasm (spastic entropion).
- Predisposed breeds (dogs)—spastic entropion, if ocular irritation (e.g., distichia, ectopic cilia, trichiasis, foreign body, and irritant conjunctivitis) leads to excessive blepharospasm.
- Non-predisposed breeds—may be the result of a primary irritant causing secondary spastic entropion.

- Severe weight loss or muscle atrophy caused by masticatory myositis (dogs)—loss of orbital fat or periorbital musculature may lead to enophthalmos and entropion.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Usually obvious clinically—underlying causes of spastic entropion (lash anomalies, foreign bodies, infectious keratitis/conjunctivitis) should be ruled out and corrected, if possible, before an attempt at surgical correction is made.
- Puppies—common for first-time breeders of chows and shar-peis to mistakenly think that the eyelids have not opened at 4–5 weeks of age, when puppies actually have severe blepharospasm and spastic entropion.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Application of a topical anesthetic may reduce spastic component and allow for differentiation of spastic versus physiologic entropion.

TREATMENT

PUPPIES

- Young (especially shar-peis and chows)—do NOT initially perform skin resection surgery.
- If cornea is ulcerated—topical antibiotic (e.g., neomycin/polymyxin B/bacitracin) ointment q6–8h.
- If mildly entropic and cornea not ulcerated, lubricate with artificial tear ointment q8–12h.
- If moderate to severe entropion, temporarily evert eyelid margins with sutures to try to break the spasm-irritation-spasm cycle; if successful, permanent procedure is unnecessary. May need to be repeated every 2–4 weeks until an adult facial conformation is achieved.
- Permanent skin resection technique—postponed until patient's facial conformation matures (usually 6 months of age in most breeds), as this increases success rates.

MEDIAL ENTROPION

- Temporary eversion of the medial canthus with sutures may aid in determining the contribution of medial entropion to epiphora in toy dog breeds and brachycephalic dogs/cats.
- Medial canthal reconstruction should be performed if the entropion results

in pigmentary keratitis, chronic epiphora, or corneal scarring.

MATURE DOGS AND CATS

- Chronic entropion—requires some type of eyelid margin—everting surgery; ranges from simple Hotz-Celsius procedure or more radical lateral canthoplasty procedures.
- No history of previous entropion and clinical signs of acute condition—examine meticulously for cause of spastic condition and correct; may attempt a temporary eversion suture technique before performing permanent skin resection, if necessary.

MEDICATIONS

DRUG(S)

- Topical ophthalmic ointment—triple antibiotic or antibiotic based on culture and sensitivity testing of corneal ulcer bed/conjunctival surfaces; q6–12h; may be used if the cornea is ulcerated, postoperatively, or as a presurgical lubricant.
- Topical petrolatum-based artificial tear ointments (Duratears, Puralube, or Lacrilube) q8–12h may be used temporarily in mild cases in which the cornea is not ulcerated.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

Temporary eversion suture technique—entropion may revert when sutures are removed or spontaneously pull through the skin; repeat as necessary until the patient is mature enough to undergo a more permanent form of skin resection repair (approximately 6 months of age).

EOSINOPHILIC GRANULOMA COMPLEX

BASICS

DEFINITION

- Cats—also called feline eosinophilic skin disease; often confusing term for four distinct syndromes: eosinophilic plaque, eosinophilic granuloma, indolent ulcer, and allergic miliary dermatitis; grouped primarily according to their clinical similarities, their frequent concurrent (and recurrent) development, and their positive response to corticosteroids.
- Dogs—eosinophilic granuloma in dogs (EGD) rare; not part of a disease complex; specific differences from cats listed separately.

PATHOPHYSIOLOGY

- Eosinophilic plaque—hypersensitivity reaction, most often to insects (fleas, mosquitos); less often to food or environmental allergens; exacerbated by mechanical trauma; often associated with secondary bacterial infection.
- Eosinophilic granuloma—multiple causes, including genetic predisposition and hypersensitivity.
- Indolent ulcer—may have both hypersensitivity and genetic causes; often associated with secondary bacterial infection.
- Allergic miliary dermatitis—very common hypersensitivity reaction, most often to fleas.
- Eosinophil—major infiltrative cell for eosinophilic granuloma, eosinophilic plaque, and allergic miliary dermatitis, but not indolent ulcer; leukocyte located in greatest numbers in epithelial tissues; most often associated with allergic or parasitic conditions, but has a more general role in the inflammatory reaction.
- EGD—may have both a genetic predisposition and a hypersensitivity cause (especially in non-genetically susceptible breeds).

SYSTEMS AFFECTED

Skin/Exocrine

GENETICS

- Related affected individuals and disease development in a colony of specific pathogen-free cats indicate that genetic predisposition (possible inheritable dysfunction of eosinophilic regulation) is a significant component for development of eosinophilic granuloma and indolent ulcer.
- Genetically predisposed development of hypersensitivity.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Seasonal incidence in some geographic locations—Insect or environmental allergen exposure.

SIGNALMENT

Species

- Cats—eosinophilic granuloma and plaque, indolent ulcer, allergic miliary

dermatitis. • Dogs and cats—eosinophilic granuloma.

Breed Predilections

- Cats—none. • Dogs—EGD: Siberian husky (76% of cases), Cavalier King Charles spaniel, possibly German shepherd dog.

Mean Age and Range

- Eosinophilic plaque—2–6 years of age
- Genetically initiated eosinophilic granuloma—< 2 years of age
- Allergic disorder—> 2 years of age
- Indolent ulcer—no age predisposition reported
- EGD—usually < 3 years of age

Predominant Sex

- Cats—predilection for females reported
- EGD—males (72% of cases)

SIGNS

General Comments—Cats

• Distinguishing among the syndromes depends on both clinical signs and histopathologic findings. • Lesions of more than one syndrome may occur simultaneously.

Historical Findings—Cats

- Lesions of all four syndromes may develop spontaneously and acutely.
- Development of eosinophilic plaques may be preceded by periods of lethargy.
- Seasonal incidence possible (related to insects and allergy).
- Waxing and waning of clinical signs common in all four syndromes.

Physical Examination Findings

- Eosinophilic plaque—alopecic, erythematous, erosive patches or well-demarcated, steep-walled plaques; usually occur in the inguinal, perineal, lateral thigh, ventral abdomen, and axillary regions; frequently moist or glistening; may appear striated due to pattern of licking; regional lymphadenopathy common.
- Eosinophilic granuloma—five, occasionally overlapping presentations:
 - Distinctly linear orientation (linear granuloma) on the caudal thigh.
 - Individual or coalescing plaques located anywhere on the body; ulcerated with a “cobblestone” or coarse pattern; white or yellow, possibly representing collagen degeneration.
 - Lip margin and chin swelling (“pouting”).
 - Footpad swelling, pain, and lameness (more common in cats under 2 years of age).
 - Oral cavity ulcerations (especially on the tongue, palate, and palatine arches); cats with oral lesions may be dysphagic, have halitosis, and may drool.
- Spontaneous regression—especially in young cats with the inheritable form.
- Allergic miliary dermatitis—multiple brown/black crusted and erythematous papules; lesions more often palpated than visualized; may be associated with alopecia; usually associated with pruritus; frequently affects the dorsum.
- Indolent ulcer—classically concave and indurated ulcerations with a granular, orange-yellow color, confined to the upper lips adjacent to the philtrum; affected cats are

rarely painful or pruritic.

- EGD—ulcerated plaques and masses; dark or orange color; most often affects the tongue and palatine arches; uncommon cutaneous lesions on the digits, prepuce and flanks.
- Cavalier King Charles spaniels—lesions on the soft palate or near the tonsils.

CAUSES

- Hypersensitivity—flea or insect (mosquito bite), food hypersensitivity, and atopy; a heritable dysfunction of eosinophil proliferation has been proposed.
- EGD—unknown; genetics in susceptible breeds; a hypersensitivity reaction often suspected (insect bite) in non-genetically susceptible breeds.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Includes the other diseases in the complex.
- Herpes virus dermatitis.
- FeLV or FIV.
- Unresponsive lesions—pemphigus foliaceus, dermatophytosis and deep fungal infection, demodicosis, pyoderma, and neoplasia (metastatic adenocarcinoma, squamous cell carcinoma, and epitheliotrophic lymphoma).
- EGD—neoplasia, histiocytosis, infectious and non-infectious granuloma, trauma.

CBC/BIOCHEMISTRY/URINALYSIS

CBC—mild to moderate eosinophilia

OTHER LABORATORY TESTS

FeLV and FIV—pruritic diseases associated with these viruses

DIAGNOSTIC PROCEDURES

- Impression smears from lesions—large numbers of eosinophils.
- Comprehensive flea and insect control—assist in excluding flea or mosquito bite hypersensitivity.
- Food-elimination trial and provocation—appropriate in all cases.
- Atopy—intradermal skin testing (preferred); serum allergy testing if intradermal testing not available; followed by immunotherapy.

PATHOLOGIC FINDINGS

- Histopathologic diagnosis—required for distinguishing the syndromes.
- Eosinophilic plaque—severe epidermal and follicular spongiosis and mucinosis with eosinophilic exocytosis; intense perivascular to diffuse dermal eosinophilic infiltrate; eroded or ulcerated epidermis.
- Eosinophilic granuloma—distinct foci of eosinophilic degranulation and collagen degeneration similar to granuloma formation (“flame figures”); keratinocyte apoptosis associated with eosinophils; eroded, ulcerated, and exudative acanthotic epidermis.
- Indolent ulcer—severe ulceration of the epidermis or mucosa with eosinophilic degranulation at the level of necrosis; fibrosing dermatitis and neutrophilic inflammation; significant

EOSINOPHILIC GRANULOMA COMPLEX

(CONTINUED)

eosinophilic infiltration unusual. • Allergic miliary dermatitis—discrete foci of epidermal erosion and necrosis with brightly eosinophilic crusts; dermal perivascular to interstitial eosinophil-rich infiltrate. • EGD—foci of palisading granulomas and flame figures surrounding collagen fibers; infiltrate with eosinophils mixed with macrophages, mast cells, plasma cells, and lymphocytes.

TREATMENT

APPROPRIATE HEALTH CARE

- Most patients treated as outpatients unless severe oral disease prevents adequate fluid intake.
- Identify and eliminate offending allergen(s) before providing medical intervention.
- Atopy: hyposensitization of intradermal skin-test-positive cats—successful in a majority of cases; preferable to long-term corticosteroid administration.

NURSING CARE

Discourage patient from damaging lesions by excessive grooming.

ACTIVITY

No restrictions

DIET

No restrictions unless a food allergy is suspected. Elimination diet—suspected food allergy.

CLIENT EDUCATION

- Inform clients about the possible allergic or heritable causes.
- Discuss the waxing and waning nature of these diseases.

SURGICAL CONSIDERATIONS

EGD—individual lesions may be excised if being mechanically traumatized and medically unresponsive.

MEDICATIONS

DRUG(S) OF CHOICE

- Cases may improve with antibiotics: cephalaxin 22 mg/kg q12h, amoxicillin trihydrate-clavulanate 12.5 mg/kg q12h, or clindamycin 11 mg/kg q24h.
- Injectable methylprednisolone 20 mg/cat, repeat in 2 weeks (if needed—maximum two injections); most common treatment; steroid tachyphylaxis common with repeated injections; not advised for long-term therapy.
- Oral corticosteroids—ongoing treatment necessary unless the primary cause is controlled; prednisolone (2–4 mg/kg q48h

then as required to control lesions); steroid tachyphylaxis may occur and may be specific to the drug administered; may be useful to change the form; other drugs: dexamethasone (0.1–0.2 mg/kg q24–72h) and triamcinolone (0.1–0.2 mg/kg q24–72h); higher induction dosages may be required but should be tapered as quickly as possible.

- Cyclosporine 7 mg/kg q24–48h.
- Topical: fluocinolone/DMSO (Synotic lotion) to individual lesions; not practical and/or may cause systemic effects in patients with large numbers of lesions.

Alternate Therapies

- Chlorambucil 0.1–0.2 mg/kg q48–72h.
- Doxycycline 5–10 mg/kg q24h.
- α -interferon 300–1000 IU/day; limited success.
- Megestrol acetate 2.5–5 mg every 2–7 days; significant incidence of side effects (e.g., diabetes, mammary cancer) preclude use in all but severe, recalcitrant cases.

EGD

- Oral prednisolone 0.5–2.2 mg/kg/day initially; then taper gradually.
- Intralesional corticosteroids 5 mg/lesion methylprednisolone.
- Cessation of therapy without recurrence is common.

FOLLOW-UP

PATIENT MONITORING

- Corticosteroids—baseline and frequent hemograms, serum chemistry profiles, and urinalyses with culture; excessive or too-frequent use of corticosteroids increases risk for development of diabetes mellitus and acquired skin fragility.
- Cyclosporine—baseline and frequent hemograms, serum chemistry profiles, and urinalyses with culture; measurement of plasma cyclosporine levels as needed to establish dosage within therapeutic levels (especially cats).
- Selective immunosuppressant drugs—frequent hemograms (biweekly at first, then monthly or bimonthly as therapy continues) to monitor for bone marrow suppression; routine serum chemistry profiles and urinalyses with culture (monthly at first, then every 3 months) to monitor for complications (renal disease, diabetes mellitus, and urinary tract infection).

EXPECTED COURSE AND PROGNOSIS

- Lesions should resolve permanently if a primary cause can be identified and controlled.
- Most lesions wax and wane, with

or without therapy; an unpredictable schedule of recurrence should be anticipated.

- Drug dosages should be tapered to the lowest possible level (or discontinued, if possible) once the lesions have resolved.
- Lesions in cats with the inheritable disease may resolve spontaneously after several years.
- EGD—lesions may be recalcitrant to medical intervention.

MISCELLANEOUS

PREGNANCY/FERTILITY/BREEDING

Systemic glucocorticoids and immunosuppressive drugs should not be used during pregnancy.

SYNONYMS

- Eosinophilic granuloma—feline collagenolytic granuloma; feline linear granuloma.
- Indolent ulcer—eosinophilic ulcer; rodent ulcer; feline upper lip ulcerative dermatitis.

SEE ALSO

- Atopic Dermatitis
- Food Reactions, Dermatologic

ABBREVIATIONS

- EGD = eosinophilic granulomas in dogs
- FeLV = feline leukemia virus
- FIV = feline immunodeficiency virus

available online**

EPIDIDYMITIS/ORCHITIS**BASICS****OVERVIEW**

- Epididymitis—inflammation of the epididymis; most significant and severe clinical sign of brucellosis.
- Orchitis—inflammation of the testis.
- May be acute or chronic.
- Direct trauma to the scrotum—most common cause of acute form.
- May occur separately or concurrently (orchiepididymitis); extension into the vaginal tunics possible (periorchiepididymitis).

SIGNALMENT

- Not uncommon in dogs; rare in cats
- No genetic basis or breed predilections
- Mean age 3.7 years; range 11 months–10 years

SIGNS

- Swollen testis
- Pain (acute)
- Licking of the scrotum—may lead to dermatitis
- Listlessness
- Anorexia
- Reluctance to walk
- Reluctance to breed
- Open wound or abscess
- Infertility
- Pyrexia

CAUSES & RISK FACTORS

- *Brucella canis*—predilection for infecting the tail of the epididymis.
- Distemper.
- Rocky Mountain spotted fever.
- Ascending infection—associated with prostatitis (especially in brucellosis) and cystitis.
- Retrograde urine contamination of the ductus deferens—sequel to high intra-abdominal pressure as caused by automobile trauma.
- Bite wounds and other puncture wounds—isolated from infected testes: *Staphylococcus*, *Streptococcus*, *Escherichia coli*, *Proteus*, and *Mycoplasma*.
- Auto-immune response to spermatozoa antigens—secondary to trauma or inflammation.
- Lymphocytic auto-immune thyroiditis and orchitis—familial in beagles.

**DIAGNOSIS****DIFFERENTIAL DIAGNOSIS**

- Inguinoscrotal hernia
- Scrotal dermatitis
- Torsion of the spermatic cord
- Hydrocele

- Sperm granuloma
- Testicular neoplasia
- Prostatitis
- Cystitis

CBC/BIOCHEMISTRY/URINALYSIS

- Leukocytosis—may be found with acute or infectious orchitis.
- Pyuria, hematuria, proteinuria—may be found if epididymitis/orchitis is secondary to prostatitis or cystitis.

OTHER LABORATORY TESTS

- *B. canis* antibodies—perform immediate testing in any dog with scrotal enlargement (see Brucellosis).
- Rapid slide agglutination test—used as a screen; sensitive but not specific (D-Tec® CB, Zoetis, (888)-963-8471).
- If positive results—recommend recheck by an agar gel immunodiffusion test (Cornell University Diagnostic Laboratory, (607)253-3900) or bacterial culture of whole blood or lymph node aspirate.

IMAGING

- Ultrasonographic evaluation of the prostate—guided aspiration for cytologic examination and bacterial culture.
- Ultrasonographic evaluation of the testes and epididymides—inflamed testes have patchy hypoechoic areas; inflamed epididymides have irregular contours and hypoechoic or hyperechoic areas; obtain measurements for future comparisons.

DIAGNOSTIC PROCEDURES

- Semen—collect if possible; cytologic evaluation; bacterial culture.
- Cytology (semen)—leukocytes; bacteria; spermatozoa with coiled tails, detached heads, and retained proximal and distal cytoplasmic droplets; head-to-head agglutination (*B. canis*).
- Prostatic massage—cytologic examination; bacterial culture; sample collected aseptically by urethral catheter.
- Open wounds—bacterial culture.
- Fine-needle aspirate—sample enlarged testes/epididymides for cytology and culture; leukocytes vary from numerous neutrophils (suppurative) to minimal inflammatory cells (granulomatous).
- Postmortem diagnosis—bacteria can be isolated from the non-gravid pregestational uterus and spleen in bitches, and the prostate gland in male dogs.

**TREATMENT**

- If fertility is not a concern—culture appropriate specimen; medically stabilize; administer needed antibiotics preoperatively to avoid scirrhouss cord; castrate.

- If fertility is a concern (unilateral orchitis)—unilateral castration when the patient's future as a sire must be maintained; administer appropriate antibiotics preoperatively.

**MEDICATIONS****E****DRUG(S)**

- Antibiotics—Brucellosis.
- Combined regimes generally more successful; if culture and sensitivity is available, use appropriate antibiotics; treatments may fail to completely eliminate the bacteria; therefore, reproductive sterilization is strongly recommended.
- Reported success with doxycycline (10 mg/kg PO q12h), gentamicin (5 mg/kg SC q24h for 7 days and repeated every 3 weeks), rifampin (5 mg/kg PO q24h), enrofloxacin (5 mg/kg PO q12h) for 1–3 months.

CONTRAINdicATIONS/POSSIBLE INTERACTIONS

N/A

**FOLLOW-UP**

- Prognosis for fertility—guarded to poor, especially with bilateral orchitis.
- Testicular heating causes testicular degeneration—degeneration in contralateral testis can result from primary disease or from elevated intrascrotal temperature following unilateral castration.
- Trauma or inflammation can cause obstruction of efferent tubules or epididymal duct, leading to spermatocele or sperm granuloma.
- Semen (dogs)—evaluate characteristics 3 months after treatment for orchitis is completed.

Author Carlos R.F. Pinto

Consulting Editor Sara K. Lyle

EPILEPSY, GENETIC (IDIOPATHIC)—DOGS

BASICS

DEFINITION

Syndrome that is only epilepsy, with no demonstrable underlying brain lesion or other neurologic signs or symptoms; age-related; assumed genetic. The term 'idiopathic' replaced by 'genetic' according to the ILAE classification. (See Appendix VIII.)

PATHOPHYSIOLOGY

- Exact mechanism unknown.
- Likely different mechanisms between breeds.

SYSTEMS AFFECTED

Nervous

GENETICS

Genetic basis suspected in Australian shepherd, beagle, Belgian shepherd (Groenendael and Tervuren), Bernese mountain dog, border collie, dachshund, English springer spaniel, Finnish Spitz, German shepherd, golden retriever, Keeshond, Irish wolfhound, Italian spinone, Labrador retriever, Shetland sheepdog, standard poodle, vizsla.

INCIDENCE/PREVALENCE

0.5–2.3% of all dogs

GEOGRAPHIC DISTRIBUTION

Widespread

SIGNALMENT

Species

Dog

Breed Predilections

Beagles; all shepherds (German, Australian, Belgian); Bernese mountain dogs; boxers; cocker spaniels; border collies; dachshunds; golden retrievers; Irish setters; Labrador retrievers; poodles (all sizes); Saint Bernards; Shetland sheepdogs; Siberian huskies; springer spaniels; Welsh corgis; wirehaired fox terriers. Can occur in any breed.

Mean Age and Range

- Mean age 10 months–3 years
- Range 6 months–5 years

Predominant Sex

Male predisposition in Bernese mountain dog.

SIGNS

General Comments

• Seizures may be generalized (convulsive) from onset, or have a short aura (focal onset) with rapid secondary generalization. • An aura (animal appears frightened, dazed, seeks attention, or hides, etc.) frequently precedes the generalized seizure. • Focal seizures reported in the border collie, Finnish spitz dog, English springer spaniel, Labrador retriever, vizsla, Belgian shepherd, standard poodle.

Historical Findings

- First seizure—between 6 months and 5 years.
- Seizures—often when patient is

resting or asleep; often at night or early morning; frequency tends to increase if left untreated; affected animal falls on its side, becomes stiff, chomps its jaw, salivates profusely, urinates, defecates, vocalizes, and paddles with all limbs in varying combinations. Short duration (30–90 seconds). • Postictal behavior—confusion, disorientation; aimless, compulsive, blind, pacing; frequent polydipsia and polyphagia; recovery immediate or may take up to 24 hours. • Dogs with established epilepsy might have clustered generalized seizures at intervals of 1–4 weeks. • No asymmetry should be observed during seizure, e.g., twitching more pronounced on one side, limb contractions on one side, compulsive circling just prior or after the seizure. • Stimulus-induced seizures: seizures only upon specific stimulus (sound, event).

Physical Examination Findings

- Patients often have recovered at time of presentation.
- Patients may have postictal behavior.

CAUSES

Genetic in some breeds; of unknown cause in others.

RISK FACTORS

Known epilepsy in the family line

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Seizure pattern (breed, age at onset, type and frequency of seizures)—most important factor toward diagnosis.
- Acute onset of cluster seizures or status epilepticus—rule out toxicity or structural brain disease.
- > 2 seizures within the first week of onset—consider diagnosis other than genetic epilepsy.
- Seizures at < 6 months or > 5 years of age—consider metabolic, or intracranial structural disease; rule out hypoglycemia in older dogs.
- Focal seizures, or presence of neurologic deficits—rule out intracranial structural disease.

CBC/BIOCHEMISTRY/URINALYSIS

- Usually normal
- Perform before initiating drug therapy as baseline data.

OTHER LABORATORY TESTS

Bile acids to rule out hepatic encephalopathy unnecessary in dogs with seizures without accompanying episodic abnormal behavior.

IMAGING

MRI—if seizure pattern does not fit genetic (idiopathic) epilepsy, neurologic deficits are present, or intracranial structural disease is suspected.

DIAGNOSTIC PROCEDURES

- CSF—for suspected structural intracranial diseases.
- Electroencephalography—may see

interictal spikes, polyspikes, and spike slow wave complexes.

PATHOLOGIC FINDINGS

- No primary lesion.
- Secondary neuronal loss and gliosis from prolonged seizures.

TREATMENT

APPROPRIATE HEALTH CARE

- Outpatient—recurrence of isolated seizures.
- Inpatient—for cluster seizures (> 1 seizure q24h) or status epilepticus.

NURSING CARE

Inpatients with seizure disorders require constant monitoring.

DIET

- Dogs on chronic PB and KBr treatment often become overweight; weight-reducing program as necessary.
- KBr treatment—insure steady levels of salt in diet; an increase in salt causes an increase in bromide excretion preferentially over chloride, with subsequent decreased serum KBr levels. Alternatively, a decrease salt content increases KBr serum level.
- Trial with high-fat, low-carbohydrate diet—no improvement in seizure control.

CLIENT EDUCATION

- Severe cluster seizures and status epilepticus are life-threatening emergencies requiring immediate medical attention.
- Keep a seizure calendar noting date, time, length, and severity of seizures to assess response to treatment.
- Once treatment instituted, medication is life-long in most cases.
- Abrupt drug withdrawal may cause seizures.

MEDICATIONS

DRUG(S) OF CHOICE

- Initiate treatment at second generalized seizure if dog < 2 years; when interictal period gradually shortens in the others.
- Antiepileptic treatment—decreases frequency, severity, and length of seizures; perfect control rarely achieved.
- Tolerance and refractoriness to treatment may develop.

Phenobarbital

- Most efficacious AED in the dog.
- Traditional first-line drug; initial dosage 3–5 mg/kg PO q12h; steady-state reached at 12–15 days but levels decrease significantly in the first 6 months owing to activation of lysosomal enzymes.
- Optimal therapeutic serum levels—100–120 µmol/L or 23–28 µg/mL.
- Oral loading dose (if needed)—6–10 mg/kg PO q12h for 2–3 days to reach therapeutic range rapidly.

Zonisamide

- First-line drug when seizure frequency allows (< 1/week); 5 mg/kg PO q12h; 10 mg/kg PO q12h as add-on to PB; half-life

(CONTINUED)

EPILEPSY, GENETIC (IDIOPATHIC)—DOGS

E

15 hours; steady state 4 days; therapeutic range in human 10–45 µg/mL.

Levetiracetam

- First-line drug when seizures have focal onset; < 1 seizure/week; 20 mg/kg PO q8h; must be given q8h to reach adequate levels; no hepatic metabolism; safe; steady state 3 days; therapeutic range in human 10–40 µg/mL.

Potassium Bromide

- Traditional first-line drug; initial dosage 30 mg/kg PO q24h or divided q12h; half-life 24–46 days; steady-state 3–4 months; varies with salt concentration in diet; bioavailability differs between dogs.
- Optimal therapeutic serum levels—20–25 mmol/L or 1.6–2 mg/mL; if sole antiepileptic drug, 25–32 mmol/L or 2–2.25 mg/mL can be safely used.
- Add-on to PB if seizures uncontrolled with optimal PB level—beneficial and synergistic effect.
- Loading dose—may cause vomiting, diarrhea, profound longstanding sedation; if needed, double daily PO doses for 2 weeks.
- Renal insufficiency decreases bromide elimination; half initial dosage.

Diazepam (At-Home Use)

- To abort ongoing seizures—dogs with cluster seizures or status epilepticus.
- Insert 0.5–1 mg/kg injectable drug in rectum via 1-inch teat cannula as soon as a seizure occurs; repeat 20 and 40 minutes later for a total of 3 insertions within 40 minutes; can be safely repeated once more in a 24-hour period.
- Given early in the course of ongoing seizures, help abort subsequent seizures.

CONTRAINDICATIONS

Aminophylline, theophylline

PRECAUTIONS

α -adrenergic agonists (e.g., phenylpropanolamine)—central nervous system excitation

POSSIBLE INTERACTIONS

- Cimetidine and chloramphenicol—interfere with PB metabolism; may cause toxic PB levels.
- PB lowers serum levels of zonisamide and levetiracetam.
- PB may lower T₄ and cause an upward trend in TSH without signs of hypothyroidism.
- PB does not interfere with low-dose dexamethasone suppression tests regardless of dose and treatment.
- Zonisamide decreases total T₄.
- Whenever animals on lifetime medication, refer to manufacturer's drug profile or to a pharmacist for interaction information.

ALTERNATIVE DRUG(S)

- With polypharmacy, initiate add-on gradually to avoid sedation.
- Gabapentin 10–20 mg/kg PO q8h; low efficacy as add-on.
- Newer analog pregabalin may be more efficacious (2–4 mg/kg q8h PO).
- Clorazepate 0.5–1 mg/kg PO q8h.
- Felbamate 30–70 mg/kg q12h–8h.
- Topiramate 2–10 mg/kg PO q12h.
- Phenytoin, valproic acid, carbamazepine, and ethosuximide—unsuitable

pharmacokinetics in dogs.

- Others—acupuncture, vagal nerve stimulation, transcranial magnetic motor stimulation.

**FOLLOW-UP****PATIENT MONITORING**

- Serum drug levels—preferentially at trough, at same time for each sampling; use same laboratory.
- Phenobarbital—measure PB level 4 weeks after initiating therapy; adjust dose as needed; then repeat level every 2 weeks until optimal levels reached; with chronic use perform CBC, biochemistry, and PB level every 6–12 months; tabulate albumin, liver enzymes and serum drug levels to monitor trend; drug essentially hepatotoxic; most dogs eventually develop hepatotoxicity if serum levels > 140 µmol/L (> 33 µg/mL) for long time (> 6–8 months). If hepatotoxicity suspected, perform bile acids.
- KBr—serum level (along with PB level) 4–6 weeks after initiating (should be 8–12 mmol/L or 0.5–1 mg/mL) and at 3–4 months. If diet change required, consider diet salt content; monitor level accordingly. Monitor KBr level closely if renal insufficiency (isosthenuria or azotemia).
- Zonisamide—measure level at 1 week. Monitor electrolytes and acid-base status to check for renal tubular acidosis.
- Levetiracetam—measure level at 4 days.

PREVENTION/AVOIDANCE

- Abrupt discontinuation of medication may precipitate seizures.
- Avoid salty treats in dogs treated with KBr.

POSSIBLE COMPLICATIONS

- Recurrent episodes of cluster seizures and status epilepticus.
- PB and KBr—polyuria, polydipsia, polyphagia, weight gain.
- Phenobarbital-induced C-AP occurs frequently; may be an early sign of hepatotoxicity but of less concern if ALT is within reference range.
- Phenobarbital-induced hepatotoxicity—after chronic treatment at high serum levels (> 140 µmol/L or > 33 µg/mL); often insidious in onset; only biochemical abnormality may be a decreased albumin.
- Higher incidence of pancreatitis in patients treated with PB and/or KBr; once pancreatitis develops, recurrence is frequent.
- Phenobarbital—rare bone marrow suppression with severe neutropenia (\pm sepsis) early in the course of treatment; discontinue drug.
- Paradoxical hyperexcitability; discontinue drug. Risk factor for superficial necrotolytic dermatitis.
- KBr—when levels are > 22 mmol/L or > 1.8 mg/mL, owners may complain of patient's unsteadiness while managing stairs.
- Zonisamide—mild sedation, decreased appetite, gastrointestinal signs.
- One case of renal tubular acidosis and one case of acute idiosyncratic hepatic necrosis reported.
- Levetiracetam—transient sedation.

EXPECTED COURSE AND PROGNOSIS

- Treatment for life.
- Some dogs are well controlled with same drug and dosage for years; others remain poorly controlled despite polypharmacy.
- Patient may develop status epilepticus and die.
- Early treatment does not decrease occurrence of status epilepticus.
- Normal expected lifespan but survival time shorter if episodes of status epilepticus.
- Treatment with 2 AEDs not linked to poor prognosis.
- Increased risk of premature death.
- Marked breed differences in incidence and mortality rates.
- Prognosis depends on combined veterinary expertise, therapeutic success, and owner's motivation.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Idiopathic epilepsy can be a reason for euthyroid sick syndrome in dogs.

AGE-RELATED FACTORS

If onset < 2 years of age, epilepsy more likely to be difficult to control; condition may becomes intractable.

PREGNANCY/FERTILITY/BREEDING

- Avoid breeding affected animals.
- Reported association between estrus and onset of seizures in intact bitches with presumptive 'idiopathic' epilepsy; two hormonally based patterns recognized: (1) during heat and (2) during a specific time point at the end of diestrus.

EPIPHORA

BASICS

DEFINITION

Abnormal overflow of the aqueous portion of the precorneal tear film.

E

PATHOPHYSIOLOGY

Caused by one of three common problems:

- (1) Overproduction of the aqueous portion of tears (usually in response to ocular irritation).
- (2) Poor eyelid function secondary to eyelid malformation or deformity.
- (3) Blockage of the nasolacrimal drainage system.

SYSTEMS AFFECTED

Eye and periocular skin

SIGNALMENT

See "Causes"

SIGNS

N/A

CAUSES

Overproduction of Tears Secondary to Ocular Irritants

Congenital

- Distichiasis or trichiasis—common in young shelties, shih tzus, Lhasa apsos, cocker spaniels, miniature poodles.
 - Entropion—shar-peis, chow chows, Labrador retrievers.
 - Eyelid agenesis—domestic shorthair cats.
- ###### Acquired
- Corneal or conjunctival foreign bodies—usually young, large-breed, active dogs.
 - Eyelid neoplasms—old dogs (all breeds).
 - Blepharitis—infectious or immune mediated.
 - Conjunctivitis—infectious or immune mediated.
 - Ulcerative keratitis.
 - Anterior uveitis.
 - Glaucoma.

Eyelid Abnormalities or Poor Eyelid Function

- Tears never reach the nasolacrimal puncta but instead spill over the eyelid margin.
- eyelid function does not direct tears to the medial canthus and nasolacrimal puncta.

Congenital

- Macropalpebral fissures—brachiocephalic breeds.
- Ectropion—Great Danes; bloodhounds; spaniels.
- Entropion—brachycephalic dogs—medial lower eyelid; Labrador retrievers—lateral lower eyelid.

Acquired

- Post-traumatic eyelid scarring.
- Facial nerve paralysis.

Obstruction of the Nasolacrimal Drainage System

Congenital

- Imperforate nasolacrimal puncta—cocker spaniels, bulldogs, poodles.
- Ectopic nasolacrimal openings—extra openings along the side of the face ventral to the medial canthus.
- Nasolacrimal atresia—lack of distal openings into the nose.

Acquired

- Rhinitis or sinusitis—causes swelling adjacent to the nasolacrimal duct.
- Trauma or fractures of the lacrimal or maxillary bones.
- Foreign bodies—grass awns, seeds, sand, parasites.
- Neoplasia—of the third eyelid, conjunctiva, medial eyelids, nasal cavity, maxillary bone, or periocular sinuses.
- Dacryocystitis—inflammation of the canaliculi, lacrimal sac, or nasolacrimal ducts.

RISK FACTORS

- Breeds prone to congenital eyelid abnormalities (see "Causes").
- Active outdoor dogs—at risk for foreign bodies.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other ocular discharges (e.g., mucous or purulent)—epiphora is a watery, serous discharge.
- Eye—usually red when caused by overproduction of tears; quiet when secondary to impaired outflow.
- Irritative causes and some congenital causes of obstruction—thorough ocular examination.
- Acute onset, unilateral condition with ocular pain (blepharospasm)—usually indicates a foreign body or corneal injury.
- Chronic, bilateral condition—usually indicates a congenital problem.
- Facial pain, swelling, nasal discharge, or sneezing—may indicate nasal or sinus infection; may indicate obstruction from neoplasm.
- With mucous or purulent discharge at the medial canthus—may indicate dacryocystitis.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

- Skull radiographs—may show a nasal, sinus, or maxillary bone lesion.
- Dacryocystorhinography—radiopaque contrast material to help localize obstruction.

- MRI or CT—may help localize obstruction (usually with contrast media) and characterize associated lesions.

DIAGNOSTIC PROCEDURES

- Bacterial culture and sensitivity testing and cytologic examination of the material—with purulent material at the medial canthus (e.g., dacryocystitis); performed before instilling any substance into the eye.
- Topical fluorescein dye application to the eye—most physiologic test for nasolacrimal function; should be performed first (after culture); dye flows through the nasolacrimal system and reaches the external nares in approximately 10 seconds in normal dogs.
- Nasolacrimal irrigation—see information below.
- Rhinoscopy—with or without biopsy or bacterial culture; may be indicated if previous tests suggest a nasal or sinus lesion.
- Surgical exploratory—may be the only way to obtain a definitive diagnosis.
- Temporary tacking out of the lower medial eyelid with suture—may help determine whether repair of medial lower entropion or repositioning of the eyelid would reduce epiphora secondary to eyelid conformational abnormalities.

Nasolacrimal Irrigation

- Confirms obstruction.
- May dislodge foreign material.
- A nasolacrimal cannula is inserted into the upper nasolacrimal punctum.
- Eyewash is irrigated through the cannula—if fluid does not exit the lower nasolacrimal punctum, the obstruction is in the upper or lower canaliculi, the nasolacrimal sac, or the lower punctum (imperforate).
- Lower punctum is manually obstructed—if flushed fluid does not exit the external nares, the obstruction is in the nasolacrimal duct or at its distal opening (atresia or blockage from a nasal sinus lesion).

TREATMENT

- Remove cause of ocular irritation—removal of a conjunctival or corneal foreign body; treatment of the primary ocular disease (e.g., conjunctivitis, ulcerative keratitis, and uveitis); cryosurgery or electroepilation for distichiasis, entropion correction; medial or lateral canthoplasty (for medial trichiasis and macropalpebral fissures); correction of cicatricial eyelid abnormalities.
- Treat primary obstructing lesion (e.g., third eyelid mass, nasal or sinus mass, and infection)—do initially; successful management may allow normal nasolacrimal flow to resume.

(CONTINUED)

EPIPHORA

- Warn client that patient is predisposed to nasolacrimal obstruction and that recurrence is common.
- Inform client that early detection and intervention provide a better long-term prognosis.

SURGICAL CONSIDERATIONS***Imperforate Puncta***

- Surgical opening of the puncta is indicated.
- If one of the puncta is patent (usually the upper punctum), flushing eyewash through the upper opening will cause “tenting” of the conjunctiva at the site of the lower punctum. Place patient under topical or general anesthesia. Grasp conjunctiva overlying the lower canaliculi with forceps and cut with scissors to leave a patent punctum. Puncta closed by conjunctival scarring (sympblepharon) caused by severe conjunctivitis (e.g., herpesvirus conjunctivitis in cats)—use same procedure. Recurrent disease—may be necessary to suture Silastic tubing in place to prevent stricture formation.

Obstructed or Obliterated Distal Nasolacrimal Duct

- Dacryocystorhinotomy or conjunctivorhinostomy—create an opening to drain the tears into the nasal cavity.
- See “Suggested Reading” for surgical technique.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Topical broad-spectrum antibiotic ophthalmic solutions—while awaiting diagnostic test results (e.g., bacterial culture and sensitivity testing; diagnostic radiographs); q4–6h; may try neomycin, gramicidin, polymyxin B triple ophthalmic antibiotic solution, or ophthalmic ciprofloxacin solution.
- Dacryocystitis—based on bacterial culture and sensitivity test results; continued for at least 21 days.

CONTRAINDICATIONS

- Topical corticosteroids or antibiotic—corticosteroid combinations—avoid unless a definitive diagnosis has been made.
- Topical corticosteroids—never use if the cornea retains fluorescein stain.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

Tetracycline 5 mg/kg PO q24h; may help reduce idiopathic tear staining of the periocular facial hair; staining recurs when the drug is discontinued.

**FOLLOW-UP****PATIENT MONITORING*****Dacryocystitis***

- Reevaluate every 7 days until the condition is resolved.
- Continue treatment for at least 7 days after resolution of clinical signs to help prevent recurrence.
- Problem persists more than 7–10 days with treatment or recurs soon after cessation of treatment—indicates a foreign body or nidus of persistent infection; requires further diagnostics (e.g., dacryocystorhinography).
- Nasolacrimal catheter.
- Commonly required for persistent dacryocystitis.
- Maintains patency of the duct and prevents structuring.
- Catheter—Silastic or polyethylene (PE90) tubing; left in place 2–4 weeks.
- Procedure—pass 2-0 nylon via the upper punctum and thread it through the nasolacrimal duct to exit the external nares; pass tubing retrograde over the suture; suture the upper and lower portions of the tubing to the face.
- Most dogs tolerate the tubing well, however, an Elizabethan collar may be needed to prevent self-trauma.
- Continue topical antibiotics as before.

Dacryocystorhinotomy/Conjunctivo-Rhinostomy

- Tubing—reevaluate every 7 days to ensure it remains intact; may need to resuture if it becomes loosened or dislodged.
- After tubing has been removed—reevaluate in 14 days; for this and future examinations, place fluorescein on the eye and check nasolacrimal patency by examining the external nares for fluorescein; may evaluate the nasolacrimal system further by cannulating and flushing with eyewash.
- Dacryocystorhinography contrast study—repeated 3–4 months after surgery to evaluate size of the nasal opening; repeated for recurrence or with no nasolacrimal fluorescein drainage.

POSSIBLE COMPLICATIONS

Recurrence—most common complication; caused by recurrence of ocular irritation (e.g., corneal ulceration, distichiasis, entropion), recurrence of dacryocystitis, or closure of the dacryocystorhinotomy or conjunctivorhinostomy openings into the nasal cavity.

E

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- Chronic conjunctivitis—cats
- Chronic conjunctivitis—dogs
- Recurrent eye “infections”
- Moist dermatitis (hot spots) ventral to the medial canthus
- Nasal discharge

EPISCLERITIS

BASICS

OVERVIEW

- Focal or diffuse infiltration of the episclera and/or scleral stroma by a varying mix of inflammatory cells and fibroblasts.
- Primary—affects only the eye; probably immune mediated; appears either as a perilimbal episcleral/scleral nodule (nodular episcleritis) or as a diffuse thickening of the episclera (diffuse episcleritis); nodular form may affect cornea and third eyelid with similar-appearing nodules.
- Secondary—usually diffuse; from the spillover of inflammatory cells into the episclera from other ocular disorders (e.g., endophthalmitis and panophthalmitis); may affect virtually any other organ system.

SIGNALMENT

- Dog
- Young to middle-aged collie, Shetland sheepdog

SIGNS

- Nodular—typically appears as a smooth, painless, localized, raised, pink-tan, firm episcleral/scleral mass.
- Diffuse—less common; appears as a diffuse reddening and thickening of the entire episclera/sclera; accompanied by variable amounts of ocular pain.
- Secondary—uveitis often pronounced.
- Conjunctiva—usually moves freely over the surface of the lesion.
- Nodules—tend to be slowly progressive, bilateral, and prone to recurrence.

CAUSES & RISK FACTORS

- Nodular and diffuse primary—idiopathic; believed to be immune mediated.
- Secondary—may result from deep fungal or bacterial ocular infection, lymphoma, systemic histiocytosis in Bernese mountain dogs, chronic glaucoma, and ocular trauma.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of a red eye—differentiated by careful ophthalmic examination and tonometry.
- Other mass-like lesions—differentiated by biopsy or cytologic examination.
- Neoplasia—lymphoma; squamous cell carcinoma; extension of an intraocular mass; other tumors.
- Granuloma—deep fungal infection; retained foreign body.
- Granulation tissue—trauma; healing corneal ulcer; globe perforation with uveal prolapse.

CBC/BIOCHEMISTRY/URINALYSIS

- Usually normal if the lesion is confined to eye or adnexa.
- Secondary—may see abnormalities consistent with other systemic diseases (e.g., deep fungal or systemic histiocytosis).

OTHER LABORATORY TESTS

- Rheumatoid factor, antinuclear antibody, and lupus erythematosus cell preparations—usually not helpful.
- Serologic testing—may help rule out deep fungal infection.

IMAGING

- Abdominal ultrasound or thoracic/abdominal radiographs—may help rule out deep fungal infection or disseminated neoplasia.
- Ocular ultrasound—may help reveal other ocular abnormalities if ocular media opacities prevent a thorough ocular examination.

DIAGNOSTIC PROCEDURES

- Incisional biopsy and histopathologic examination of affected tissue.
- Nodular—typified by varying numbers of histiocytes, lymphocytes, plasma cells, and fibroblasts.
- If uveitis prominent—perform a uveitis workup (see Anterior Uveitis—Dogs).

TREATMENT

- Try to verify the diagnosis histologically or cytologically before treatment.
- Primary nodular—tends to have a benign course; observation alone may be appropriate with mild disease.
- Outpatient treatment if ocular pain, diffuse scleral involvement, eyelid function is disrupted, cornea is affected, or vision threatened.

MEDICATIONS

DRUG(S)

- Progress down the list only if the previous modality was ineffective.
- Topical 1% prednisolone acetate q4h for 1 week, then q6h for 2 weeks, then tapered.
- Systemic prednisolone 1–2 mg/kg/day; tapered with improvement.
- Systemic azathioprine 1–2 mg/kg/day for 3–7 days; then tapered to as low a dosage as possible.
- Cryosurgery or attempt excision.
- Alternative to listed drugs or surgery—may try a combination of tetracycline and niacinamide (q8h PO); 250 mg each for dogs < 10 kg; 500 mg each for dogs > 10 kg; may not observe good clinical response for at least

8 weeks; side effects uncommon and primarily the result of gastrointestinal upset by niacinamide.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Avoid systemic immunosuppressive drugs with deep fungal infections.
- Systemically administered prednisolone or azathioprine—may precipitate pancreatitis; potentially hepatotoxic.
- Azathioprine—may induce potentially fatal myelosuppression.
- Niacin—do not substitute for niacinamide.

FOLLOW-UP

PATIENT MONITORING

- Primary—monitor for nodule regression or reduction in episcleral thickening or reddening every 2–3 weeks for 6–9 weeks and then as needed; prognosis usually good; may require therapy for months to rest of life.
- Secondary—follow-up, prognosis, and complications usually depend on the primary disease.
- Azathioprine—repeat CBC, platelet count, and measurement of liver enzymes every 1–2 weeks for the first 8 weeks, then periodically.

POSSIBLE COMPLICATIONS

- Vision loss
- Chronic ocular pain
- Uveitis
- Secondary glaucoma

MISCELLANEOUS

SYNOMYMS

- Collie granuloma
- Fibrous histiocytoma
- Limbal granuloma
- Necrogranulomatous sclerouveitis
- Nodular fasciitis
- Nodular granulomatous episcleritis
- Proliferative keratoconjunctivitis

Suggested Reading

Author Paul E. Miller

Consulting Editor Paul E. Miller

BASICS

DEFINITION

Bleeding from the nose

PATHOPHYSIOLOGY

Results from one of three abnormalities—coagulopathy; local disease or space-occupying lesion; vascular or systemic disease.

SYSTEMS AFFECTED

- Respiratory—hemorrhage; sneezing
- Gastrointestinal—melena
- Hemic/Lymphatic/Immune—anemia

GENETICS

Varies depending on underlying cause

INCIDENCE/PREVALENCE

Varies depending on underlying cause

SIGNALMENT

Species

Dog and cat

Age, Breed, and Sex Predilections

Varies depending on underlying cause

SIGNS

Historical Findings

- Nasal hemorrhage—unilateral or bilateral possible.
- Sneezing and/or stertorous respiration.
- Melena.
- With coagulopathy—hematochezia, melena, hematuria, or hemorrhage from other areas of the body.
- With hypertension—possibly blindness, intraocular hemorrhage, neurologic signs, cardiac or renal signs.

Physical Examination Findings

- Nasal hemorrhage.
- Melena—from swallowing blood or concurrent upper GI hemorrhage.
- Nasal stridor—may be present with neoplasia, foreign body or advanced inflammatory disease.
- With coagulopathy—possibly petechiae, ecchymosis, hematomas, intracavitory bleeds, hematochezia, melena, and hematuria.
- With coagulopathy or hypertension—possibly retinal or intraocular hemorrhages or retinal detachment; with hypertension—possibly heart murmur or arrhythmia.

CAUSES

Coagulopathy

THROMBOCYTOPENIA

- Immune-mediated disease—idiopathic disease; drug reaction; MLV vaccine reaction.
- Infectious disease—ehrlichiosis; anaplasmosis; Rocky Mountain spotted fever, babesiosis, FeLV or FIV-related illness.
- Bone marrow disease—neoplasia; aplastic anemia; infectious (fungal, rickettsial, or viral).
- Paraneoplastic disorder.
- DIC.

THROMBOPATHIA

- Congenital—von Willebrand disease; thrombasthenia; thrombopathia.
- Acquired—NSAIDs; clopidogrel;

hyperglobulinemia (*Ehrlichia*, multiple myeloma); uremia; DIC.

COAGULATION FACTOR DEFECTS

- Congenital: hemophilia A (factor VIIIc deficiency) and hemophilia B (factor IX deficiency).
- Acquired: anticoagulant rodenticide (warfarin) intoxication, hepatobiliary disease, DIC.

Local Lesion

- Foreign body.
- Trauma.
- Infection—fungal (*Aspergillus*, *Cryptococcus*, *Rhinosporidium*); viral or bacterial. Usually blood-tinged mucopurulent exudate rather than frank hemorrhage.
- Neoplasia—adenocarcinoma; carcinoma; chondrosarcoma; squamous cell carcinoma; fibrosarcoma; lymphoma; transmissible venereal tumor.
- Dental disease—oronasal fistula, tooth root abscess.
- Lymphoplasmacytic rhinitis.

Vascular or Systemic Disease

- Hypertension—renal disease; hyperthyroidism; hyperadrenocorticism; pheochromocytoma; idiopathic disease.
- Hyperviscosity—hyperglobulinemia (multiple myeloma, *Ehrlichia*); polycythemia.
- Vasculitis—immune-mediated and rickettsial diseases.

RISK FACTORS

Coagulopathy

- Immune-mediated disease—young to middle-aged, small-to medium-sized female dogs.
- Infectious disease—dogs living in or traveling to endemic areas; tick exposure.
- Thrombasthenia—Otter hounds.
- Thrombopathia—Basset hounds, Spitz.
- von Willebrand disease—Doberman pinschers, Airedales, German shepherds, Scottish terriers, Chesapeake Bay retrievers, and many other breeds; cats.
- Hemophilia A—German shepherds and many other breeds; cats.
- Hemophilia B—Cairn terriers, coonhounds, St Bernards, and other breeds; cats.

Space-Occupying Lesions

- Aspergillosis—German shepherds, rottweilers, mesocephalic and dolichocephalic breeds.
- Neoplasia—dolichocephalic breeds.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

See "Causes"

CBC/BIOCHEMISTRY/URINALYSIS

- Anemia—if enough hemorrhage has occurred.
- Thrombocytopenia—possible.
- Neutrophilia—infection; neoplasia.
- Pancytopenia—if bone marrow disease.
- Hypoproteinemia—if enough hemorrhage has occurred.
- High BUN with normal creatinine—possible, owing to blood ingestion.
- Hyperglobulinemia—possible

with ehrlichiosis, multiple myeloma.

- Azotemia—with renal failure-induced hypertension.
- High ALT, AST, and total bilirubin—with coagulopathy from severe hepatic disease.
- Urinalysis—usually normal; possible to see hematuria (if coagulopathy), isosthenuria (if renal failure-induced hypertension), and proteinuria (if glomerulotubular disease and hypertension).

OTHER LABORATORY TESTS

- Coagulation profile—prolonged times with coagulation factor defects; normal with thrombocytopenia and thrombopathia.
- Platelet function testing (e.g., buccal mucosal bleeding time, von Willebrand factor analysis)—may be abnormal with platelet dysfunction (platelet count and coagulation profile may be normal).
- Ehrlichia*, *Anaplasma*, Rocky Mountain spotted fever, or *Babesia* testing—may be positive in thrombocytopenia or thrombopathia-induced epistaxis.
- Aspergillus* serology—may help establish a diagnosis of fungal rhinitis; false negative results are common so results must be interpreted in light of other clinical and diagnostic findings.
- Thyroid hormone assay—elevated in cats with epistaxis due to hyperthyroid-induced hypertension.

IMAGING

- Thoracic radiograph—screen for metastasis.
- Nasal series—under anesthesia, including open-mouth ventrodorsal and skyline sinus views when space-occupying or local lesion is suspected; osteolysis with neoplasia and fungal sinusitis; foreign bodies usually not seen; dental disease may be identified.
- CT or MRI—more sensitive than radiographs.

DIAGNOSTIC PROCEDURES

- Blood pressure evaluation—indicated when coagulopathies and space-occupying lesions have been ruled out and particularly when azotemia or proteinuria is noted.
- Rhinoscopy, nasal lavage, nasal biopsy (blind or guided via rhinoscopy or CT)—indicated for space-occupying disease; aimed at removing foreign bodies and evaluating and sampling nasal tissue for a causal diagnosis (e.g., evaluate nasal tissue samples for neoplasia, inflammation, and infection via cytology and/or histopathology and bacterial/fungal culture and sensitivity testing).
- Bone marrow aspiration biopsy—indicated if pancytopenia identified.

TREATMENT

APPROPRIATE HEALTH CARE

- Coagulopathy—usually inpatient management.
- Space-occupying lesion or vascular or systemic disease—outpatient or inpatient management, depending on the disease and its severity.
- Nasal tumors—radiotherapy; various response rates.

EPISTAXIS

(CONTINUED)

NURSING CARE

Provide basic supportive care if needed (fluids, nutrition).

ACTIVITY

Minimize activity or stimuli that precipitate hemorrhage episodes.

CLIENT EDUCATION

- Inform client about the disease process.
- Teach client how to recognize a serious hemorrhage (e.g., weakness, collapse, pallor, and blood loss > 30 mL/kg body weight).

SURGICAL CONSIDERATIONS

- Surgery indicated if a foreign body is unable to be removed by rhinoscopy or blind attempt.
- Fungal rhinitis (e.g., *Aspergillus* and *Rhinosporidium*) require debulking (also see "Medications").

MEDICATIONS

DRUG(S) OF CHOICE

General

- Whole blood, packed RBC, or hemoglobin solution transfusion—can be needed with severe anemia.
- Acepromazine (0.05–0.1 mg/kg SC, IV if normothermic and no platelet disorder present) to lower blood pressure and promote clotting; may help control serious hemorrhage.
- Discontinue all NSAIDs.

Coagulopathy

- Immune-mediated thrombocytopenia—prednisone (1.1 mg/kg q12h; taper over 4–6 months); other drugs can be used in addition to prednisone for refractive cases (see Immune Mediated Thrombocytopenia).
- Infectious disease—rickettsial disease (doxycycline, 5 mg/kg PO q12h for 3–6 weeks); *Babesia* (imidocarb, 6.6 mg/kg SC, 2 doses 2 weeks apart, diminazene acetate 5 mg/kg IM once, or 10 days of atovaquone 13.3 mg/kg PO q8h with azithromycin 10 mg/kg PO q24h).
- Bone marrow neoplasia—see Myeloproliferative Disorders.
- Thrombopathia and thrombasthenia—no treatment unless lymphoproliferative disease.
- von Willebrand disease—plasma or cryoprecipitate for acute bleeding; DDAVP 1 µg/kg SC or IV diluted in 20 mL of 0.9% NaCl given over 10 minutes may help control or prevent hemorrhage prior to invasive procedures (intranasal formulation [less expensive] may be used after passing through a bacteriostatic filter).
- Hemophilia A—plasma or cryoprecipitate for acute bleeding; no long-term treatment.
- Hemophilia B—plasma for acute bleeding; no long-term treatment.
- Anticoagulant rodenticide intoxication—plasma for acute bleeding; vitamin K at 5 mg/kg loading dose followed by 1.25 mg/kg q12h for 1 week (if warfarin formulation) to 4 weeks (longer-acting formulation).
- Hyperglobulinemia—

plasmapheresis.

- Polycythemia—phlebotomy; hydroxyurea.
- Liver disease and DIC—treat and support the underlying cause; plasma may be beneficial.

Space-Occupying Lesion

- Secondary bacterial infection—antibiotics based on culture and sensitivity testing.
- Fungal infection—for aspergillosis, topical treatment of nasal cavity and frontal sinuses with 1% clotrimazole in polyethylene glycol (see "Precautions") or 1–5% enilconazole (see Aspergillosis, Nasal, for protocol); for cryptococcosis—oral and injectable antifungal agents (see Cryptococcosis); for rhinosporidiosis—surgery followed by dapsone (1 mg/kg PO q8h for 2 weeks, then 1 mg/kg PO q12h for 4 months).

Vascular or Systemic Disease

- Hyperviscosity—treat underlying disease (e.g., ehrlichiosis, multiple myeloma, or polycythemia); plasmapheresis.
- Vasculitis—doxycycline for rickettsial disease (5 mg/kg q12h for 3–6 weeks); prednisone for immune-mediated disease (1.1 mg/kg q12h; taper over 4–6 months).

Hypertension

- Treat underlying disease—renal disease, hyperthyroidism, hyperadrenocorticism.
- Reduce weight if over-conditioned.
- Restrict sodium.
- Calcium channel blockers—amlodipine (dogs, 0.1 mg/kg PO q12–24h; cats, 0.625–1.25 mg/cat PO q12–24h)—treatment of choice.
- ACE inhibitors—benazepril (0.5 mg/kg q24h); enalapril (0.25–0.5 mg/kg q12–24h).
- β-blockers—propranolol (0.5–1 mg/kg q8h); atenolol (0.25–1.0 mg/kg q12–24h).
- Diuretics—hydrochlorothiazide (2–4 mg/kg q12h); furosemide (0.5–2 mg/kg q8–12h).
- Phenoxybenzamine 0.2–1.5 mg/kg q12h for pheochromocytoma.

CONTRAINDICATIONS

- Avoid drugs that may predispose patient to hemorrhage—NSAIDs; heparin; clopidogrel; phenothiazine tranquilizers.
- Topical antifungals—do not use in patients with disruption of the cribriform plate.

PRECAUTIONS

- Chemotherapeutic drugs (Immune-mediated thrombocytopenia therapy, e.g., azathioprine)—monitor neutrophil counts and liver enzymes weekly until a pattern has been established that shows that the patient is tolerating the drug.
- Enalapril and/or diuretics—closely monitor patients with renal failure; avoid severe salt restriction when using ACE inhibitors.
- Avoid topical clotrimazole preparations with propylene glycol as life-threatening mucosal irritation, ulceration, and nasopharyngeal swelling can occur.

FOLLOW-UP

PATIENT MONITORING

- Platelet count with thrombocytopenia
- Coagulation profile with coagulation factor defects
- Blood pressure with hypertension
- Clinical signs

PREVENTION/AVOIDANCE

- Restrict access to areas that might contain anticoagulant rodenticides.
- Practice dental preventative care.

POSSIBLE COMPLICATIONS

Anemia and collapse (rare)

EXPECTED COURSE AND PROGNOSIS

Varies depending on underlying cause.

MISCELLANEOUS

PREGNANCY/FERTILITY/BREEDING

Avoid teratogenic drugs (e.g., itraconazole).

ABBREVIATIONS

- ACE = angiotensin converting enzyme
- ALT = alanine transaminase • AST = aspartate aminotransferase • CT = computed tomography • DDAVP = 1-desamino-8-d-arginine vasopressin • DIC = disseminated intravascular coagulation
- FeLV = feline leukemia virus • FIV = feline immunodeficiency virus • MLV = modified live virus • MRI = magnetic resonance imaging • NSAID = nonsteroidal anti-inflammatory drug • RBC = red blood cell

BASICS

OVERVIEW

- American Veterinary Dental College (AVDC) nomenclature: the term “epuli” (epulides) is a general term referring to a gingival mass lesion of any type.
- Classically considered as tumors of non-odontogenic origin that arise from periodontal connective tissue stroma and do not metastasize.
- Categories of epulides are fibromatous (FE), ossifying (OE), and acanthomatous (AE).
- FE and OE have been grouped together as variants of a fibromatous category. FE compared to and deemed equivalent to human peripheral odontogenic fibroma (POF).
- World Health Organization’s (WHO) “Histological classification of tumors of odontogenic origin of domestic animals” describes FE:
 - Primarily composed of periodontal ligament-type stroma: presence of regularly positioned stellate mesenchymal cells, smooth fibrillar collagen matrix, and regularly positioned and dilated but empty blood vessels.
 - Commonly observed cords of odontogenic epithelium and cell-poor collagen matrix resembling alveolar bone, cementum or even dentin.
 - Benign tumors.
- Recent retrospective study subdivided the WHO FE category into focal fibrous hyperplasia (FFH) and POF based on the presence of odontogenic epithelium.
 - FFH: inflammatory lesion, nonneoplastic; reactive lesions resulting from irritation caused by plaque and calculus. Dense fibrous connective tissue with mature fibroblasts widely scattered. Foci of dystrophic calcification and cellular fibrous tissue. Absence of odontogenic epithelium. Strands of surface epithelium often visible within the fibrous tissue. Superficial aspect may be ulcerated with associated inflammation.
 - Canine FE and human POF: equivalent. Mass of cellular, fibroblastic connective tissue separated from surface epithelium by a zone of histologically normal fibrous connective tissue, often in the form of strands of interwoven epithelium within a looser connective matrix; connective tissue highly vascular. Rest of odontogenic epithelium in the connective tissue may vary in number. Bone and collagenous matrix (osteoid, dentoid or cementum-like) present in variable amounts.
- Acanthomatous lesions are most distinct: termed either AE or canine (peripheral) acanthomatous ameloblastomas (CAA). Consists of islands and cords of squamous

epithelium that have invaded irregularly through a connective tissue stroma. Basal cells arranged in palisades, vacuolated cytoplasm with reverse polarization. No precise human equivalent. AE/CAA has clear clinicopathologic, morphologic and biologic differences from other categories. Characteristic aggressive infiltrative growth of epithelial cell components in spite of minimal cell atypia and few mitotic figures.

SIGNALMENT

- Dog—fourth most common oral malignancy
- Cat—rare
- Most common in brachycephalic breeds
- Boxers have a higher incidence of FE/fibrous changes
- Mean age—7 years
- No sex predisposition
- Fiani retrospective study (see “Suggested Reading”)
 - CAA: 45% (higher than other studies, but possibly based on more referral cases). Rostral mandible most common site (2.3 to 1 compared to maxilla). Mean 8.8 years. Golden retriever, Akita, cocker spaniels, shelties.
 - POF: 31%. Rostral maxilla (1.7 to 1 compared to mandible). Male to female ratio 1.8 to 1. Mean 8.5 years.
 - FFH: 16% (lower than other studies). Rostral mandible. Mean 9.0 years.

SIGNS

Historical Findings

- Often minimal—incidental finding detected on routine physical examination.
- If severe (AE, CAA): Excessive salivation, halitosis, dysphagia, bloody oral discharge, weight loss.

Physical Examination Findings

- Oral mass—in early cases, may appear as small pedunculated masses.
- Displacement of tooth structures due to the expansile nature of the mass (AE/CAA).
- Possible facial deformity due to asymmetry of the maxilla or mandible.
- Occasionally cervical lymphadenopathy.

CAUSES & RISK FACTORS

None identified

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Fibroma
- Benign polyp
- Ameloblastoma
- Malignant oral tumor
- Gingival hyperplasia/enlargement
- Abscess
- Differentiated from other types of masses by excisional biopsy coupled with radiographic appearance.

CBC/BIOCHEMISTRY/URINALYSIS

Results usually normal

OTHER LABORATORY TESTS

Cytologic preparations are rarely diagnostic

IMAGING

- Determine tumor borders by intraoral radiographs.
- Radiographs of AE/CAA typically demonstrate significant osseous changes with expansion into adjacent tissues; POF/FE-OE do not have well-defined borders on radiographs; tooth structures are usually displaced; may have ossified component.
- CT scan may be necessary to detail the invasiveness of a canine (peripheral) acanthomatous ameloblastoma.

DIAGNOSTIC PROCEDURES

A large, deep tissue biopsy (down to bone) is required to differentiate from other oral malignancies—fibroma, fibrosarcoma, or low-grade fibrosarcoma.

TREATMENT

DIET

Soft foods may be recommended to prevent tumor ulceration or after conservative or radical oral excision.

SURGICAL CONSIDERATIONS

- POF—surgical excision with at least 1 cm margins is usually curative; these tumors are of periodontal ligament stromal origin, so extraction of affected teeth and curettage of the alveolar socket are indicated; more advanced cases may require en bloc tooth and bone excision.
- Ossifying lesion—characteristically have a bony matrix and excision is often more difficult.
- Peripheral acanthomatous ameloblastoma—because of the aggressiveness of this tumor, at least 2 cm margins are recommended; partial mandibulectomy or maxillectomy is often indicated by the location of the tumor.
- Radiotherapy offers long-term control in dogs with a peripheral acanthomatous ameloblastoma deemed inoperable; most radiotherapy plans attempt 40–60 Gy over 3–6 weeks.

MEDICATIONS

DRUG(S)

- Efficacy of outpatient chemotherapy is unreported; most tumors of mesenchymal origin respond poorly.
- Local control (palliation) with intrathecally administered cisplatin has been reported.

EPULIS

(CONTINUED)

- Bleomycin injected locally has been successful in treating acanthomatous epulis.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Chemotherapy can be toxic; seek advice before initiating treatment if you are unfamiliar with cytotoxic drugs.

E**FOLLOW-UP****PATIENT MONITORING**

- Thorough oral, head, and neck examination regularly after treatment.
- Periodic intraoral radiographs, especially for AE/CAA.

EXPECTED COURSE AND PROGNOSIS

- AE/CAA are highly invasive into bone.
- Good prognosis expected when excisional margins are free of neoplastic cells.
- Mean survival time after surgery of peripheral acanthomatous ameloblastoma is 43 months (range, 6–134 months); mean survival times for patients with peripheral acanthomatous ameloblastoma, ossifying, and peripheral odontogenic fibroma are 52, 29, and 47 months, respectively. Survival times above are from different sources.

- Mean survival after radiotherapy in dogs with peripheral acanthomatous ameloblastoma ranges from 1–102 months (median, 37 months); the 1-year survival rate is 85%; the 2-year survival rate is 67%.

- Malignant transformation of an acanthomatous epulis (peripheral acanthomatous ameloblastoma) has been reported in up to 20% of irradiated patients years after treatment, suggesting that it may be a precancerous lesion.

**MISCELLANEOUS****SYNOMYMS**

- Peripheral ameloblastoma
- Peripheral acanthomatous ameloblastoma
- Peripheral odontogenic fibroma

ESOPHAGEAL DIVERTICULA

BASICS

OVERVIEW

- Pouch-like sacculations of the esophageal wall that accumulate fluids and ingesta.
- Diverticula may be congenital or acquired and are rare.
- Pulsion diverticula occur secondary to increased intraluminal pressure. Seen with esophageal obstructive disorders such as foreign body or mass lesions.
- Traction diverticula occur secondary to periesophageal inflammation where fibrosis and contraction pull out the wall of the esophagus into a pouch.
- Diverticuli most commonly occur at the thoracic inlet or near the hiatus.
- Organ systems affected include the gastrointestinal (regurgitation), musculoskeletal (weight loss), and respiratory (aspiration pneumonia).

SIGNALMENT

- Rare; more common in dog than cat
- Congenital or acquired (no genetic basis proven)
- No important breed or sex predisposition

SIGNS

- Postprandial regurgitation, dysphagia, anorexia, coughing
- Weight loss, respiratory distress

CAUSES & RISK FACTORS

Pulsion Diverticulum

- Embryonic developmental disorders of the esophageal wall.
- Esophageal foreign body, mass or focal motility disturbances (uncommon).

Traction Diverticulum

- Inflammatory processes associated with the trachea, lungs, hilar lymph nodes, or pericardium; resultant fibrous connective tissue adheres to the esophageal wall.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Esophageal Redundancy

Barium contrast accumulation in the region of the thoracic inlet can occur normally in young dogs (especially brachycephalic breeds and Chinese Shar-Pei).

Periesophageal Mass

Esophagram or esophagoscopy should differentiate the presence of a mass causing luminal narrowing.

CBC/BIOCHEMISTRY/URINALYSIS

Usually within normal limits

OTHER LABORATORY TESTS

N/A

IMAGING

- Thoracic radiography—may show air or soft tissue opacity cranial to the diaphragm or cranial to the thoracic inlet.
- Contrast esophagram—shows contrast accumulation within the diverticulum.
- Videofluoroscopy—useful to evaluate for disturbances in esophageal motility.

DIAGNOSTIC PROCEDURES

Esophagoscopy confirms ingesta/debris within outpouchings of the esophagus.

TREATMENT

- If the diverticulum is small and not causing significant clinical signs, treat conservatively with elevated feedings of a soft, bland diet followed by copious liquids.
- If the diverticulum is large or is associated with significant clinical signs, surgical resection is recommended.
- Client education should include the importance of dietary management and the potential for aspiration pneumonia.
- Fluid therapy, antibiotics, and aggressive nursing, if concurrent aspiration pneumonia is present; alternative enteral nutrition via gastrostomy tube may be necessary in patients with aspiration pneumonia.
- Treat for esophagitis if present.

MEDICATIONS

DRUG(S)

- Drug therapy for esophagitis, if present.
- Give H₂ histamine antagonists (e.g., ranitidine 2 mg/kg PO q12h or famotidine 0.5–1 mg/kg PO q12h) if the patient has concurrent esophagitis.

- Proton pump inhibitors such as omeprazole are more potent and effective antacids than the H₂ histamine antagonists for management (0.7–1.5 mg/kg PO q24h) of severe esophagitis.

- Use broad-spectrum antibiotics if the patient has concurrent aspiration pneumonia; if severe pneumonia is present, base antibiotic selection on culture and sensitivity of samples obtained by transtracheal wash or bronchoalveolar lavage.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

PATIENT MONITORING

- Evaluate for evidence of infection or aspiration pneumonia.
- Maintain positive nutritional balance throughout disease process.

POSSIBLE COMPLICATIONS

Patients with diverticula and impaction are predisposed to perforation, fistula, stricture, and postoperative incisional dehiscence.

EXPECTED COURSE AND PROGNOSIS

Prognosis is guarded in patients with large diverticula and overt clinical signs.

ESOPHAGEAL FOREIGN BODIES

BASICS

DEFINITION

Ingestion of foreign material or foodstuffs too large to pass through the esophagus, causing partial or complete luminal obstruction.

E

PATHOPHYSIOLOGY

Esophageal foreign bodies cause mechanical obstruction, mucosal inflammation with edema, and possibly ischemic necrosis and esophageal stricture formation.

SYSTEMS AFFECTED

- Gastrointestinal
- Respiratory—if aspiration pneumonia

GENETICS

N/A

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Due to the indiscriminate eating habits of many dogs, they have a higher incidence than cats.

Breed Predilections

More common in small-breed dogs; terrier breeds often overrepresented.

Mean Age and Range

More common in young to middle-aged animals

Predominant Sex

N/A

SIGNS

General Comments

The pet may have been observed ingesting a foreign body.

Historical Findings

Most common include retching, gagging, lethargy, anorexia, ptalism, regurgitation, restlessness, dysphagia, odynophagia, and persistent gulping.

Physical Examination Findings

- Ptyalism.
- Can be unremarkable.
- Occasional discomfort when palpating the neck or cranial abdomen.

CAUSES

Occurs most often with an object whose size, shape, or texture does not allow free movement through the esophagus, causing it to become lodged before it can pass.

RISK FACTORS

N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Esophagitis
- Esophageal stricture
- Esophageal neoplasia
- Megaeosophagus
- Other esophageal disorders

CBC/BIOCHEMISTRY/URINALYSIS

- Usually unremarkable.
- Occasionally, electrolyte abnormalities, an inflammatory leukogram, and/or hemoconcentration, depending upon the severity of signs and degree of dehydration.

OTHER LABORATORY TESTS

N/A

IMAGING

Thoracic Radiography

- Most esophageal foreign bodies are radiodense and are readily visualized. These objects most commonly lodge at points of minimal esophageal distension including the thoracic inlet, base of the heart, and the esophageal hiatus.
- Esophageal distension with air may be visualized cranial to the foreign body. Retained air in the esophagus is not always associated with esophageal foreign bodies.
- A contrast esophagram or videofluoroscopy is required to identify radiolucent objects. If perforation is suspected, use an aqueous organic iodide contrast agent for imaging studies.
- Air and/or fluid in the mediastinum or pleural space suggests esophageal perforation; depending on severity, this can be an indication for surgery instead of esophagoscopy.
- Pulmonary infiltrates suggest aspiration pneumonia.

DIAGNOSTIC PROCEDURES

Esophagoscopy affords direct visualization of both the foreign object and the esophageal mucosa, allowing assessment of the extent of esophageal injury. It also allows for visual interrogation of the mucosa for trauma post-foreign body removal.

PATHOLOGIC FINDINGS

N/A

TREATMENT

APPROPRIATE HEALTH CARE

- Emergencies—treat as inpatient and perform endoscopy as soon as possible after diagnosis.

- If endoscopic retrieval of the foreign body succeeds and esophageal damage is minimal, the patient may be discharged the same day.

NURSING CARE

- If the procedure to remove the foreign body is atraumatic and the esophagus has sustained minimal damage, no special aftercare is needed.
- Severe mucosal trauma may require placing a gastrostomy tube for enteral nutritional support during esophageal healing. Fluid therapy may also be required to maintain normal hydration status during periods of prolonged esophageal rest.

ACTIVITY

The patient may resume normal activity after a foreign body has been routinely removed.

DIET

No change needed other than, perhaps, altering the food to a more liquid consistency.

CLIENT EDUCATION

Discuss the possibility of complications and repeat offenders.

SURGICAL CONSIDERATIONS

- Endoscopic foreign body extraction is much less traumatic and invasive than surgery.
- Surgery is indicated when endoscopy fails to retrieve the foreign body; when endoscopy enables advancement of the object into the gastric lumen but it is too large to pass through the gastrointestinal tract; or when a large esophageal perforation or area of necrosis requires resection.
- It is often less traumatic to advance a bone foreign body into the stomach than to attempt retrieval transorally via endoscopy. Gastrostomy, if required, may then be performed.
- Most bone foreign bodies can be safely left to dissolve in the stomach without need for surgical removal. Non-digestible foreign objects (wood, metal, plastic) passed into the stomach may need to be removed surgically.

MEDICATIONS

DRUG(S) OF CHOICE

- If there is significant mucosal injury (i.e., esophagitis), recommendations include:
- Sucralfate slurry (0.5–1 g/dog PO q8h) for mucosal cytoprotection and healing.
- Proton pump inhibitor (omeprazole or pantoprazole at 1 mg/kg q24h) for robust suppression of gastric secretions which may contribute to reflux esophagitis. H₂-receptor antagonists (e.g., ranitidine, 1–2 mg/kg PO, IV, SC q12h, or famotidine, 0.5–1 mg/kg, PO q12h) may be used in animals with less severe esophagitis.

(CONTINUED)

ESOPHAGEAL FOREIGN BODIES

E

- Broad-spectrum antibiotics (amoxicillin or Clavamox) may be administered to animals having small mucosal perforations.
- Metoclopramide (0.2–0.5 mg/kg IV, SC, PO q8h) or cisapride (0.5 mg/kg q8–12h PO) to stimulate gastric motility and minimize reflux esophagitis.
- Gastrostomy tube placement for enteral nutrition in animals with severe mucosal trauma.
- Viscous lidocaine gel administered with water and given 2–3 times daily can be used to help reduce esophageal pain if warranted.

CONTRAINDICATIONS

N/A

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

N/A

**FOLLOW-UP****PATIENT MONITORING**

- Examine the esophagus closely via endoscopy for mucosal damage post-foreign body removal.
- Mild erythema/erosions are not uncommon and tend to heal uneventfully.
- If an esophageal laceration/perforation is detected—parenteral nutrition or gastrostomy tube feedings allow esophageal rest and healing.

- Advise post-procedural survey thoracic radiographs to assess for pneumomediastinum/pneumothorax.
- Monitor at least 2–3 weeks for evidence of stricture formation.
- Esophageal stricture—most common clinical sign is regurgitation with evidence of odynophagia in many animals; esophagram or videofluoroscopy and/or esophagoscopy may be indicated to confirm a stricture.

PREVENTION/AVOIDANCE

Carefully monitor the environment and what is fed to the pet.

POSSIBLE COMPLICATIONS

- Approximately 25% of patients with foreign bodies develop complications.
- Complications most frequently encountered include esophageal perforation, esophageal strictures, esophageal fistulas, and severe esophagitis. Focal, transient esophageal motility disturbances can occur secondary to esophageal trauma.
- Pneumomediastinum, pneumothorax, pneumonia, pleuritis, mediastinitis, and bronchoesophageal fistulas can all occur secondarily to perforation.

EXPECTED COURSE AND PROGNOSIS

- Most patients do well and recover uneventfully.
- With complications, the prognosis is guarded.

ESOPHAGEAL STRICTURE

BASICS

DEFINITION

An abrupt fixed narrowing of the esophagus due to scar tissue, resulting in partial or complete obstruction.

E

PATHOPHYSIOLOGY

- Benign strictures occur when there is severe esophagitis, occurring for greater than 270° of the esophageal circumference. Regardless of the initiating event, once esophagitis develops, there is a decrease in LES tone. This results in more acid reflux and subsequent worsening of the esophagitis. Once severe esophagitis is present, damage can extend to the lamina propria and muscularis layers. This incites a fibroblastic proliferation and contraction, leading to stricture formation.
- Malignant strictures occur rarely in dogs and cats, and stricture results from direct tumor invasion.

SYSTEMS AFFECTED

- Gastrointestinal—the esophagus is usually affected focally, although multiple strictures can occur.
- Respiratory—regurgitation is common with strictures, with secondary aspiration pneumonia.

GENETIC

None.

INCIDENCE/PREVALENCE

Uncommon

GEOGRAPHIC DISTRIBUTION

Spirocercus lupi granuloma occurs in the southern USA, parts of Europe, South Africa, and Israel. There is no other geographic distribution.

SIGNALMENT

Dog and cat. No known breed or sex predilections. Puppies and kittens with vascular ring anomaly become symptomatic at weaning.

SIGNS

- Pain during swallowing (odynophagia), dysphagia, increased salivation, regurgitation, anorexia, and weight loss. Signs tend to be progressive as the stricture progressively narrows.
- If regurgitation leads to aspiration pneumonia, cough and dyspnea can develop.

CAUSES

- Reflux during anesthesia is the most common cause of benign esophageal stricture, accounting for about ~65% of cases. It is presumed that decreased LES tone occurring during anesthesia allows for gastroesophageal reflux, which results in subsequent acid injury to the esophageal mucosa.
- Severe esophageal foreign bodies (if > 270° mucosal damage occurs).
- Tablets and capsules can induce esophagitis leading to stricture. The most commonly incriminated drugs are doxycycline, clindamycin and aspirin.

- Gastroesophageal reflux independent of anesthesia.
- Prolonged vomiting of gastric contents.
- Swallowing of caustic substances.
- Esophageal neoplasia (squamous cell carcinoma and lymphoma most common).
- Vascular ring anomaly (congenital).
- Spirocercus lupi* granuloma.

RISK FACTORS

- General anesthesia, especially with drugs that decrease LES tone or when the table is tilted head-down.
- Oral medications given with a dry swallow (60–80% of capsules do not pass into the stomach after 5 minutes following a “dry” swallow)
- Foreign body ingestion.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Megaesophagus
- Esophageal foreign body
- Esophageal neoplasia
- Extrinsic esophageal compression (mass, abscess)
- Gastroesophageal reflux
- Vomiting (any cause)
- Oropharyngeal dysphagia

CBC/BIOCHEMISTRY/URINALYSIS

Usually unremarkable. May have neutrophilic leukocytosis if secondary aspiration pneumonia develops.

OTHER LABORATORY TESTS

Usually unremarkable

IMAGING

- Thoracic radiographs—usually unremarkable, unless secondary aspiration pneumonia develops. Occasionally gas-filled dilation cranial to the stricture may be seen.
- Videofluoroscopic barium swallow—procedure of choice. If videofluoroscopy is not available, barium swallow of liquid, paste, or food followed immediately by radiography is performed. Peristalsis proximal to the stricture site can be abnormal with concurrent esophagitis. Usually recognize an abrupt narrowing of the esophageal lumen at the stricture site. Most easily demonstrated with canned food or kibble mixed with barium. May demonstrate more than one stricture.
- Most cases of reflux-induced strictures are between the heart base and diaphragm. Most cases of pill-induced strictures are near the thoracic inlet (especially cats).

DIAGNOSTIC PROCEDURES

Endoscopy—There is an abrupt decrease in luminal diameter at the stricture site. Usually the mucosa is normal (smooth and pink), but can appear hyperemic and ulcerated if esophagitis is present. Often the scope cannot be advanced beyond the stricture without balloon dilation. The location of the stricture should be measured from the upper canine teeth.

PATHOLOGIC FINDINGS

If an esophageal mass is present, biopsy with histopathology is warranted. Otherwise, benign strictures do not need to be biopsied. Variable degree of esophagitis may be seen.

TREATMENT

APPROPRIATE HEALTH CARE

Outpatient medical management is only successful for mild strictures. More severe strictures will lead to progressive malnutrition and possible aspiration pneumonia, and require inpatient intervention. If there are complications (esophageal perforation, aspiration pneumonia), then inpatient care is required.

NURSING CARE

With mild strictures, gruel feeding (ideally partially elevated) may be possible. With more severe strictures, oral alimentation is not possible. Intravenous fluids may be necessary if animal is dehydrated. Other medications depend on the presence of esophagitis, complications, and results of dilation.

ACTIVITY

Mild exercise restriction may be necessary after dilation. If pneumonia is present, the degree of hypoxia will determine appropriate activity level.

DIET

With mild strictures, gruel feeding (ideally partially elevated) may be possible. Recommend feeding a fat-restricted diet to enhance gastric emptying. Canned food can be fed in small frequent amounts following dilation, even when severe esophageal tearing occurs. In some cases, re-strictureting occurs necessitating percutaneous endoscopic gastrostomy (PEG) tube feeding while multiple dilations are employed.

CLIENT EDUCATION

- With mild strictures, gruel feeding (ideally partially elevated) may be possible. Otherwise dilation procedures are necessary.
- Owners should be aware that dilation procedures are not always successful, and that multiple attempts are required in some patients. It is important that medical management for esophagitis be diligently employed following dilation procedures to reduce the risk of re-stricture.
- Most cases have a successful outcome.
- If there is failure after ~5–8 attempts, rescue procedures (such as stent placement) should be considered.
- Patients with esophageal neoplasia have a poor prognosis.

SURGICAL CONSIDERATIONS

- The first-line treatment of benign esophageal strictures is mechanical dilatation of the stricture. Techniques have evolved from rigid bougienage, to flexible bougies, to

(CONTINUED)

balloon dilation. The latter technique is generally thought to be superior to bougienage, but objective evidence for this is lacking in human and veterinary patients. The theoretical advantage of balloon dilatation is that the forces applied to the stricture are a radial stretch, whereas some of the forces applied with bougienage are also longitudinal, resulting in greater potential for esophageal perforation. • Esophageal dilatation balloons are made of special plastic that makes the balloon extremely rigid when maximally inflated at high pressures, generally up to 45 psi. Balloons are positioned within the stricture under direct endoscopic visualization. The balloon is slowly inflated until it reaches the manufacturer's rated pressure for that balloon. Sequentially larger balloons are used until the clinician subjectively judges the degree of mucosal tearing to be acceptable. • The technique is very subjective in veterinary medicine, with many variables not defined by controlled studies. These include the sequence of dilatation, the optimal final dilation diameter, use of corticosteroids intralesionally, post-dilation drugs, post-dilation feeding regime, the elective use of percutaneous endoscopic gastrostomy (PEG) tubes, and repeat elective dilatations (and at what interval). Typically, an initial balloon diameter is selected that is 50–100% larger than the estimated stricture diameter. If there is doubt, selection of a smaller balloon with gradually larger subsequent dilations is safest. The sequence of subsequent larger dilations is then determined by the degree of mucosal tearing. The final dilation diameter is usually chosen by the degree of mucosal tearing and the size of the patient. As a general guideline, the end diameter is as follows: cats and dogs < 8 kg, 12 mm; dogs 8–15 kg, 16 mm; dogs 15–30 kg, 20 mm; dogs 30–50 kg, 25 mm; and dogs > 50 kg, 30 mm. This is subjective, and is a balance between the desire to achieve a large enough lumen at the completion of procedure and the risk of perforation when too large a balloon is used. • Injection of intralesional submucosal triamcinolone in a 4-quadrant pattern just prior to dilation may reduce the frequency of re-stricture. Similarly, topical application of mitomycin-C may also reduce the frequency of re-stricture. Both methods can be employed in the same patient. • Some authors recommend elective dilations at 1-week intervals to decrease the likelihood of re-stricture formation. I do not routinely recommend this since the published median number of dilations required for successful treatment is 2 (range 1–5). If 3 dilations are required, then I often recommend an elective dilation 1 week later. • If >5–8 dilations have been performed with subsequent stricture recurrence, a salvage procedure with placement of a self-expanding covered metal stent can be employed. It is

important that the stent be secured with sutures to prevent stent migration. • Surgical management (resection and anastomosis) is only performed as a last resort.

MEDICATIONS

DRUG(S) OF CHOICE

- Following dilation, give sucralfate suspension (0.5–1 gram/patient PO q6h) to reduce esophagitis and pain. Medications for esophagitis are used, including cisapride (0.5–0.75 mg/kg PO q8h) to increase LES tone and enhance gastric emptying, and omeprazole (1 mg/kg PO q12h) to decrease gastric acid. • Broad-spectrum antibiotics are used if aspiration pneumonia is present.

CONTRAINDICATIONS

Caustic substances and emetic medications

PRECAUTIONS

Esophageal perforation can occur with overzealous balloon dilation of the stricture. Therefore sequentially increase diameter of balloons.

POSSIBLE INTERACTIONS

Sucralfate may inhibit the absorption of other drugs.

ALTERNATIVE DRUG(S)

Metoclopramide can be used to increase LES tone (although cisapride is superior). Histamine H₂-receptor blockers can be used to decrease gastric acid (although proton pump inhibitors are superior).

FOLLOW-UP

PATIENT MONITORING

- Clinical signs are monitored for stricture recurrence (mainly regurgitation). An appropriate consistency food should be fed. Repeat stricture dilation should be considered based on recurrence of clinical signs.
- Aspiration pneumonia is monitored by clinical signs and radiographic resolution.

PREVENTION/AVOIDANCE

- Peanesthetic administration of cisapride decreases the number of reflux events in anesthetized dogs, but the low incidence of stricture may make this an overly aggressive part of routine preanesthetic management.
- Peanesthetic administration of omeprazole will minimize the likelihood of acid reflux and potentially decrease the likelihood of stricture formation. • Medications with ulcerogenic potential (such as doxycycline, clindamycin, and aspirin) should be given with at least 6 mL of water or food (a "wet swallow").

POSSIBLE COMPLICATIONS

- Complications of balloon dilatation include perforation, severe mucosal tearing and

ESOPHAGEAL STRicture

esophagitis, and re-stricture. • Aspiration pneumonia secondary to regurgitation.

- Complications of stent placement include stent migration, tissue ingrowth into the stent resulting in stent occlusion, food obstruction, hemorrhage, perforation, airway compression, pressure necrosis/fistula formation, dysphagia, and pain.

EXPECTED COURSE AND PROGNOSIS

- The overall successful treatment rate of balloon dilatation is reported to be between 70% and 88% in dogs and cats. The median number of dilations required for successful treatment is 2, but can require up to 5–8 before considered a failure. Prognosis is poorer with narrower and more chronic strictures. The prognosis for esophageal neoplasia is poor.

MISCELLANEOUS

E

ESOPHAGITIS

BASICS

DEFINITION

- Inflammation of the esophagus typically affecting the esophageal body and gastroesophageal sphincter (lower esophageal sphincter, LES); most commonly due to gastroesophageal reflux (GER) or secondary to vomiting; the cricopharyngeal sphincter (proximal esophageal sphincter) is less commonly affected.
- Varies from mild self-limiting esophagitis to severe ulcerative esophagitis involving the submucosa and muscularis which can result in stricture formation.

PATOPHYSIOLOGY

- Physiologic defense mechanisms protecting the esophagus from inflammation are the esophageal mucosal barrier (stratified squamous epithelium, intracellular tight junctions, mucus gel, surface bicarbonate), the LES, clearance by esophageal motility, and the neutralizing effect of alkaline saliva.
- Disruption of these esophageal defense mechanisms can result in esophageal inflammation with erosion, and/or ulceration.
- Esophagitis can result in impaired esophageal motility and LES incompetence which may result in further GER perpetuating esophagitis and esophageal damage.

SYSTEMS AFFECTED

- Gastrointestinal (GI)—esophagus (esophageal body and LES most commonly affected) and in the vomiting patient primary or secondary GI disease.
- Respiratory—with regurgitation aspiration pneumonia may develop and possibly laryngitis, pharyngitis and rhinitis (reflux rhinitis).

INCIDENCE/PREVALENCE

Unknown—relatively common clinical diagnosis based on the history or clinical circumstances; incidence probably underestimated, as most cases are not definitively diagnosed.

GEOGRAPHIC DISTRIBUTION

Esophagitis caused by *Pythium* spp. (typically in states that border the Gulf of Mexico) and rarely *Spirocerca lupi* (southern states).

SIGNALMENT

Species

Dog and cat

Breed Predilections

Reflux esophagitis resulting from upper airway obstruction in brachycephalic breeds; thought to occur due to negative intrathoracic pressure upon inspiration resulting in GER and possibly hiatal hernia.

Mean Age and Range

- Animals of any age can be affected.
- Young animals with congenital esophageal

hiatal hernia and older animals that are anesthetized are at greater risk of developing GER and reflux esophagitis.

Predominant Sex

None

SIGNS

Historical Findings

- Regurgitation.
- Ptyalism.
- Dysphagia (difficulty swallowing, gagging, retching).
- Odynophagia (pain when swallowing, repeated swallowing efforts and extension of the head and neck during swallowing).
- Hyporexia or anorexia.
- Weight loss.
- Coughing and/or nasal discharge if there is aspiration pneumonia or nasopharyngeal reflux.

Physical Examination Findings

- Often normal physical examination.
- Oral and pharyngeal inflammation and/or ulceration if caustic or irritating substances have been ingested.
- Fever and pain in some patients with severe ulcerative esophagitis or aspiration pneumonia.
- Halitosis, ptyalism, and possibly pain on palpation of neck and esophagus.
- Cachexia and weight loss, chronic esophagitis or esophageal stricture.
- Respiratory signs including nasal discharge, cough, increased bronchovesicular sound, pulmonary crackles and dyspnea as well as systemic signs including lethargy and fever in patients with aspiration pneumonia.

CAUSES

- Most commonly GER secondary to general anesthesia, hiatal hernia, persistent or chronic vomiting, gastrointestinal disease resulting in delayed gastric emptying and malpositioned esophageal tubes.
- Gastroesophageal reflux disease (GERD) secondary to a primary LES abnormality is poorly understood in veterinary patients.
- Esophageal retention of tablets or capsules (doxycycline most common in cats, clindamycin, NSAIDs).
- Esophageal foreign body.
- Infectious agents—pythiosis, *Spirocerca lupi*, *Candida* infection secondary to immune-suppression.
- Uncommon causes of esophagitis include esophageal tumors, radiation injury, megaeosophagus, vascular ring anomalies and gastrinoma (Zollinger-Ellison syndrome).
- Eosinophilic esophagitis—has emerged as a common cause of esophagitis in children and adults and is one of the most common causes of esophagitis in humans; reported but rare in veterinary patients.
- Idiopathic.

RISK FACTORS

- Anesthetic premedications, induction agents, and maintenance drugs including all opioid class drugs, glycopyrrolate, atropine, acepromazine, diazepam, xylazine, propofol, and halogenated anesthetic agents have been associated with decreased LES tone and GER.
- Hiatal hernia—increases risk for gastroesophageal reflux.
- Preanesthetic fasting for prolonged periods (≥ 24 h) puts patients at greater risk for gastroesophageal reflux and increased gastric acidity.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Esophageal foreign body—usually detected by survey radiography or esophagoscopy.
- Esophageal stricture—segmental narrowing revealed by barium contrast radiography or esophagoscopy.
- Oropharyngeal dysphagia—diagnosed by evaluating swallowing of barium under fluoroscopy.
- Hiatal hernia—usually recognized as a gas- or fluid-filled opacity in the caudodorsal thoracic cavity at the level of the esophageal hiatus; contrast studies with fluoroscopy may be required to document a hiatal hernia.
- Megaeosophagus—survey radiography usually reveals diffuse dilation of the esophageal body.
- Esophageal diverticula—focal pouches detected by survey or contrast radiography or esophagoscopy.
- Vascular ring anomaly—usually revealed by barium contrast radiography as a focal dilation of the proximal esophageal body.
- Caudal esophageal neoplasia—esophageal mass effect with possible esophageal dilation.

CBC/BIOCHEMISTRY/URINALYSIS

Usually unremarkable; patients with ulcerative esophagitis or aspiration pneumonia may have leukocytosis and neutrophilia.

IMAGING

- Survey thoracic radiography—often unremarkable but may reveal mild esophageal dilation or fluid accumulation in the distal esophagus; aspiration pneumonia may be evident in the dependent portions of the lung; potentially dilation of the esophagus cranial to a stricture, an esophageal foreign body, hiatal hernia or an intraluminal or extraluminal mass may be detected.
- Barium contrast esophagram (static images and/or fluoroscopic)—may reveal esophageal dilation with retention of barium in esophagus, strictures, foreign bodies or masses; fluoroscopic studies allow for evaluation of swallowing, esophageal motility, strictures which may not be apparent on a static esophagram, sliding hiatal hernia and

(CONTINUED)

ESOPHAGITIS

E

GER (the latter two conditions may require abdominal compressions to demonstrate).

DIAGNOSTIC PROCEDURES

- Endoscopy and biopsy—most reliable means of diagnosis; mild cases of esophagitis may be endoscopically normal; visual findings of mucosal hyperemia and edema are common and in more severe cases ulceration and active bleeding; in patients with GER changes are usually most apparent in the distal third of the esophagus. Gastroduodenoscopy should also be performed to evaluate for GI causes of vomiting which can be associated with esophagitis.
- Diagnostic quality esophageal biopsies are difficult to obtain endoscopically due to the composition of the esophageal mucosa which has a tough stratified squamous epithelium. Histopathology provides the most definitive evidence of esophagitis; endoscopy and biopsies are usually reserved for cases unresponsive to therapy.
- Most cases of aspiration pneumonia will resolve when treated with supportive care and broad-spectrum antibiotics; endotracheal or transtracheal aspiration and/or bronchoscopy with bronchoalveolar lavage for cytology, and culture and sensitivity testing may be performed in patients not responding to therapy.

PATHOLOGIC FINDINGS

- Mucosal squamous hyperplasia or dysplasia with erosions and ulcers and lymphocytic plasmacytic and neutrophilic inflammation more in the acute phase.
- Barrett's esophagus (squamous metaplasia associated with chronic GERD which can lead to dysplasia and esophageal cancer in humans) has been reported in cats.

**TREATMENT****APPROPRIATE HEALTH CARE**

Mildly affected animals can be managed as outpatients; those with more severe esophagitis (persistent regurgitation, dehydration) and complications (aspiration pneumonia) require hospitalization. Eliminating predisposing factors such as hiatal hernia and management of any underlying GI or metabolic/endocrine disease that may result in vomiting or gastric hyperacidity is imperative. Treatment of esophagitis involves protecting the esophageal mucosa from further injury and reducing GER by increasing LES pressure and promoting gastric emptying with prokinetic drugs and suppressing gastric acid production.

NURSING CARE

- Intravenous fluids to maintain hydration—more severe cases.
- Medications—may need to be given parenterally during hospitalization.

- Oxygen therapy—may be necessary in patients with severe aspiration pneumonia.

DIET

- Severe esophagitis— withhold food and water until regurgitation is resolved; severe cases may require gastrostomy tube feedings or rarely total parenteral nutrition.
- For patients that can be fed orally:
 - Feed small amounts in multiple feedings.
 - A highly digestible-low residue diet that is moderately fat restricted and has a soft or gruel consistency is recommended; Hill's i/d, Purina EN, Iams Intestinal Plus Low-Residue, and Royal Canin Gastrointestinal Moderate Calorie are appropriate choices.

CLIENT EDUCATION

- Discuss need to restrict food intake in patients with severe esophagitis.
- Discuss potential complications, including aspiration pneumonia, esophageal stricture, esophageal perforation, and/or esophageal motility abnormalities.

SURGICAL CONSIDERATIONS

Percutaneous endoscopic gastrostomy (PEG) or surgical gastrostomy tube placement is indicated in severe cases.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Given parenterally (except for sucralfate) in severe cases; when administered enterally, dissolve in water and administer orally with a syringe or dropper, or by gastrostomy tube.
- Gastric acid suppressants and GI prokinetic drugs are the most established treatments for esophagitis and GER.
 - H_2 receptor antagonists (H_2 RAs)—famotidine 0.5–1.0 mg/kg PO, SC, IV q12h; ranitidine 2.0 mg/kg PO, SC, IV q8–12h; less effective than famotidine, may have prokinetic activity; cimetidine and nizatidine used less commonly.
 - Proton pump inhibitors (PPIs) provide superior gastric acid suppression compared to H_2 RAs—omeprazole 0.7–1.0 mg/kg PO q24h or 1 mg/kg PO q12h for more rapid onset of activity and greater efficacy; give 1 hour before a meal; pantoprazole 0.7–1.0 mg/kg IV q12–24h, lansoprazole and esomeprazole 1 mg/kg PO q24h have also been recommended.
- GI prokinetic agents—increase LES pressure and gastric emptying.
 - Cisapride 0.5–0.75 mg/kg PO q8h; more effective prokinetic than metoclopramide, must be obtained from a compounding pharmacy, must be administered enterally.
 - Metoclopramide 0.2–1.0 mg/kg PO, SC q8h or 1.0–3.0 mg/kg/day CRI; the higher

end of the dose range may be necessary depending on the response.

- Sucralfate 0.5–1 g PO q8h as a suspension or tablets mixed into a slurry with water. Sucralfate is a mucosal protectant that binds to inflamed tissue creating a protective barrier, stimulates growth factors, mucus and bicarbonate; efficacy for esophagitis has been questioned as drug activity requires an acidic environment and the esophageal environment is not expected to be acidic.
- Antibiotics—indicated with aspiration pneumonia, severe esophageal ulceration or esophageal perforation.
- Analgesics to manage esophageal pain.
 - Lidocaine solution (2.0 mg/kg PO q4–6h) for local analgesia.
 - Tramadol 2–4 mg/kg PO q8–12h.
- Anti-inflammatory dosage of corticosteroids (e.g., prednisone 0.5–1 mg/kg PO per day or divided q12h) may decrease fibrosis and esophageal stricture formation in severe cases; controversial and efficacy has not been supported by the literature. Should not be given when there is evidence of aspiration pneumonia.

CONTRAINDICATIONS

None

PRECAUTIONS

None

POSSIBLE INTERACTIONS

Sucralfate may interfere with gastrointestinal absorption of other drugs and it is best to separate dosing by 2 hours from other drugs; may not be clinically important.

ALTERNATIVE DRUG(S)

- Fentanyl analgesic patches—may be useful in severe cases of painful esophagitis.
- Ranitidine 2.0 mg/kg PO q12h, nizatidine 2.5–5.0 mg/kg PO q24h and erythromycin 0.5–1.0 mg/kg PO, IV have GI prokinetic effects and may be alternate or additive drugs.

**FOLLOW-UP****PATIENT MONITORING**

- Patients with mild esophagitis do not necessarily require follow-up endoscopy; tracking of clinical signs may be sufficient.
- Consider follow-up endoscopy in patients with ulcerative esophagitis and those at risk for esophageal stricture.

PREVENTION/AVOIDANCE

- Consider omeprazole 1 mg/kg PO to reduce gastric acidity 4 hours prior to anesthesia and cisapride 1 mg/kg 12–18 hours prior to anesthesia to reduce GER during anesthesia and surgery.
- Maropitant citrate has been recently shown to reduce nausea and vomiting post hydromorphone administration; may be useful to prevent vomiting and regurgitation

ESOPHAGITIS

(CONTINUED)

associated with the use of anesthesia and opioid premedications.

- If gastroesophageal reflux is the cause of esophagitis, owners should avoid late-night feedings; this tends to diminish gastroesophageal sphincter pressure during sleep.
- Proper patient preanesthesia fasting decreases the risk of GER; general recommendations are 0–2 hours preanesthesia removal of water and 6–8 hour preanesthesia removal of food.
- Follow oral administration of capsules and tablets with 5–10 mL bolus of water (especially for doxycycline), a meal or give with a treat such as a Pill Pocket to hasten transit time of pills to stomach. For cats coating pills with butter or applying Nutrical to the nose to stimulate licking after administration of tablets may also be effective.

POSSIBLE COMPLICATIONS

- Esophageal stricture formation.
- Esophageal perforation (rare).
- Aspiration pneumonia.
- Permanent esophageal dysmotility.
- Chronic reflux esophagitis.
- Barrett's esophagus (rare complication of chronic reflux esophagitis in cats).

EXPECTED COURSE AND PROGNOSIS

- Best results when patients are treated with a gastric acid suppressant (e.g., famotidine or omeprazole), a GI prokinetic (e.g., cisapride or metoclopramide), and a mucosal protectant (e.g., sucralfate).
- Mild esophagitis—generally favorable prognosis.
- Severe or ulcerative esophagitis—greater potential for complications and guarded prognosis.

- Complete recovery is possible if the disorder is recognized and treated before serious complications develop.

MISCELLANEOUS ZOONOTIC POTENTIAL

None

PREGNANCY/FERTILITY/BREEDING

H_2 RAs, PPIs, and glucocorticoids should all be used with caution during pregnancy.

SYNONYMS

Esophageal inflammation

ETHANOL TOXICOSIS

BASICS

OVERVIEW

- Ethanol (CH_3OH)—short-chain alcohol; highly miscible with water; less volatile than comparable hydrocarbons (e.g., ethane); solvent for medications; component of alcoholic beverages; metabolized to acetaldehyde.
- Used intravenously to treat ethylene glycol poisoning.
- Denatured forms may contain other toxic fractions (e.g., acetone, benzene, camphor, castor oil, phthalates, kerosene, sulfuric acid, terpinols); may complicate effects.
- Alcohol concentration—expressed as proof (twice the percentage concentration).
- Acute oral lowest toxic dosage—5–8 mL/kg as pure alcohol; consider % alcohol in specific product consumed.
- Other alcohols (isopropanol, methanol) cause signs similar to ethanol. Toxicity of methanol is similar to ethanol; isopropanol is about half the toxicity of ethanol.
- Cell membrane damage; impaired sodium and potassium nerve conduction.
- May inhibit glutamate receptors in brain with reduction of cyclic guanosine monophosphate (GMP).

SIGNALMENT

- Most common in dogs.
- No breed or sex predilections.
- Young animals more susceptible.
- Exposure to beverages, dyes, ink, disinfectants, gasoline, mouthwashes, paint, varnishes, perfume, pharmaceuticals.
- Fermenting bread dough causes intoxication with gastric dilatation.

SIGNS

- CNS—predominant; develop within 15–30 minutes after ingestion on an empty stomach or 1–2 hours on a full stomach.
- High dosages—ataxia; reduced reflexes; behavioral changes; excitement or depression; hypothermia.
- Flatulence if source is bread dough.
- Polyuria and/or incontinence.
- Advanced—depression or narcosis; slowed respiratory rate; metabolic acidosis; cardiac arrest; death.

CAUSES & RISK FACTORS

- Alcoholic beverages, either accidental or intentional, most common source
- Spilled beverages, commercial products, or medications containing alcohol
- Intentional—by owners or others; dogs may readily consume beer if offered
- Fermented products—bread dough, rotten apples
- Dermal exposure—alcohol-containing products

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other alcohols—methanol; isopropanol; butanol
- Abused drugs—marijuana, barbiturates, benzodiazepines
- Early stages of ethylene glycol (antifreeze) toxicosis
- Halogenated or aliphatic hydrocarbon solvents
- Pesticides—amitraz; macrolide antiparasiticides

CBC/BIOCHEMISTRY/URINALYSIS

- Packed cell volume, total solids.
- Monitor for hypoglycemia; blood glucose < 60 mg/dL considered serious.
- Metabolic acidosis is likely from ethanol-induced lactic acidemia.

OTHER LABORATORY TESTS

- Blood ethanol—clinical signs in puppies at > 0.6 mg/mL and in adults at > 1–4 mg/mL; available at human and some veterinary laboratories.
- Blood gases and increased anion gap—evaluate potential acidosis.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

N/A

TREATMENT

- Activated charcoal—not effective.
- Emesis or gastric lavage—only with caution in depressed animals and protection of airway to prevent aspiration.
- Respiratory depression—provide artificial ventilation.
- IV isotonic crystalloid fluids—correct dehydration.
- Acidosis—sodium bicarbonate carefully according to severity of acidosis.
- Cardiac arrest—cardiac therapy (see Cardiopulmonary Arrest).
- CNS depression reported improved with yohimbine.

MEDICATIONS

DRUG(S)

- Fomepizole (4-methyl pyrazole)—possible inhibition of alcohol metabolism (see Ethylene Glycol Toxicosis) but not specifically cleared for use against ethanol.

- Epinephrine and bicarbonate—cardiac arrest (see Cardiopulmonary Arrest).

- Treatment for acidosis may include administration of sodium bicarbonate.
 - Use if cause is not readily reversible, arterial pH is < 7.2, and ventilator procedures have not reduced acidemia.
 - mEq of bicarbonate required = $0.5 \times \text{bw}$ in kg \times (desired total CO_2 mEq/L – measured CO_2 mEq/L).
 - Give half the total calculated dose slowly over 3–4 hours.
 - Recheck blood gases and clinical status of the animal.
- Yohimbine for CNS depression—0.1–0.2 mg/kg IV. Start with lower dosage. IV half-life is short (< 2 hours) so repeat therapy may be needed. Not specifically approved for this use but reported effective.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Do not administer other CNS depressive drugs.

FOLLOW-UP

- Monitor blood pH, blood gases, urine pH, anion gap—evidence of acidosis.
- Recovery from clinical signs—usually within 8–12 hours.

MISCELLANEOUS

ABBREVIATIONS

- CNS = central nervous system
- GMP = guanosine monophosphate

Consulting Editor Lynn R. Hovda

ETHYLENE GLYCOL TOXICOSIS

BASICS

DEFINITION

Results primarily from ingesting substances containing ethylene glycol (e.g., antifreeze). Rarely from other products.

E

PATHOPHYSIOLOGY

- Ethylene glycol—rapidly absorbed from the gastrointestinal tract; food in the stomach delays absorption.
- Toxicity—initially causes CNS depression, ataxia, gastrointestinal irritation, and polyuria or polydipsia; rapidly metabolized in the liver by alcohol dehydrogenase to glycoaldehyde, glycolic acid; glyoxalic acid, and oxalic acid; leads to severe metabolic acidosis and renal epithelial damage.
- Minimum lethal dosage—cats, 1.4 mL/kg; dogs, 6.6 mL/kg.

SYSTEMS AFFECTED

- Gastrointestinal—irritated mucosa.
- Nervous—inebriation from ethylene glycol and glycoaldehyde owing to inhibition of respiration, glucose metabolism, and serotonin metabolism and alteration of amine concentrations.
- Renal/Urologic—initially, osmotic diuresis; later, metabolites, especially calcium oxalate monohydrate crystals, are directly cytotoxic to renal tubular epithelium, resulting in renal failure. The mechanism of toxicity is now thought to involve attachment of oxalate to cell plasma membrane, activation of enzyme activity, and production of free radicals and lipid peroxidation, leading to cell necrosis.

INCIDENCE/PREVALENCE

- Common in small animals.
- Highest fatality rate of all poisons; fatality rates higher for cats than dogs.
- Incidence similar in cats and dogs.

GEOGRAPHIC DISTRIBUTION

Higher incidence in colder areas where antifreeze is more commonly used.

SIGNALMENT

Species

Dogs, cats, and many other species, including birds

Mean Age and Range

- Any age susceptible (3 months–13 years)
- Mean, 3 years

SIGNS

General Comments

- Dose-dependent.
- Almost always acute.
- Caused by unmetabolized ethylene glycol and its toxic metabolites (frequently fatal).

Physical Examination Findings

- Early—from 30 minutes to 12 hours post-ingestion in dogs; nausea and vomiting; mild to severe depression; ataxia and knuckling; muscle fasciculations; nystagmus; head tremors; decreased withdrawal reflexes

and righting ability; polyuria and polydipsia.

- Dogs—with increasing depression, patient drinks less but polyuria continues, resulting in dehydration; CNS signs abate transiently after approximately 12 hours, but recur later.
- Cats—usually remain markedly depressed; do not exhibit polydipsia.
- Oliguria (dogs, 36–72 hours; cats, 12–24 hours) and anuria (72–96 hours post-ingestion)—often develop if untreated.
- May note severe hypothermia.
- Severe lethargy or coma.
- Seizures.
- Anorexia.
- Vomiting.
- Oral ulcers.
- Salivation.
- Kidneys—often swollen and painful, particularly in cats.

CAUSES

Ingestion of ethylene glycol, the principal component (95%) of most antifreeze solutions.

RISK FACTORS

Access to ethylene glycol—widespread availability; somewhat pleasant taste; small minimum lethal dose; lack of public awareness of toxicity.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Acute (30 minutes–12 hours post-ingestion)—ethanol, methanol, and marijuana toxicosis; ketoacidotic diabetes mellitus; pancreatitis; gastroenteritis.
- Renal stage—acute renal failure by nephrotoxins (e.g., aminoglycoside antibiotics, amphotericin B, cancer chemotherapeutic drugs, ibuprofen, oxalate-containing plants such as philodendrons, plants of the lily family [cats], cyclosporin, grape and raisin toxicosis [causes hypercalcemia, unlike ethylene glycol toxicosis], and heavy metals); leptospirosis, tubulointerstitial nephritis; glomerular and vascular disease; renal ischemia (hypoperfusion).

CBC/BIOCHEMISTRY/URINALYSIS

- PCV and total protein—often high owing to dehydration.
- Stress leukogram—common.
- High BUN and creatinine—dog, 36–48 hours post-ingestion; cat, 12 hours post-ingestion.
- Hyperphosphatemia may occur transiently 3–6 hours post-ingestion, owing to phosphate rust inhibitors in the antifreeze; hyperphosphatemia is also seen with azotemia owing to decreased glomerular filtration.
- Hyperkalemia if oliguric or anuric.
- Hypocalcemia—occurs in approximately half of patients, owing to chelation of calcium by oxalic acid; clinical signs infrequently observed because of acidosis.
- Hyperglycemia—occurs in approximately half of patients, owing to inhibition of glucose metabolism by aldehydes, increased epinephrine and endogenous corticosteroids, and uremia.
- Isosthenuria—by 3 hours post-ingestion,

owing to osmotic diuresis and serum hyperosmolality-induced polydipsia; continues in the later stages of toxicosis because of renal dysfunction.

- Calcium oxalate crystalluria—consistent finding; as early as 3 hours post-ingestion in cats and 6 hours in dogs; monohydrate form is more common.
- Urine—pH consistently decreases; inconsistent findings—hematuria; proteinuria; glucosuria; may note granular and cellular casts, WBCs, RBCs, and renal epithelial cells.

OTHER LABORATORY TESTS

Blood Gases

- Metabolites cause severe metabolic acidosis.
- Total CO₂, plasma bicarbonate concentration, and blood pH—low by 3 hours post-ingestion; markedly low by 12 hours.
- PCO₂—decreases, owing to partial respiratory compensation.
- Anion gap—increased by 3 hours post-ingestion; peaks at 6 hours post-ingestion; remains increased for approximately 48 hours (ethylene glycol metabolites are unmeasured anions). Glycolate, a metabolite of EG, can result in a false increase in plasma lactate, which could lead to the assumption that acidosis is due to increased lactate, rather than EG toxicosis.

Other

- Serum osmolality and osmole gap—high by 1 hour post-ingestion, in parallel with serum ethylene glycol concentrations; dose-related; usually remain high for approximately 18 hours post-ingestion; ethylene glycol toxicosis most common cause of a high osmolal gap.
- EG serum concentration—peaks 1–6 hours post-ingestion; usually not detectable in the serum or urine by 72 hours.
- Commercial kits: PRN Pharmacol REACT EG measures concentrations at > 50 mg/dL; estimate by multiplying the osmole gap by 6.2.
- Test does not detect metabolites so must be used within the first few hours post-ingestion.
- Results are available in 6 minutes but should not be read over 10 minutes.
- Labeled for dogs and cats.
- Some cats may have toxicosis at levels below 50 mg/dL.
- False-positive test results can be seen with propylene glycol, glycerol, mannitol, and sorbitol. Ethanol may combine with propylene glycol or glycerol to give a false positive.
- Woods lamp examination of urine, face, paws, or vomitus may detect fluorescein that is sometimes added to antifreeze. This method is non-specific and may be unreliable.

IMAGING

Ultrasonography—renal cortices may be hyperechoic as a result of crystals.

DIAGNOSTIC PROCEDURES

- Kidney biopsy—with anuria; confirm diagnosis.
- Cytologic examination of kidney imprints—often diagnostic; numerous calcium oxalate crystals.

(CONTINUED)

ETHYLENE GLYCOL TOXICOSIS

E

PATHOLOGIC FINDINGS

- Kidneys often swollen.
- Post-mortem examination of kidney reveals the presence of calcium oxalate crystals in the tubules.

**TREATMENT****APPROPRIATE HEALTH CARE**

- Cats—usually inpatient.
- Dogs—usually outpatient if < 5 hours post-ingestion and treated with fomepizole; inpatient if > 5 hours for intravenous fluids to correct dehydration, increase tissue perfusion, and promote diuresis.

NURSING CARE

- Goals—prevent absorption; increase excretion; prevent metabolism.
- Induction of vomiting and gastric lavage with activated charcoal not recommended unless can be performed in first 30 minutes following ingestion due to the rapid absorption of ethylene glycol.
- Intravenous fluids—correct dehydration, increase tissue perfusion, and promote diuresis; accompanied by bicarbonate given slowly intravenously to correct metabolic acidosis.
- Monitor serial plasma bicarbonate concentrations— $0.5 \times$ body weight (kg) \times (24 – plasma bicarbonate) = sodium bicarbonate needed (mEq).
- Monitor urine pH in response to therapy.
- Azotemia and oliguric renal failure (dogs)—most of the ethylene glycol has been metabolized; little benefit from inhibition of ADH; correct fluid, electrolyte, and acid-base disorders; establish diuresis; diuretics (particularly mannitol) may help; hemodialysis or peritoneal dialysis may be useful; may need extended treatment (several weeks) before renal function is re-established.

SURGICAL CONSIDERATIONS

Kidney transplantation—successfully employed in cats with ethylene glycol-induced renal failure.

**MEDICATIONS****DRUG(S) OF CHOICE****Dogs**

Fomepizole (4-methyl pyrazole; Antizol-Vet)—effective and non-toxic liver ADH inhibitor; more expensive than ethanol but less intensive care required; 5% (50 mg/mL) at 20 mg/kg IV initially; then 15 mg/kg IV at 12 and 24 hours; then 5 mg/kg IV at 36 hours.

Cats

• Fomepizole—cats must be given a higher dose of fomepizole than dogs; 125 mg/kg IV

initially, then 31.25 mg/kg at 12, 24, and 36 hours.

- Ethanol—use if fomepizole not available; 20% at 5 mL/kg diluted in fluids and given in an IV drip over 6 hours for 5 treatments; then over 8 hours for 4 more treatments.

CONTRAINDICATIONS

Avoid drugs that cause CNS depression, including ethanol.

PRECAUTIONS

- Competitive substrates (alcohols, such as ethanol) contribute to CNS depression; monitor respiration.
- Cats may become hypothermic; require heat.
- Other pyrazoles—may be toxic to the marrow and liver; do not substitute for fomepizole.

POSSIBLE INTERACTIONS

- Fomepizole—contributes slightly to CNS depression in cats; none in dogs.
- Ethanol—contributes to CNS depression; further increases serum osmolality.

ALTERNATIVE DRUG(S)

- Ethanol, propylene glycol, and 1,3-butanediol have—higher affinity for ADH than does ethylene glycol; effectively inhibit ethylene glycol metabolism; may cause CNS depression and increase serum osmolality; constant serum ethanol concentrations of 100 mg/dL will inhibit most ethylene glycol metabolism.
- Ethanol treatment requires hospitalization, constant intravenous infusion (ethanol and fluids); continuous monitoring for respiratory and acid-base status.

**FOLLOW-UP****PATIENT MONITORING**

BUN, creatinine, acid-base status, and urine output—monitored daily.

PREVENTION/AVOIDANCE

- Increasing client awareness of the toxicity helps prevent exposure; earlier treatment of patients.
- Use of antifreeze products (e.g., Sierra, Prestone LowTox) that contain propylene glycol, which is much less toxic.

POSSIBLE COMPLICATIONS

- Without azotemia—usually no complications.
- Urine concentrating ability—may be impaired with azotemia; may recover.

EXPECTED COURSE AND PROGNOSIS

- Untreated—oliguric renal failure (dogs, 36–72 hours; cats, 12–24 hours); anuria by 72–96 hours post-ingestion.
- Dogs treated < 5 hours post-ingestion—prognosis excellent

with fomepizole treatment.

- Dogs treated up to 8 hours post-ingestion—most recover.

- Dogs treated up to 36 hours post-ingestion—may be of benefit to prevent metabolism of any remaining ethylene glycol.

- Cats treated within 3 hours post-ingestion—prognosis good.
- If a large quantity of EG is ingested, prognosis is poor, unless treated within 4 hours of ingestion.
- Patients with azotemia and oliguric renal failure—prognosis poor; almost all of the ethylene glycol will have been metabolized.

**MISCELLANEOUS****AGE-RELATED FACTORS**

Patients < 6 months of age with oliguric renal failure sometimes fully recover.

SYNOMYMS

Antifreeze poisoning

EXCESSIVE VOCALIZATION AND WAKING AT NIGHTS

BASICS

DEFINITION

- Vocalization that is uncontrollable, excessive, at inappropriate times of day or night or that disrupts owners, neighbors or other animals.
- In night-time waking, the pet wakes during the night, does not fall asleep at bedtime, or awakens early leading to disruption of owner's sleep.

PATHOPHYSIOLOGY

- Varies with cause.
- Barking may be normal canine communication (social, threat, warning, care-soliciting) but unacceptable to owners.
- Owner responses may reinforce or increase anxiety (punishment).
- Cats are crepuscular, so early morning waking may be normal.
- May be due to medical conditions that cause anxiety, discomfort, irritability, or altered sleep-wake cycles.
- Hearing decline may be associated with increased vocalization.
- CDS can lead to sleep disturbances, anxiety and excessive vocalization.
- Night waking may be due to a change in schedule, environment, or activity, especially in senior pets that are more sensitive to change.

SYSTEMS AFFECTED

- Behavioral
- Diseases of other systems may cause or contribute to signs

GENETICS

N/A

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Dog and cat

Breed Predilections

- Asian breeds of cats may be prone to excess vocalization.
- Working and hunting breeds may be more prone to barking.

Mean Age and Range

- Puppies may not be able to sleep through the night without waking to eliminate.
- Senior pets may be more prone to vocalization and night waking due to underlying medical conditions.

Predominant Sex

Intact females during estrus and mating

SIGNS

Historical Findings

- Vocalization at times or in intensity that disturbs owners or neighbors.
- Sleeping pattern altered—does not fall asleep at bedtime, awakens during the night, or sleeps more during the day.
- Signs reported vary with how disruptive they are to the family, neighbors, and the pet's quality of life.
- Pets with CDS may pace, wander aimlessly, have decreased interest in social interactions, less responsive to stimuli and increasingly anxious.
- Additional signs related to medical causes.

Physical Examination Findings

Signs associated with underlying medical issues.

CAUSES

- Vocalization and night waking:
Medical—gastrointestinal, metabolic (renal, hepatic), urogenital, CNS disorders, CDS, hyperadrenocorticism or hypothyroidism (dog), hyperthyroidism (cat), pain, sensory decline
- Night waking
 - Anxiety or conflict
 - Normal for individual or breed
 - Alarm barking—response to novel stimuli
 - Territorial—warning or guarding
 - Owner inadvertently reinforces
 - Also reinforced each time stimulus retreats
 - Distress vocalization, e.g., howl or whine may be related to separation from social group
 - Growl—associated with agonistic displays
 - Stereotypic behaviors—dogs
 - Mating/Sexual (cats)

RISK FACTORS

- Increasing age
- Changes in schedule or environment

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Sleep disorders

CBC/BIOCHEMISTRY/URINALYSIS

To determine if underlying medical cause

OTHER LABORATORY TESTS

- T₄—senior cats
- Rule out hypothyroidism and hyperadrenocorticism in dogs

IMAGING

To rule out medical/neurologic if indicated

DIAGNOSTIC PROCEDURES

- Behavioral diagnosis based on history; observation of pet, owner, and their interactions; video if available.
- BAER if indicated to rule out auditory decline.
- Endoscopy and biopsy if GI suspected.

PATHOLOGIC FINDINGS

N/A

TREATMENT

APPROPRIATE HEALTH CARE

If any medical issues

NURSING CARE

If any medical issues

ACTIVITY

Insure behavioral needs are adequately met including sufficient daytime enrichment and programming.

DIET

- Feed from toys (work for food)
- Timed feeders to schedule feedings

CLIENT EDUCATION

Individualize for the pet, home, and problem

BEHAVIOR MODIFICATION

- Identify and minimize or avoid exposure to inciting stimuli.
- Provide a quiet and calm environment for security, rest and sleep.
- Structure all interactions (i.e., calm sit or down for all rewards).
- Reward-based training to teach calm/settle on cue ("Sit," "Down," "Mat").
- Response substitution—Use settle commands to train alternative acceptable behaviour.
- Head halter may provide more immediate control to quiet and calm.
- Eliminate any owner reinforcement.
- Owner anxiety, verbal reprimands, and punishment may increase anxiety and potentiate barking.
- Desensitize and counter-condition—expose the pet to the inciting stimulus at a low level (under the response threshold) and pair a favored reward (e.g., food treat) with each exposure to change the emotional response. Gradually progress to more intense stimulus.
- Devices that disrupt or inhibit vocalization may help to achieve quiet, which can then be reinforced; however, aversive techniques may increase anxiety.

ENVIRONMENTAL MODIFICATION

Modify environment to avoid or minimize exposure to stimuli that incite vocalization or wake the pet, e.g., covered crate, quiet room, thunder cap, classical music, white noise.

(CONTINUED)

EXCESSIVE VOCALIZATION AND WAKING AT NIGHTS**SURGICAL CONSIDERATIONS**

N/A

**MEDICATIONS****DRUG(S) OF CHOICE**

- Short-term or as-needed for situations of anxiety or for inducing sleep
- Benzodiazepines: dog, alprazolam 0.02–0.1 mg/kg; clonazepam 0.05–0.25 mg/kg; diazepam 0.5–2.2 mg/kg; cat, oxazepam 0.2–0.5 mg/kg; alprazolam 0.125–0.25 mg per cat; clonazepam 0.02–0.2 mg/kg
- Trazodone: dog, 3–12 mg/kg
- Melatonin: dog and cat, 3–6 mg (1.5–12 mg)
- For ongoing therapy for chronic anxiety or compulsive disorders: clomipramine (TCA): dog, 1–3 mg/kg PO q12h, cat, 0.5 mg/kg PO q24h; fluoxetine or paroxetine (SSRIs): dog, 1–2 mg/kg PO q24h, cat, 0.5 mg/kg PO q24h.
- Natural products that might be used adjunctively for anxiety: Adaptil, Feliway, l-theanine, alpha-casozepine, HarmonEase, SAMe or aromatherapy (lavender).
- For CDS: selegiline and cognitive supplements (see Cognitive Dysfunction Syndrome).

CONTRAINDICATIONS

Review contraindications and side effects for each drug used.

PRECAUTIONS

- Caution with drugs that might sedate in elderly pets.
- Monitor for undesirable behavioral effects.
- Avoid anticholinergic drugs in pets with CDS.

POSSIBLE INTERACTIONS

Do not use SSRIs and TCAs together with MAOIs such as selegiline and amitraz and use cautiously or avoid with buspirone and tramadol.

ALTERNATIVE DRUGS

- Concurrent sedation with acepromazine 0.5–2.2 mg/kg might be considered but it is not anxiolytic and may increase noise sensitivity and vocalization.
- For a less sedating anxiolytic consider buspirone at 0.5–1 mg/kg (q8–12h in dogs and q12h in cats).
- Analgesics for pain control.
- Gabapentin dog 10–30 mg/kg q8–12h, cat 5–20 mg/kg q8–24h.

**FOLLOW-UP****PATIENT MONITORING**

Modify the program based on response to therapy.

PREVENTION/AVOIDANCE

- Train calm and settle on cue (sit, down, go to mat).
- Predictable interactions, e.g., insure calm sit or down before any reward given.
- Reward desirable, do not punish undesirable behavior.
- Socialize and habituate pet when young to a wide range of people, pets, stimuli, and environments.
- Provide enrichment and scheduling to meet needs.

POSSIBLE COMPLICATIONS

- Night-time waking can lead to fatigue, increased irritability, and possibly aggression.
- Both night waking and vocalization can be particularly distressing to the pet owner's health and well-being and greatly weaken the bond.

EXPECTED COURSE AND PROGNOSIS

- Variable—based on diagnosis, environment, pet, and owner expectations.
- Most can be improved over time but might not eliminated.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

CDS

AGE-RELATED FACTORS

Increased anxiety and night waking more common in senior pets.

E

ZOONOTIC POTENTIAL

None but sleep disruption and anxiety in pets can contribute to sleep disruption and anxiety in the owners.

PREGNANCY/FERTILITY/BREEDING

EXERCISE-INDUCED WEAKNESS/COLLAPSE IN LABRADORS

BASICS

OVERVIEW

Inherited disorder causing weakness and collapse during intensive exercise in otherwise normal Labrador retrievers.

E

SIGNALMENT

- Labrador retrievers—nearly 10% of all pet, show, and field Labrador retrievers are affected.
- Also seen in Chesapeake Bay retrievers, curly-coated retrievers, Boykin spaniels and rarely in Old English sheepdogs, German wirehaired pointers, Bouvier des Flandres, Pembroke Welsh corgis, and cocker spaniels.
- Signs typically become apparent between 5 months and 3 years of age (average 12 months).
- No sex or color predilection.

SIGNS

General Comments

- No systemic signs.
- Collapse episodes are typically infrequent and occur only with extremes of exercise and excitement.
- Dogs can engage normally in hiking, swimming, jogging, and other activities that are not associated with a high level of excitement or stress.
- Symptomatic dogs are commonly reported to have an excitable temperament.

Physical Examination Findings

Between weakness/collapse episodes, physical and neurologic examinations are normal.

Features of Weakness/Collapse Episodes

- Weakness occurs after 5–20 minutes of intense exercise with excitement or stress.
- First abnormality noticed is a rocking or forced gait.
- The rear limbs become weak and unable to support weight.
- Many dogs will continue to run, dragging their rear limbs in a crouched posture.
- During a severe episode, all four limbs can be affected and rarely the dog may become recumbent and unable to move its limbs or raise its head.
- Some dogs are uncoordinated with a wide-based stance, and falling to the side during recovery from an episode.
- Dogs remain conscious and fully alert during the episodes.
- Rear limb muscles are flaccid during collapse and there is a loss of patellar reflexes.
- There may be increased extensor tone in the forelimbs of some collapsed dogs when they are lying in lateral recumbency.
- There is no apparent pain or discomfort on palpation or manipulation of the muscles, joints, or spine during or after collapse.

- Complete recovery occurs within 5–30 minutes.
- Rectal temperature is elevated (mean $> 107^{\circ}\text{F}$; $> 41.6^{\circ}\text{C}$) but not different from Labradors without exercise-induced collapse doing similar exercise.
- A few dogs with EIC have died during collapse—death is usually preceded by a short generalized seizure. The cause of death is uncertain but weakness of the respiratory muscles and extreme hyperthermia are suspected.

CAUSES

- Genetic disorder— inherited as an autosomal recessive trait.
- Symptomatic dogs—homozygous for a mutation in the dynamin 1 gene. Dynamin 1 (*DNM1*) is a protein important in neurotransmission in the brain and spinal cord during high-level neuronal activity. Evidence that the *DNM1* mutation associated with EIC has its most profound effect on DNM1 function when body temperature is elevated, as normally occurs with exercise.

RISK FACTORS

- Genetically affected dogs are at risk for collapse when participating in high-intensity exercise with concurrent excitement or stress.
- Affected dogs with a sedentary lifestyle or calm temperament may never exhibit weakness or collapse but most genetically affected dogs (> 80%) will have at least one episode of collapse before they reach 3 years of age.
- Collapse only occurs during specific trigger activities associated with a high level of excitement or anxiety.
- Trigger activities most likely to induce collapse include repetitive fun or training retrieves, upland bird hunting, intense play with other dogs, and running alongside an all-terrain vehicle.
- Increased ambient temperature and humidity seem to increase the risk of collapse in affected dogs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- The episodic nature of the collapse, association with exercise and excitement, typical features of collapse including rear limb weakness and normal mentation, progression of weakness during an episode, and rapid complete recovery should lead to a presumptive diagnosis of EIC in an otherwise healthy Labrador retriever. Physical and neurologic examinations are normal; further evaluation is required to eliminate other causes of weakness and collapse and to confirm genetic susceptibility to collapse caused by EIC.
- Dogs with metabolic myopathies, polymyositis, and myasthenia gravis are typically much more exercise intolerant than dogs with EIC and they will collapse with mild exercise of short duration.
- Centronuclear myopathy (previously called hereditary Labrador retriever myopathy or Type II myofiber deficiency)—inherited muscle disorder in Labrador retrievers that causes generalized muscle atrophy, constant weakness that worsens with exercise, and absent patellar reflexes at rest. Diagnosis of this disorder is by muscle biopsy or DNA testing (www.labradorcnm.com).
- Cardiac arrhythmia—as a cause of exercise intolerance can be ruled-out by cardiac auscultation, palpation of femoral pulses and performing an ECG at rest and during collapse. Holter monitor or an ECG event recorder may be required to rule out intermittent cardiac arrhythmia as a cause of collapse.
- Pulmonary hypertension—can cause exercise intolerance and syncopal episodes as exercise and excitement increase systolic pressure in an already overloaded right ventricle and pulmonary arteries, resulting in reflex bradycardia, vasodilation, and hypotension.
- Hypoglycemia—ruled out by measuring blood glucose during an episode.
- Hypo- or hyperkalemia—ruled out by measuring potassium during collapse.
- Hypoadrenocorticism (Addison's disease)—can cause exercise induced hypoglycemic collapse or seizures; should be ruled-out with ACTH stimulation test.
- Seizures—abrupt in onset and usually associated with altered or loss of consciousness, convulsive activity, rapid recovery and postictal signs.
- Atypical epilepsy/paroxysmal dyskinesia—brief episodes of abnormal crouched gait, disequilibrium, head-bobbing, or incoordination can be seen in Labrador retrievers as a seizure or movement disorder. Episodes may be induced by exercise/excitement in some dogs, leading to confusion with EIC. The onset of signs is peracute, the episodes are short (usually less than 5 minutes), all limbs are involved, and recovery is immediate, helping to distinguish this disorder from the more progressive gait disturbance caused by EIC. Diagnosis can only be made by ruling out other disorders (including EIC) with testing.
- Cataplexy—peracute, non-progressive, brief episodes of flaccid paralysis.
- Heat stroke—collapse due to heat stroke is usually associated with bleeding, shock, and abnormal mentation. Acute renal failure, DIC, and death are common. Recovery, if it does occur, is prolonged.
- Malignant hyperthermia—hypermetabolic state triggered by certain anesthetics, extreme

(CONTINUED) EXERCISE-INDUCED WEAKNESS/COLLAPSE IN LABRADORS

E

heat, intense activity, or psychological stress in genetically susceptible dogs. Hyperthermia, generalized skeletal muscle contraction, rhabdomyolysis, and DIC occur and many dogs die. Recovery, if it does occur, is prolonged. In vitro contracture tests on muscle biopsies or identification of the causative genetic mutation of the ryanodine receptor (*RYR1*) is required for diagnosis.

CBC/BIOCHEMISTRY/URINALYSIS

Normal at rest and during collapse

OTHER LABORATORY TESTS

- Arterial blood gas—normal at rest, extreme respiratory alkalosis and mild metabolic acidosis during collapse identical to intensively exercising Labradors without EIC.
- Lactate and pyruvate—normal at rest, not consistently different during collapse from exercising Labradors without EIC.
- Thyroid evaluation—normal.
- ACTH stimulation test—normal.
- Analysis for mutation in the ryanodine receptor (*RYR1*) causing malignant hyperthermia—negative.
- Testing for acetylcholine receptor antibodies causing acquired myasthenia gravis—negative.

IMAGING

Thoracic and abdominal radiographs, abdominal ultrasound, echocardiography—normal.

DIAGNOSTIC PROCEDURES

ECG findings at rest and during collapse—normal.

DNA Testing

- Definitive diagnosis requires demonstration that a dog has two copies of the *DNM1* mutation.
- Testing can be performed on blood, cheek swabs, puppy dewclaws, or semen.
- Approximately 10% of all tested Labrador retrievers have two copies of the *DNM1* mutation (affected); > 30% of all tested Labrador retrievers have one copy of the *DNM1* mutation (carrier).
- Finding two copies of the *DNM1* mutation confirms that a dog is EIC affected but does not necessarily rule out other causes of exercise intolerance or collapse. It is important to do the necessary tests to rule out other causes of collapse that may be potentially more treatable.

PATHOLOGIC FINDINGS

- Muscle histology—normal.
- Complete post-mortem examinations of dogs dying during collapse due to EIC—normal.

**TREATMENT****ACTIVITY**

Most affected dogs can live normal active lives if specific trigger activities are avoided or done in moderation.

CLIENT EDUCATION

- Signs commonly worsen in the 3–5 minutes after exercise is terminated; some (< 5%) affected dogs die during collapse.
- All activity should be halted at the first sign of weakness or incoordination.
- Consider offering cool water orally, spraying with water, or immersing in water to lower body temperature.

SURGICAL CONSIDERATIONS

Some male dogs have experienced fewer episodes of collapse following neutering.

**MEDICATIONS****DRUG(S)**

There is no recommended drug therapy for this disorder. Treatment with phenobarbital or sedatives may decrease the excitement level in affected dogs, making them less likely to collapse, but this response is not consistent. Owners are advised to limit participation in trigger activities rather than chronically medicating their dogs.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS**FOLLOW-UP**

Most affected dogs can be managed effectively by avoiding trigger activities and carefully observing for the first signs of weakness.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Dogs with EIC do not develop other associated medical conditions as they age.

AGE-RELATED FACTORS

Episodes of collapse may become less frequent as dogs age, perhaps because of less excitement associated with trigger activities.

PREGNANCY/FERTILITY/BREEDING

- Animals should be tested to establish their EIC status prior to breeding.
- Affected dogs (with two copies of the *DNM1* mutation) should not be bred or should be bred only to known non-carriers to avoid producing affected offspring.
- Carrier dogs (with one copy of the *DNM1* mutation) should only be bred to known non-carriers to avoid producing affected offspring.

ABBREVIATIONS

- ACTH = adrenocorticotropin hormone
- DIC = disseminated intravascular coagulation
- *DNM1* = dynamin 1
- ECG = electrocardiogram
- EIC = exercise-induced collapse
- *RYR1* = ryanodine receptor

Consulting Editor Joane M. Parent

EXOCRINE PANCREATIC INSUFFICIENCY

BASICS

DEFINITION

Syndrome that is caused by inadequate amounts of pancreatic digestive enzymes in the small intestinal lumen.

E

PATHOPHYSIOLOGY

- Most commonly caused by insufficient synthesis and secretion of pancreatic enzymes from the exocrine pancreas.
- In rare cases can be caused by an obstruction of the pancreatic duct.
- Insufficient synthesis of pancreatic digestive enzymes can be due to destruction of acinar cells resulting from chronic pancreatitis (approximately 50% of cases in dogs and almost all cases in cats) or can be due to idiopathic pancreatic acinar atrophy (PAA; most common cause of exocrine pancreatic insufficiency in German shepherd dogs).
- Deficient exocrine pancreatic secretion results in maldigestion and nutrient malabsorption, leading to weight loss and loose stools with steatorrhea.
- Malabsorption contributes to small intestinal dysbiosis.

SYSTEMS AFFECTED

Nutritional—protein-calorie malnourishment.

GENETICS

Assumed to be hereditary in the German shepherd dog and probably transmitted by a complex trait (early studies have suggested an autosomal recessive trait, but this has not been substantiated).

INCIDENCE/PREVALENCE

- PAA is very commonly seen in the German shepherd dog. PAA is less commonly seen in rough-coated collies and Eurasians.
- Other causes of EPI may be seen in all dog and cat breeds.
- Less common in cats than in dogs.

GEOGRAPHIC DISTRIBUTION

SIGNALMENT

Species

Dog and cat

Breed Predilections

German shepherd dogs, rough-coated collies, and Eurasians

Mean Age and Range

- Pancreatic acinar atrophy in young adult dogs.
- Chronic pancreatitis in dogs and cats of any age.

SIGNS

General Comments

- Consider in young adult (age range approximately 1–4 years) German shepherd dogs with weight loss and loose stools.
- Severity—varies depending on the time until diagnosis and therapy.

Historical Findings

- Weight loss with a normal to increased appetite.
- Chronically loose stools or

diarrhea.

- Diarrhea often resembles cow feces and may be continuous or intermittent.
- Fecal volumes are larger than normal and may be associated with steatorrhea.
- Flatulence and borborygmus are common, especially in dogs.
- May show coprophagia and/or pica.
- May be accompanied by polyuria/polydipsia with diabetes mellitus as a sequel to chronic pancreatitis.

Physical Examination Findings

- Thin body.
- Decreased muscle mass.
- Poor-quality hair coat.
- Cats with steatorrhea may have greasy “soiling” of the hair coat in the perineal area, but this is seen in the minority of cases.

CAUSES

- Pancreatic acinar atrophy
- Chronic pancreatitis
- Pancreatic adenocarcinoma leading to pancreatic duct obstruction

RISK FACTORS

- Breed—German shepherd dogs, rough-coated collies, and Eurasians
- Any condition predisposing dogs or cats to chronic pancreatitis

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Secondary causes of chronic diarrhea and weight loss (e.g., hepatic failure, renal failure, hypoadrenocorticism, and hypothyroidism in dogs or hyperthyroidism in cats).
- Primary gastrointestinal disease (i.e., infectious, inflammatory, neoplastic, mechanical, or toxic).

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal

OTHER LABORATORY TESTS

Direct/Indirect Fecal Examinations

Negative for parasites

Exocrine Pancreatic Function Tests—Trypsin-Like Immunoreactivity

- Diagnostic test of choice in both dogs and cats.
- Principle of test—serum TLI can be measured by an assay that detects trypsinogen and trypsin that is directly released into the blood from pancreatic acinar tissue; serum TLI is detected in the serum of all normal dogs and cats with a functional exocrine pancreatic mass.
- Serum TLI concentrations are dramatically reduced with EPI.
- In dogs—cTLI $\leq 2.5 \mu\text{g/L}$.
- In cats—fTLI $< 8.0 \mu\text{g/L}$.
- Canine and feline TLI tests are species-specific.
- Advantages—simple; quick; single serum specimen (fasted); highly sensitive and specific for EPI in both species.

Other Exocrine Pancreatic Function Tests

- Assays of fecal proteolytic activity using casein-based substrates have been used to diagnose EPI in both dogs and cats. However,

fecal proteolytic activity is associated with false-positive and false-negative test results and should only be used in exotic species for which a serum TLI test is not available.

- An assay for the measurement of fecal elastase has recently been validated for the dog. However, this test is associated with high rate of false-positive test results and can not be recommended at this point. A positive test result, suggesting EPI, must be verified by measurement of a serum cTLI concentration.

Screening Tests for Malassimilation

Microscopic examination of feces for undigested food, assessment of fecal proteolytic activity and the plasma turbidity test are unreliable and *not* recommended.

Cobalamin and Folate

- Often run as a panel with TLI.
- Used to assess for concurrent dysbiosis or concurrent small intestinal disease (such as IBD).
- Cobalamin (vitamin B₁₂) is frequently deficient in both dogs and cats with EPI and can lead to treatment failure or complications if not addressed.

IMAGING

Abdominal radiography and ultrasonography are unremarkable unless the patient has additional conditions.

PATHOLOGIC FINDINGS

- Chronic pancreatitis—microscopically, acini and possibly islets are depleted and replaced by fibrous tissue. There may also be an active infiltrative infiltration.
- Pancreatic acinar atrophy—marked atrophy/absence of pancreatic acinar tissue on gross and histopathologic inspection in dogs with PAA.

TREATMENT

APPROPRIATE HEALTH CARE

- Outpatient medical management.
- Patients with concurrent diabetes mellitus may initially require hospitalization for insulin regulation of hyperglycemia.

DIET

- Supplementation of the diet with pancreatic enzyme replacement is the mainstay of therapy.
- The type of diet does not play a role in the management of EPI in dogs and cats.
- However, low-fat and high-fiber diets should be avoided.
- Approximately 80% of all dogs with EPI and virtually all cats with EPI are cobalamin deficient and require cobalamin supplementation (pure injectable cobalamin at 250 µg/injection in cats and 250–1,500 µg/injection in dogs; once a week for 6 weeks, one more dose a month after that, and a recheck of serum cobalamin concentration a month after the last dose).
- Severely malnourished dogs may also require supplementation with tocopherol.

(CONTINUED)

EXOCRINE PANCREATIC INSUFFICIENCY

E

Body stores of other fat-soluble vitamins are probably also decreased in dogs and cats with EPI, but supplementation does not appear to be crucial.

CLIENT EDUCATION

- Discuss hereditary nature in German shepherd dogs.
- Discuss expense of pancreatic enzyme supplementation and need for life-long therapy.
- Discuss the possibility of diabetes mellitus in patients with chronic pancreatitis.

SURGICAL CONSIDERATIONS

Mesenteric torsion has been reported in German shepherd dogs with EPI in Finland but not North America.

MEDICATIONS

DRUG(S) OF CHOICE

- Powdered, pancreatic enzymes are the treatment of choice.
- Initially—mix enzyme powder in food at a dosage of 1 teaspoon/10 kg body weight with each meal; feed at least two meals daily to promote weight gain.
- Preincubation of enzymes with food does *not* improve the effectiveness of oral enzyme therapy.
- Cobalamin supplementation is crucial if the patient is cobalamin deficient.
- Administration of a proton pump inhibitor (e.g., omeprazole at 0.7–1.0 mg/kg q12h) may improve the condition in non-responsive patients.
- Most dogs and cats respond to therapy within 5–7 days. After a complete response has been achieved the amount of the pancreatic enzyme supplement may be gradually reduced to a dose that prevents return of clinical signs.
- Oral antibiotic therapy (tylosin, 25 mg/kg PO q12h) may be required for 4–6 weeks in patients with concurrent dysbiosis, but in most patients dysbiosis resolves spontaneously upon commencement of enzyme replacement therapy.

CONTRAINDICATIONS

Avoid tablets and capsules as mixing of enzymes and chyme is unpredictable.

ALTERNATIVE DRUG(S)

- The cost of pancreatic enzyme replacement is very high. Also, some cats refuse to consume the pancreatic enzyme supplement. These patients can often be successfully managed by administration of raw beef, pork, or game pancreas.
- Each teaspoon of

pancreatic enzyme supplement needs to be replaced with 1–3 ounces (approximately 30–90 g) of raw chopped pancreas.

- Raw pancreas can be kept frozen for months without losing enzymatic activity.

FOLLOW-UP

PATIENT MONITORING

- Weekly for first month of therapy.
- Diarrhea improves markedly—fecal consistency typically normalizes within 1 week.
- Gain in body weight.
- Patients that fail to respond after 2 weeks of enzyme therapy and cobalamin supplementation if indicated should be placed on antibiotics for concurrent dysbiosis.
- Once body weight and conditioning normalize, gradually reduce the daily dosage of enzyme supplements to a level that maintains normal body weight.

PREVENTION/AVOIDANCE

Do not breed patients that belong to a breed predisposed to pancreatic acinar atrophy.

POSSIBLE COMPLICATIONS

- Approximately 20% of dogs fail to respond to pancreatic enzymes and need further evaluation and therapy.
- Most patients with EPI have cobalamin deficiency and need to be managed accordingly.
- Some dogs treated with pancreatic enzyme supplements develop oral ulcerations. In most of these dogs the dose of pancreatic enzyme supplements can be decreased, while maintaining therapeutic response. In a few patients, the dose of the pancreatic enzyme supplement needs to be adjusted frequently to avoid treatment failure and oral ulceration.

EXPECTED COURSE AND PROGNOSIS

- Most causes are irreversible, and life-long therapy is required.
- Patients with EPI alone have a good prognosis with appropriate enzyme supplementation and supportive management.
- Prognosis is more guarded in patients with EPI and concurrent diabetes mellitus.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Dysbiosis.
- Inflammatory bowel disease.

- Diabetes mellitus.
- Associated vitamin K-responsive coagulopathy has been reported in two cats.

AGE-RELATED FACTORS

Consider EPI in young adult dogs with weight loss and loose stools.

PREGNANCY/FERTILITY/BREEDING

Do not breed animals with EPI suspected to be due to PAA.

SYNONYMS

- None

EYELASH DISORDERS (TRICHIASIS/DISTICHIASIS/ECTOPIC CILIA)

BASICS

OVERVIEW

- Trichiasis—when hair arising from normal skin contacts the corneal or conjunctival surfaces.
- Distichiasis—when extra lashes emerge from or near the meibomian gland orifices on the lid margin; these hairs may or may not contact the cornea.
- Ectopic cilia—single or multiple hairs that arise from the palpebral conjunctival surface several millimeters from the lid margin, most commonly near the middle of the superior lid. Occasionally ectopic cilia can arise on the back of the third eyelid.

SIGNALMENT

- Common in dog; rare in cat.
- Most common in young dogs.
- Any breed may be affected.
- Trichiasis: (a) facial fold trichiasis—common in brachycephalic breeds with prominent facial folds (e.g. Pekingese, pug and bulldog); (b) eyelid agenesis—sporadic. Usually bilateral at lateral aspect of upper lids in cats. Often associated with concurrent intraocular abnormalities;
- (c) entropion—conformational entropion is common in young dogs in predisposed breeds (Shar Pei, retriever, Chow Chow, among many others). Can be associated with blepharospasm (spastic entropion), scarring (cicatricial entropion), or enophthalmos; occasionally seen in cats.
- Distichiasis—predisposed breeds include cocker spaniel, American water spaniel, English bulldog, beagle, flat-coated retriever and dachshund. Dogs with distichiasis are also prone to have ectopic cilia. Rare in cats.
- Ectopic cilia—predisposed breeds include Pekingese, shih tzu and English bulldog.

SIGNS

Facial-Fold Trichiasis

- Epiphora.
- Pigmentary keratitis (especially nasally).
- Often associated with lagophthalmos.
- Occasional blepharospasm, especially if ulcerative keratitis is present.

Eyelid Agenesis

- Keratitis, including ulcerative keratitis
- Lagophthalmos
- Blepharospasm

Entropion

- Blepharospasm
- Epiphora
- Keratitis, including ulcerative keratitis

Distichiasis

- Usually asymptomatic.
- Stiff, stout cilia contacting the cornea—may note blepharospasm, epiphora, pigmentary and ulcerative keratitis.

Ectopic Cilia

- Severe blepharospasm.
- Epiphora.
- Superficial corneal ulcers with a rounded appearance (corresponding to lid movement) on the superior cornea; resistant to healing or

recurrent until the underlying problem is corrected.

CAUSES & RISK FACTORS

Usually related to facial conformation or breed predisposition, or is idiopathic.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Secondary to other adnexal abnormalities (e.g., entropion, eyelid agenesis).
- Keratoconjunctivitis sicca.
- Conjunctival foreign body.
- Infectious conjunctivitis.
- Diagnosis based on direct observation of abnormal cilia and lid conformation.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

N/A

TREATMENT

TRICHIASIS

- May be managed conservatively in some patients by protecting the cornea with topical lubricating ointments.
- Clipping the hair on facial folds may cause these hairs to become stiffer and more irritating.
- Surgical correction of adnexal abnormalities.
- May resect facial folds.
- Medial canthoplasty—often an effective procedure for nasal trichiasis; also eliminates lagophthalmos and medial entropion.
- Entropion repair.
- Repair of eyelid agenesis or treat distichiasis as noted below.
- Treat underlying cause (e.g., spastic entropion, enophthalmia).

DISTICHIASIS

- Usually asymptomatic and requires no treatment.
- Symptomatic—may treat surgically by cryoepilation, electroepilation, transconjunctival electrocautery and periodic manual epilation.
- Lid-splitting and partial tarsal plate excision techniques—avoid; postoperative scarring may predispose patient to cicatricial entropion and impaired lid function.

ECTOPIC CILIA

- May be treated surgically—en-bloc resection of the cilia and associated meibomian gland.
- Cryotherapy—may be used as the sole treatment or as an adjunct after surgical resection.
- May develop ectopic cilia at other locations.
- Recheck patient if clinical signs recur.

MEDICATIONS

DRUG(S)

- Rarely indicated.
- Lubricant ointments—sometimes valuable to soften cilia and lessen irritation before surgical correction.
- Soft contact lens—sometimes can use temporarily to relieve clinical signs before surgical correction.
- Topical antibiotics—perioperative; recommended for patients undergoing surgery to minimize conjunctival flora in the surgical sites.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

- Trichiasis—good prognosis when treated appropriately. Some corneal changes may be permanent (i.e., scarring, pigmentary keratitis).
- Distichiasis—regrowth can occur because destructive procedures must be done conservatively to minimize lid damage.
- Ectopic cilia—good prognosis. Occasionally adjacent hair follicles may not be visible at the first treatment session, or the germinal bud may not be destroyed and the hair shaft may regrow. Affected animals should not be used for breeding, especially breeds with low numbers of affected dogs.

FACIAL NERVE PARESIS AND PARALYSIS

BASICS

DEFINITION

Dysfunction of the facial nerve (CN VII) causing paresis (weakness) or paralysis of the muscles of facial expression, which include the ears, eyelids, lips, and nostrils.

PATHOPHYSIOLOGY

- Central—impairment of the facial nucleus within the rostral medulla (brainstem).
- Peripheral—impairment of the facial nerve anywhere along its length or at the neuromuscular junction.

SYSTEMS AFFECTED

- Nervous—facial nerve peripherally or its nucleus centrally.
- Ophthalmic—if parasympathetic preganglionic neurons that supply the lacrimal gland and gland of the third eyelid that course with the facial nerve proximally are affected, keratoconjunctivitis sicca develops due to lack of tear secretion.

GENETICS

N/A

INCIDENCE/PREVALENCE

More common in dog than cat

SIGNALMENT

Species

Dog and cat

Breed Predilections

Idiopathic paralysis—cocker spaniel, beagle, Pembroke Welsh corgi, boxer, English setter, golden retriever, and domestic longhair cats

Mean Age and Range

Adults

Predominant Sex

N/A

SIGNS

General Comments

- Assess strength of palpebral closure—there should be full eyelid closure when a finger is gently passed over the eyelids.
- Idiopathic—unaffected side may become affected within a few weeks to months; may rarely occur bilaterally at first presentation.
- Most patients with bilateral nerve involvement have polyneuropathy-associated systemic disease—look for other nerve deficits.
- May accompany other clinical signs and/or neurologic deficits—always perform a full neurologic examination.
- Ear droop is not always evident in cats and dogs with erect ears.

Historical Findings

- Messy eating; food left around mouth
- Excessive drooling on the affected side
- Facial asymmetry
- Eye—inability to close eyelids, rubbing, ocular discharge, ulceration

Physical Examination Findings

- Facial asymmetry—lip and ear droop, wide palpebral fissure, collapse of nostril.
- Decreased or absent palpebral reflex.
- Decreased or absent menace response (may see eye retraction rather than lid closure).
- Inability to close the eyelids.
- Excessive drooling or food falling from mouth on the affected side.
- Chronically, patients may have facial muscle contraction toward the affected side due to muscle fibrosis subsequent to paralysis and denervation.
- Decreased Schirmer tear test, mucopurulent discharge from the affected eye and exposure conjunctivitis or keratitis with concurrent keratoconjunctivitis sicca.
- Altered mentation (e.g., somnolence or stupor) and/or other cranial nerve abnormalities and gait disturbances may be noted when secondary to intracranial (brainstem) disease.
- Hemifacial spasms (facial nerve tetanus) may be infrequently observed in lesions affecting the facial nerve such as neuritis or otitis media. These patients have sustained contraction of the facial muscles giving a “grinning” appearance to the affected side of the face. This is a dynamic process and at times the face will appear normal, only to begin the “grinning” appearance once again. If one notices this clinical presentation, middle ear disease should be investigated thoroughly.
- Intermittent facial paresis can be observed in patients with a contralateral thalamocortical lesion when the patient is relaxed—due to “release” of the upper motor neuron influence on the lower motor neuron (CN VII).

CAUSES

Unilateral Peripheral

- Idiopathic
- Metabolic—hypothyroidism
- Infectious—otitis media-interna (dogs and cats)
- Inflammatory—nasopharyngeal polyps (cats), neuritis
- Iatrogenic—secondary to surgical ablation of external ear canal or bulla osteotomy; secondary to exuberant ear cleaning; idiosyncratic reaction to potentiated sulfonamides (dogs)
- Neoplastic—aural cholesteatoma, squamous cell carcinoma
- Trauma—fracture of the petrous temporal bone, direct injury to the facial nerve by laceration or compression by hematoma or other mass
- Toxic—tick bite paralysis (*Dermacentor* spp. (humans), *Ixodes holocyclus*)

Bilateral Peripheral

- Idiopathic—polyradiculoneuritis (coonhound paralysis)
- Immune-mediated—polyradiculoneuritis, polyneuropathy, myasthenia gravis

- Metabolic—paraneoplastic polyneuropathy (e.g., insulinoma)
- Toxic—botulism

CNS

- Most unilateral
- Infectious—viral, bacterial, fungal, rickettsial, protozoal encephalitis
- Inflammatory—granulomatous granulomatous meningoencephalitis (GME)
- Neoplastic—primary such as meningioma, choroid plexus tumor; metastatic tumor such as hemangiosarcoma, carcinoma, lymphoma

RISK FACTORS

Chronic otitis externa and otitis media

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Differentiate unilateral from bilateral involvement.
- Look for other neurologic deficits—behavior change, gait disturbance, other CN deficits.
- Idiopathic—diagnosis of exclusion; no historical or physical signs of ear disease and no other neurologic deficits.
- Hypothyroidism—with clinical evidence (e.g., lethargy, poor hair coat, weight gain, anemia, hypercholesterolemia, etc.).
- Otitis media-interna—Horner’s syndrome, head tilt, and KCS may be simultaneously present.
- CNS disease—if there is somnolence, gait disturbances or other CN deficits.

CBC/BIOCHEMISTRY/URINALYSIS

- Usually normal in idiopathic facial paralysis.
- Fasting hypercholesterolemia, normocytic/normochromic non-regenerative anemia may be observed with hypothyroidism-associated facial paralysis.
- Hypoglycemia with insulinoma.

OTHER LABORATORY TESTS

- Indicated for patients with suspected underlying disease
- Insulin:glucose ratio to detect insulinoma
- Acetylcholine receptor antibodies to diagnose myasthenia gravis
- Total T4 and canine TSH to diagnose hypothyroidism

IMAGING

- CT—sensitive to evaluate middle-inner ear diseases, preferred modality to evaluate bony structures in middle ear.
- MRI—superior to CT for intracranial imaging, preferable for CNS disease; contrast enhancement of facial nerve in dogs with idiopathic facial nerve paralysis; the greater the extent of enhancement, the poorer the prognosis for return to function.
- Bulla radiographs—(four views; two obliques, 30° open mouth, dorso-ventral) not sensitive for middle-inner ear diseases.

FACIAL NERVE PARESIS AND PARALYSIS

(CONTINUED)

DIAGNOSTIC PROCEDURES

- Schirmer test—evaluate tear production (normal > 15 mm in 60 seconds), should always be performed when evaluating a patient with facial paresis/paralysis.
- Fluorescein test—evaluate for presence of corneal ulceration secondary to KCS.
- Otoscopic examination—evaluate integrity of tympanic membrane and for evidence of otitis media.
- CSF—evaluate for evidence of intracranial disease; not sensitive if used alone, should be combined with diagnostic imaging (e.g., MRI).
- Facial muscle electromyography—evaluate for denervation and neuromuscular disease.
- Facial and trigeminal nerve reflex electrodiagnostic testing—evaluate peripheral nerve integrity, distinguish between peripheral and central lesions.

PATHOLOGIC FINDINGS

Idiopathic—may see degeneration of large and small myelinated fibers without evidence of inflammation.

TREATMENT

APPROPRIATE HEALTH CARE

- Outpatient—idiopathic facial paralysis
- Inpatient—initial medical workup and management of systemic or CNS disease if present

NURSING CARE

N/A

ACTIVITY

N/A

DIET

No change required

CLIENT EDUCATION

- Clinical signs may be permanent; however, as muscle fibrosis develops, there is a natural “tuck up” of the affected side that reduces asymmetry; drooling usually stops within 2–4 weeks.
- Inform client that the other side can become affected.
- Discuss eye care—the cornea on the affected side may need lubrication, extra care may be needed if the animal is a breed with natural exophthalmia, client must regularly check eyes for redness, discharge or pain.
- Inform client that most animals tolerate this nerve deficit well; there is no significant impact on quality of life.

SURGICAL CONSIDERATIONS

Bulla osteotomy may be indicated for patients with disorders of the middle ear.

MEDICATIONS

DRUG(S) OF CHOICE

- Treat specific disease if possible (e.g., thyroxine for hypothyroidism).
- Idiopathic disease—no treatment required; efficacy of corticosteroids unknown although used commonly in humans to treat Bell's palsy.
- Tear replacement if Schirmer test value low (< 15 mm), in patients with KCS or with exophthalmic globes.

CONTRAINdications

If middle ear disease is suspected, and the tympanic membrane may be ruptured, do not use topical ear cleaning solutions due to risk of ototoxicity.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

N/A

FOLLOW-UP

PATIENT MONITORING

- Reevaluate early for evidence of corneal ulcers.
- Reassess monthly (for 2–3 months) for menace responses, palpebral reflexes, and lip and ear movements to evaluate return of function, condition of affected eye and development of other neurologic deficits that would indicate progressive disease.

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

- KCS
- Corneal ulcers
- Severe contracture on side of lesion
- Permanent facial asymmetry (aesthetic only)

EXPECTED COURSE AND PROGNOSIS

- Depends on underlying cause if one is present.
- Idiopathic disease—prognosis guarded for full recovery.
- Improvement may take weeks or months or may never occur.
- Lip contracture sometimes develops.
- Corneal ulcers may perforate and require enucleation.

FALSE PREGNANCY

BASICS

DEFINITION

- Physical and behavioral changes resulting from normal hormonal changes during diestrus and early anestrus in the non-pregnant bitch. The term false pregnancy is a misnomer, since the pattern of hormonal changes is normal.
- Physical, hormonal, and behavioral changes following a non-fertile mating or spontaneous ovulation in the queen.

PATHOPHYSIOLOGY

- Hormone profile of pregnant and non-pregnant bitch very similar following ovulation.
- All cycling bitches undergo a lengthy (2+ months) diestrus following ovulation.
- Mammary development and behavioral changes occur under the influence of progesterone and prolactin in late diestrus.
- Galactorrhea (excessive production and inappropriate excretion of milk) is seen following a rise in serum prolactin at the end of diestrus; with severe hypothyroidism—due to resulting hyperprolactinemia.
- False pregnancies in the bitch are thought to occur as a holdover from a period in evolution when females of a pack would cycle at the same time but only dominant individuals would become pregnant. Non-pregnant pack members were available to nurse puppies of the more dominant females.
- Any event that results in an abrupt drop in serum progesterone and rise in prolactin can lead to a clinically overt false pregnancy. Signs are frequently created iatrogenically when ovariectomy or ovariohysterectomy is performed during mid to late diestrus.
- Queens that ovulate spontaneously or ovulate following mating but do not become pregnant experience a 6-7-week period of diestrus due to elevated progesterone concentrations; some queens develop a clinically overt false pregnancy during this time.

SYSTEMS AFFECTED

- Reproductive
- Behavioral
- Endocrine

GENETICS

N/A

INCIDENCE/PREVALENCE

- False pregnancies occur in 100% of bitches following ovulation.
- >60% of cycling bitches exhibit signs of false pregnancy.
- Spontaneous ovulation occurs frequently in the queen (35–85%) depending on presence of other queens and tom. False pregnancy occurs after every non-pregnant ovulation in the queen; overt symptoms are uncommon.

SIGNALMENT

Species

Dog and cat

Breed Predilections

None

Mean Age and Range

Any age

Predominant Sex

Female only

SIGNS

General Comments

- Although all cycling bitches have similar progesterone and prolactin hormone profiles during late diestrus and early anestrus, they vary in the magnitude of clinical symptoms associated with the false pregnancy. This may be due in part to individual sensitivities to prolactin.
- Some bitches experience repeated overt false pregnancies while others have covert false pregnancies.
- The magnitude of symptoms can vary during each false pregnancy for the same bitch.
- Overt symptoms are uncommon in queens.

Historical Findings

- Estrus ~ 6–12 weeks ago (bitch).
- Estrus ~ 40 days ago (queen).
- OHE or OVE 3–14 days ago.
- Mammary gland development.
- Galactorrhea.
- Weight gain.
- Behavior change including nesting, maternal behavior, aggression, lethargy.
- Inappetance.
- Abdominal distension (rare).

Physical Examination Findings

- Mammary gland hypertrophy.
- Galactorrhea—fluid can be clear to milky to brown in color.

CAUSES

- Decline in serum progesterone concentration and rise in serum prolactin concentration.
- Decline in serum progesterone concentrations due to OVE or OHE during diestrus.
- Hyperprolactinemia—can be due to severe hypothyroidism.

RISK FACTORS

- OHE or OVE during diestrus
- Does not impact future fertility

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Pregnancy
- Mastitis
- Mammary neoplasia.
- Mammary hyperplasia (queens)

• Pyometra

- Other causes of abdominal distension (organomegaly, ascites)
- Hypothyroidism
- Pituitary tumor causing hyperprolactinemia (rare)

CBC/BIOCHEMISTRY/URINALYSIS

- Normocytic, normochromic anemia—17–21% decrease in PCV during late diestrus.
- Hypercholesterolemia—75–94% increase during diestrus.

F

OTHER LABORATORY TESTS

Serum progesterone concentrations elevated if tested during diestrus.

IMAGING

- Ultrasonographic findings—uterine enlargement; performed after 25 days from mating; can be used to evaluate pregnancy status and uterine fluid accumulation.
- Radiographic findings—normal; performed after 54 days from mating; can be used to evaluate presence of fetal skeletons and uterine fluid accumulation.

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

N/A

TREATMENT

APPROPRIATE HEALTH CARE

- Usually no treatment needed.
- Outpatient treatment for medical management of clinical signs of false pregnancy.

NURSING CARE

- Prevent mammary gland stimulation from self-nursing with Elizabethan collar.
- Owners can cold pack mammary glands to reduce mammary gland activity.

ACTIVITY

Increase activity in sedentary dogs and cats to increase caloric expenditure and decrease calories available for lactation.

DIET

Decrease caloric intake for several days to reduce energy available for lactation.

CLIENT EDUCATION

- False pregnancies are normal in bitches and do not impact future fertility.
- Advise cat owners that pyometra can develop following spontaneous ovulations.

SURGICAL CONSIDERATIONS

- OVE or OHE if bitch or queen is not intended for use in a breeding program.
- Perform OVE or OHE during anestrus or early diestrus when possible.

FALSE PREGNANCY

(CONTINUED)

MEDICATIONS

DRUG(S) OF CHOICE

- Dopamine agonists—reduce milk production and some maternal behaviors by inhibiting prolactin release.
- Cabergoline 5 µg/kg PO q24h for 5–7 days
- Bromocriptine 10 µg/kg PO q8h for 5–7 days.

F

CONTRAINDICATIONS

Dopamine agonists can cause abortion if given to a pregnant bitch or queen as prolactin is luteotrophic. Drugs that suppress prolactin will terminate pregnancy by reducing progesterone and can cause premature parturition (abortion).

PRECAUTIONS

- Incidence of vomiting with bromocriptine administration reduced if given with food; cabergoline has fewer side effects and higher efficacy, but is more costly.
- Coat color changes in dogs possible with prolonged dopamine agonist treatment (uncommon).

POSSIBLE INTERACTIONS

Avoid acepromazine and metoclopramide; both can promote lactation and reduce the efficacy of dopamine agonists.

ALTERNATIVE DRUG(S)

- Short-term therapy with diazepam can be useful for bitches with extreme behavioral signs.
- Mibolerone 16 µg/kg PO q24h for 5–7 days to reduce symptoms of false pregnancy. Can also be used at 2.6 µg/kg/day starting at least 1 month prior to the next heat cycle to suppress estrus in bitches, which will prevent recurrence. Side effect and risks of treatment should be explained and owners should give informed consent prior to treatment. Do not give to cats.

FOLLOW-UP

PATIENT MONITORING

Have owners monitor mammary glands for inflammation and discoloration that could indicate mastitis.

PREVENTION/AVOIDANCE

- Perform OVE or OHE during anestrus or early diestrus when possible.
- Estrus suppression.

POSSIBLE COMPLICATIONS

Mastitis with significant mammary gland hypertrophy, galactostasis, and ascending infection.

EXPECTED COURSE AND PROGNOSIS

- Typically resolves in 2–4 weeks without treatment.
- Resolution in 5–7 days with dopamine agonist or mibolerone.
- May recur after any ovulation.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

N/A

PREGNANCY/FERTILITY/BREEDING

- The tendency to display overt false pregnancies has no impact on fertility.
- Bitches and queens should be evaluated for possible pregnancy before treating for false pregnancy.

SYNOMYS

- Pseudopregnancy
- Pseudocyesis
- Pseudo-gestation
- False-whelping

ABBREVIATIONS

- OHE = ovariohysterectomy
- OVE = ovariectomy
- PCV = packed cell volume

FAMILIAL SHAR-PEI FEVER

F

BASICS

DEFINITION

A familial autoinflammatory disorder in the Chinese Shar-Pei dog characterized by episodic fever and swollen hocks, and associated with progressive systemic amyloidosis.

PATOPHYSIOLOGY

• Shar-Pei dogs have a predisposition to reactive systemic amyloid deposition. The exact mechanism is multifactorial; however, it is now known that a genetic defect affecting the innate immune system plays a role. Environment and other gene modifiers play a role. The greater number of mutations in "meatmouth" (or heavily wrinkled/thick-skinned Shar-Peis) greatly increases the risk for clinical symptoms of FSF. Genetic alterations increase the levels of low molecular weight hyaluronan (LMW-HA). LMW-HA activates the release of pro-inflammatory cytokines. Interleukin-1 β is a key inflammatory mediator. Sequential production of inflammatory cytokines including TNF- α and IL-6 can induce increased levels of serum amyloid A (an acute-phase reactant). Excessive production of serum amyloid A results in the extracellular deposition of amyloid. Amyloid is deposited throughout the tissues; however, the most clinically important sites are the kidneys and liver. • Hepatic amyloidosis can lead to a friable liver susceptible to rupture and secondary hemoabdomen. • Renal amyloidosis and secondary nephrotic syndrome predispose Shar-Peis to states of hypercoagulability. • Similar to familial Mediterranean fever in people, these inflammatory mediators cause fever and serosal inflammation, affecting the pleura, peritoneum, and synovial membranes.

SYSTEMS AFFECTED

- Cardiovascular—venous thrombosis (e.g., PTE); systemic hypertension.
- Gastrointestinal—abdominal pain; vomiting; diarrhea; hemoabdomen; ascites.
- Hemic/Lymphatic/Immune—anemia; leukocytosis, with or without left shift; coagulation defects; hypercoagulable states; decreased immunoglobulin levels.
- Hepatobiliary—hepatomegaly; hepatic rupture; elevated liver enzymes; impaired hepatic function. • Musculoskeletal—joint effusion, especially of the tibiotarsi; lameness; stiffness; "walking on eggshells"; roach back; unwillingness to move. • Nervous—vascular accident; acute-onset neurologic signs (e.g., head tilt, vestibular ataxia, seizures).
- Ophthalmic—retinal detachment.
- Renal/Urologic—proteinuria; low specific gravity; polyuria; polydipsia.

- Respiratory—tachypnea or dyspnea.
- Skin—periarticular edematous soft tissue swelling, especially involving the tibiotarsal joint region; swollen muzzle; icterus; skin sloughing.

GENETICS

An autosomal recessive inherited disorder

INCIDENCE/PREVALENCE

- An estimated 23–28% of Shar-Peis are affected by this disorder. • An estimated 53% of Shar-Peis with fever have Shar-Pei fever.

SIGNALMENT

- Mean age—4 years • Range—19 weeks–9 years • Sex predisposition—female

SIGNS

General Comments

• Historical and physical examination findings vary depending on the organ affected and the severity of amyloidosis. • Some cases may have only a few of the following findings.

Historical Findings

- Episodic anorexia, lethargy, stiffness, swollen hocks and/or muzzle—self-limiting (24–36 hours) or responsive to NSAIDs.
- Intermittent bouts of abdominal pain, vomiting, and/or diarrhea. • Polyuria and polydipsia. • Weight loss.

Physical Examination Findings

- Marked fever 39.4–41.7°C (103–107°F) of 24- to 36-hour duration. • Lethargy and dehydration. • Edematous periarticular soft tissue swellings involving one or more joints. • Joint effusion. • Swollen muzzle.
- Abdominal pain. • Reluctance to move and hunched posture. • Tachypnea.
- Hepatomegaly, ascites, and icterus. • Pale mucous membranes secondary to chronic renal failure induced anemia or, in rare cases, hemoabdomen.

CAUSES

- Dysregulation of inflammatory processes in the Shar-Pei are thought to predispose the breed to development of secondary/reactive amyloidosis. • Any chronic infection, inflammation, immune-mediated disease, or neoplasia can cause reactive or secondary amyloidosis.

RISK FACTORS

Stress may trigger a fever episode.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Infectious or immune-mediated causes of polyarthritis—e.g., *Ehrlichia*, Lyme disease, systemic lupus erythematosus, idiopathic polyarthritis. • Icterus (see chapter).
- Chronic renal failure (see Renal Failure, Chronic). • Polyuria and polydipsia (see chapter). • Fever of unknown origin.

CBC/BIOCHEMISTRY/URINALYSIS

- Nonregenerative anemia—secondary to chronic renal failure or acute hemoabdomen.
- Leukocytosis with or without left shift.
- Changes compatible with renal failure—e.g., elevated urea, creatinine, and phosphorus levels, and metabolic acidosis.
- Hypoalbuminemia—secondary to proteinuria or hepatic failure.
- Hypercholesterolemia—consistent with nephrotic syndrome (hypoalbuminemia, proteinuria, ascites, and elevated cholesterol).
- Elevations in ALP and ALT activity; elevated bilirubin level. • Proteinuria—in cases where the amyloid is deposited in the renal cortex; note: proteinuria may be absent as the majority of dogs have medullary amyloid deposition • Isosthenuria—with renal involvement or hepatic failure. Bilirubinuria—secondary to cholestasis.

OTHER LABORATORY TESTS

- *Ehrlichia*, *Anaplasma*, and *Borrelia* serology/Snap 4Dx/or PCR. • Heartworm tests—to rule out glomerulonephritis secondary to heartworm-induced antigen-antibody complexes. • Coombs' test, ANA, and rheumatoid factor—to identify concurrent, underlying immune-mediated disease. • PT and PTT—factors IX and X may be lost through the glomerulus and prolong PTT; liver failure can cause prolongation of both PT and PTT; organ thrombosis may cause DIC and concurrent prolongation of PT and PTT and increased D-dimers. • Antithrombin III level—may be low secondary to loss through the glomerulus.
- Thromboelastography—may demonstrate hypercoagulability. • IgA or IgG levels—may be low in some cases; low level thought to lead to increased risk of inflammation or infection.
- UPC ratio—elevated with deposition of amyloid in the glomeruli; typically > 13 with amyloidosis (normal: ≤ 0.5).

IMAGING

- Abdominal radiography—abnormalities may include hepatomegaly or decreased detail secondary to peritoneal effusion; abdominal effusion may be secondary to hypoalbuminemia, portal hypertension, or hemorrhage. • Thoracic radiography—abnormalities may include pleural effusion secondary to severe hypoalbuminemia or pleural inflammation. • Joint radiography—typically shows periarticular swelling of the soft tissues without bony involvement.
- Abdominal ultrasonography—may reveal a diffuse homogeneous hypoechoic hepatic parenchyma and rounded liver edges; the kidneys may appear hyperechoic along with loss of corticomedullary distinction.

DIAGNOSTIC PROCEDURES

- Synovial fluid analysis—may or may not reveal evidence of acute synovitis (i.e., the presence of PMNs and decreased joint fluid

FAMILIAL SHAR-PEI FEVER

(CONTINUED)

viscosity); inflammation may be limited to the lower supporting structures of the synovium.

- Kidney (cortex) and/or liver fine-needle aspiration or biopsy (pending normal PT, PTT, platelet number, and buccal mucosal bleeding time)—amyloid deposition. Biopsy preferred; however Congo red staining and polarized light has been used to confirm amyloid on cytology samples.

PATHOLOGIC FINDINGS

- Systemic deposition of amyloid in multiple organs, e.g., the kidneys, liver, gastrointestinal tract, spleen, lymph node, adrenal glands, heart, lungs, thyroid gland, prostate gland, intestinal vessels, and pancreas. • Amyloid deposition may be associated primarily with vessels or within the parenchyma.

TREATMENT

APPROPRIATE HEALTH CARE

- Outpatient—during minor episodes of pain and fever that respond to NSAIDs.
- Inpatient—required during periods of anorexia, fever, dehydration, marked lameness or nonspecific pain, vomiting or diarrhea, ascites, or episodes of cholestasis. • Intensive care management—required during organ failure or thromboembolic events.
- Emergency stabilization—indicated for hemoabdomen or if splenic, portal, or renal vein thrombosis is suspected.

NURSING CARE

- Balanced polyionic fluids—if patient is dehydrated or anorexic, or if vomiting and/or diarrhea are present. • Oxygen—in suspected cases of pulmonary thromboembolism.
- Abdominocentesis—may be required if ascites is causing respiratory compromise.
- Blood transfusions—may be indicated if anemia is severe. • Fresh frozen plasma—may be considered for DIC or other coagulopathies.
- Antibiotics—if sepsis is suspected or concurrent infection is diagnosed; broad spectrum should be used if sepsis is suspected; otherwise, antibiotic choice should be guided by a sensitivity panel.
- Analgesics for fever and pain; NSAIDs are contraindicated in cases with concurrent renal disease or gastrointestinal signs.
- Gastroprotectants—if gastric ulcer secondary to renal or hepatic disease is suspected.

ACTIVITY

Limit during febrile episodes.

DIET

- Protein restriction and phosphorus restriction in accordance with IRIS renal staging (see www.iris-kidney.com). • Dogs showing evidence of hepatic encephalopathy should be fed a protein-restricted diet once they are stable. • Omega-3 fatty acids—may be beneficial for glomerular disease.

CLIENT EDUCATION

- There is no cure for familial Shar-Pei amyloidosis; therapy is palliative. • Early therapy may decrease further deposition of amyloid. • Diagnostics should be performed to ensure that there is no underlying or concurrent problem that may be treatable.
- Affected dogs should not be bred.

MEDICATIONS

DRUG(S)

- Colchicine 0.03 mg/kg PO q12–24h; advised early in course of disease to delay amyloid deposition; unknown if colchicine has any beneficial effect once amyloid has been deposited
- DMSO 80 mg/kg SC 3 times/week or 125 mg/kg PO q12h; controversial, generally doubted to have significant clinical effect.
- Steroids—only if a concurrent immune-mediated disease is present.
- Low-dose aspirin therapy—0.5–1 mg/kg PO q12–24h if concerned about hypercoagulability.
- ACEi and/or ARB for significant proteinuria. ACEi 0.25–0.5 mg/kg PO q12–24h.
- Address hypertension with additional therapy as indicated.

CONTRAINdications

- NSAIDs are contraindicated in renal disease and gastrointestinal ulcers. • Aspirin is contraindicated with concurrent NSAID use.
- Colchicine is contraindicated with concurrent cyclosporine use. • ACEi are contraindicated in dehydrated or hypovolemic patients.

PRECAUTIONS

- Steroid use may accelerate amyloid deposition. • Colchicine can cause gastrointestinal upset; chronic use can be associated with bone marrow suppression.
- DMSO has a very strong odor.

FOLLOW-UP

PATIENT MONITORING

- Urine specific gravity—monitor for isosthenuria. • Urine protein:creatinine ratios—to monitor glomerular disease.
- Biochemistry panel—to monitor renal and hepatic parameters, including hypoalbuminemia. • CBC monitoring—for anemia/inflammatory leukon. • Blood pressure monitoring and fundic examination—for hypertensive patients.

PREVENTION/AVOIDANCE

Avoid puppies from lines that have a history of Shar-Pei fever.

POSSIBLE COMPLICATIONS

- Death—due to hepatic rupture or pulmonary thromboembolism.

- Neutrophilic vasculitis causing severe skin sloughing, STSS causing localized necrotizing fasciitis and/or concurrent shock and multiorgan failure.

EXPECTED COURSE AND PROGNOSIS

- Waxing and waning, progressive disorder with a fair to poor prognosis, depending on the time of diagnosis. • Inevitably fatal due to CKD or hepatic failure. • Time course may be weeks to more than 10 years.

MISCELLANEOUS

AGE-RELATED FACTORS

Tends to be more severe in cases diagnosed at an early age.

PREGNANCY/FERTILITY/BREEDING

Do not breed affected dogs.

SYNONYMS

- Swollen hock syndrome • Shar-Pei autoinflammatory disorder

ABBREVIATIONS

- ACEi = angiotensin converting enzyme inhibitor • ALP = alkaline phosphatase
- ALT = alanine aminotransferase • ANA = antinuclear antibody • ARB = angiotensin receptor blocker • CKD = chronic kidney disease • DIC = disseminated intravascular coagulation • DMSO = dimethyl sulfoxide
- FSF = familial Shar-Pei fever • IL-6 = interleukin-6 • NSAID = nonsteroidal anti-inflammatory drug • PCR = polymerase chain reaction • PMN = polymorphonuclear neutrophil • PT = prothrombin time
- PTE = pulmonary thromboembolism
- PTT = partial thromboplastin time
- STSS = streptococcal toxic shock syndrome
- UPC = urine protein creatinine ratio

FANCONI SYNDROME

F

BASICS

OVERVIEW

A constellation of abnormalities caused by defective proximal renal tubular reabsorption of glucose, electrolytes, and amino acids.

SIGNALMENT

Species

Dog

Breed Predilections

Although sporadically reported in several breeds, idiopathic Fanconi syndrome primarily affects the basenji breed (approximately 75% of cases). In North America, 10–30% of basenjis are affected. It is presumed to be inherited in this breed, but the mode of inheritance is unknown.

Mean Age and Range

Age at diagnosis: 10 weeks–11 years. Affected basenjis usually are > 2 years of age; most develop clinical signs from 4 to 7 years.

Predominant Sex

No sex predilection

SIGNS

- Vary depending on the severity of specific solute losses and whether or not renal failure has developed.
- Loss of amino acids and glucose—usually not associated with clinical signs other than polyuria and polydipsia (most common clinical signs).
- Weight loss, often despite a normal appetite.
- Variable lethargy.
- May have decreased appetite.
- Poor body condition.
- Abnormal growth (rickets) may occur in young animals.

CAUSES & RISK FACTORS

- Inherited in basenjis.
- Acquired Fanconi syndrome has been reported in dogs given gentamicin, streptozotocin, maleic acid (experimental), amoxicillin, and chicken jerky treats from China; also reported secondary to primary hypoparathyroidism. Chicken jerky treat ingestion has become an important cause of Fanconi syndrome in the past 5 years. The causative toxin still has not been identified.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Primary renal glucosuria also causes glucosuria in the absence of hyperglycemia; documentation of aminoaciduria, mild proteinuria, or a hyperchloremic (normal anion gap) metabolic acidosis suggests Fanconi syndrome.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC usually normal.
- Hypokalemia in about one-third of cases.
- Hyperchloremic

metabolic acidosis.

- Azotemia if renal failure develops.
- Hypophosphatemia and hypocalcemia may occur in affected young, growing animals.
- Urine specific gravity usually low (1.005–1.018); mild proteinuria common; ketonuria may be present.

- Granular or lipid renal casts and bacteria were seen in 27–40% of dogs that developed proximal renal tubulopathy after eating chicken jerky treats.

OTHER LABORATORY TESTS

Hyperchloremic (i.e., normal anion gap) metabolic acidosis due to bicarbonaturia with urine pH < 5.5. Urine pH is > 6.0 in distal RTA (renal tubular acidosis), and this is a key diagnostic difference between proximal (Fanconi syndrome) and distal RTA. Bicarbonaturia does not occur unless a bicarbonate load is administered.

IMAGING

Radiography—young, growing dogs may have features of rickets and angular limb deformities; adult patients may exhibit decreased bone density.

DIAGNOSTIC PROCEDURES

Urinary clearance studies to document excessive excretion of solutes such as glucose, amino acids, and electrolytes are needed for confirmation. It is not recommended to test animals < 8 weeks of age because false-positive results may occur. A 24-hour urine sample can be sent to the Metabolic Genetic Disease Testing Center (University of Pennsylvania) to screen for aminoaciduria. Fractional reabsorption of amino acids in affected dogs ranges from 50% to 96% (normal range, 97–100%).

PATHOLOGIC FINDINGS

Renal papillary necrosis may occur as a late finding. Karyomegaly of the tubular cells has been reported.

TREATMENT

- Discontinue any drug that may cause Fanconi syndrome or treat for a specific intoxication.
- No treatment will reverse the transport defects in dogs with inherited or idiopathic disease.
- Because the number and severity of transport defects vary markedly among affected animals, treatment must be individualized.
- Treat for metabolic acidosis if blood bicarbonate concentration is < 12 mEq/L. Large doses of alkalinizing agents may be required because decreased proximal tubular resorptive capacity results in marked bicarbonaturia. The goal of alkali therapy is to maintain blood bicarbonate concentration at 12–18 mEq/L.
- Young, growing dogs may require vitamin D, calcium, and phosphorus supplementation.

MEDICATIONS

DRUG(S)

Use potassium citrate (1 mEq = 108 mg) at 50–500 mg/kg q12h (1 to > 10 mEq/kg/day; start with a low dosage) or sodium bicarbonate (1 mEq = 84 mg) at 80–300 mg/kg q8–12h (1 to > 10 mEq/kg/day; start with a low dosage) as dictated by blood gas and electrolyte data. These are much higher dosages than are necessary in distal RTA.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Avoid drugs that are nephrotoxic or have the potential to cause Fanconi syndrome (see “Causes & Risk Factors”).
- Avoid potassium chloride because affected patients are hyperchloremic.

FOLLOW-UP

- Monitor serum biochemistry at 14-day intervals to assess the effect of treatment; monitor serum potassium concentration regularly because bicarbonate therapy may aggravate renal potassium loss; once stable, monitor biochemistry at 3-month intervals.
- Clinical course varies; some dogs remain stable for years, others develop rapidly progressive renal failure over a few months; the cause of death usually is acute renal failure, often associated with severe metabolic acidosis.
- Some dogs (18% in one study) developed seizures or other neurologic signs several years after diagnosis.

FEAR AND AGGRESSION IN VETERINARY VISITS

BASICS

DEFINITION

- Fear—inevitable, negative emotional state caused by the anticipation/awareness of danger.
- Aggression—warning/intent to cause harm/increase distance in response to perceived threat.

F

PATOPHYSIOLOGY

See “Causes” and “Risk Factors”

SYSTEMS AFFECTED

- Behavioral—neurochemical input between the limbic system and forebrain allow for classically conditioned emotional (fear) memories, leads to defensive behavioral response.
- Sympathetic nervous system arousal.

GENETICS

Fearful/fractious temperaments are heritable.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Dog and cat

Breed Predilections

Any

Mean Age and Range

Any

Predominant Sex

Any

SIGNS

General Comments

- Displacement behaviors (yawns, lip licking, grooming, panting).
- Offensive and/or defensive threat displays.
- “4 F’s of behavior”: fight, flight, freeze, fidget.

CAUSES

- Previous/current frightening or painful veterinary visits create an involuntary fear response (“white coat effect”).
- Previous use of harsh/punitive tones of voice, physical manipulation.
- Additional exposure to individual patient’s triggers of fear (travel, dogs, strangers).
- Underlying fearful/anxious temperament; comorbid behavioral disorders.

RISK FACTORS

- Previous frightening/painful veterinary experiences.
- History of fearful/fractious behavior at previous visits or around any person.
- Harsh or punitive handling during puppy or kitten visits.
- Poor socialization during the sensitive socialization period (dog 3–12 wks; cat 2–7 wks).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Pain • Irritability from illness—gastrointestinal discomfort, urogenital inflammation, visceral neoplasia
- Forebrain lesion • Cognitive dysfunction syndrome

CBC/BIOCHEMISTRY/URINALYSIS

Endogenous corticosteroid-induced (stress) leukogram possible (neutrophilia, lymphopenia, monocytosis); hyperglycemia; glucosuria (cats)

TREATMENT

APPROPRIATE HEALTH CARE

Prior to Handling

Assess the environment, patient and yourself. What patients see, smell, feel, taste, and hear affect emotional state. Utilize assessments to ameliorate stressors and create a successful handling plan.

Assess the Environment: make it comfortable for the patient

- Eliminate exposure to patient’s known triggers of fear or aggression.
- Reduce environmental stimuli (light, noise, movement, touch).
- Thermo-neutral comfort zone is 59–86°F, dogs; 86–100°F, cats.
- Ideal ambient sound level is 60 dB (stress at 85 dB).
- Provide pheromone support (Adaptil, Feliway).
- Mindfully manipulate owner presence; many do better with social support.
- Utilize highly palatable food for distraction and CC.
- Create a comfortable exam site (no slippery, shiny, cold surfaces).
- Provide a way for fearful patients to hide, feel covered, and protected.
- Ensure all supplies are readily available.

Assess the Animal

- Recognition of fear and impending aggression and interpretation of patient body language is critical.
- Anxiety, fear, and arousal are the motivations for aggression and other fractious behavior.
- Early recognition improves intervention efficacy and safety, and

decreases handling time.

- Track body language, willingness to approach, interaction with the environment and people.
- Identify displacement behaviors to flag patients that are not coping well.
- Monitor continually. Changes in location (lobby vs. radiology), interactions (social petting vs. exam), procedures (auscultation vs. nail trim), and personnel (female vs. male) affect patients.

Assess Yourself: Avoid Perceived Threats, Track your own Body Postures and Behavior

- Avoid direct eye contact, bending over, or putting your face near a fearful patient.
- Bend at the knee, turn your body to the side, and squat down (when safe).
- Avoid reaching out, petting on top of the head, sudden grabbing of the collar or body, or reaching into a carrier. Encourage patients to approach you, or have the handler they feel safe with bring them to you.
- Cat—encourage approach by patting the surface and using a soft voice. Remove carrier tops—do not pull or dump out patients.
- Allow time to sniff your hand. Gently scratch under the chin and pet the side of the head if postures indicate safety. Avoid petting beyond the shoulder as it is often arousing.
- Start exam at the head or middle and move back; save socially invasive or painful areas for last.
- Dog—hold your hand at your side, patting your leg gently, soft verbal encouragement, hold your palm open with valued treats if the dog approaches, and allow the dog to sniff and investigate.
- Gently pet under the chin and neck area; slowly move into the desired examination position.
- Start exam at the middle or rear and move towards the head.
- Lack of patient approach in response to a non-threatening invitation indicates the animal is maintaining social distance.
- Anticipate that your approach may lead to an aggressive response.
- If you must approach, do so from the side; work from the side and from behind the point of the shoulder.
- Avoid front-facing interactions unless the patient’s head is covered.
- Avoid loud talking and sudden movements.
- Work quietly, quickly, and effectively; often a narrow window of opportunity before fear and arousal escalate.
- Encourage handlers that are fearful of working with specific patients to stop and ask their team for help; reassess if and how to proceed.
- Fearful animals and fearful handlers are a dangerous combination, and often escalate each other’s fear, arousal, and aggressive responses.
- Ensure the culture supports this and the safety of each team member.
- Monitor handler frustration.
- Adversarial and punitive language and interactions must be avoided.
- Use language that is scientifically accurate and promotes

(CONTINUED)

FEAR AND AGGRESSION IN VETERINARY VISITS

patient empathy—fearful, painful, confused; and avoid choices that result in poor handling and may be offensive to clients—mean, bad, stupid, spiteful, evil, dominant. Handler language affects their actions as well as those of others. • Punishment (verbal, physical, leash corrections, “dominance maneuvers”) must be strictly avoided. Aversives increase fear, arousal, aggression, and are contraindicated. Behavioral signals of intent can also be blunted, making handling more dangerous. Negative experiences are likely to escalate fractious behavior during subsequent handling interactions at the hospital and possibly at home. • Create cultural norms that prohibit adversarial language and interactions.

Make a Handling Plan

Handling plans are unique to individual patients/working environment, and may require adjustments dependent on patient response. Initial planning may seem time consuming, but has a high payoff in staff safety, decreased future handling time, patient welfare, and client satisfaction. Chart information including what worked well and suggested changes to make the next visit even better.

Guidelines for a Patient Handling Plan

- Determine if and what the patient can eat; plan for CC that is appropriate and safe for the animal. • Select appropriate level of restraint for the individual patient and the procedures. • Select handling tools that increase safety and decrease patient fear and arousal. • Critically consider what needs to be performed—must the procedure be done today, or at all? Consider multiple visits of shorter duration with fewer procedures.
- Place the required procedures in order of most important to least important in the event the patient is unable to tolerate all of them. • Place those procedures in order of least aversive to most, so early difficult procedures do not inhibit ability to complete later ones. Trends among patients exist, individual differences also occur. • Consider pain, invasiveness, number of procedures, and how the patient is coping with minimal handling. Consider sending the patient home with a plan for return (oral sedation prior to travel, avoidance of known triggers and environmental management, DS/CC to specific handling or tools). Use chemical restraint immediately when unlikely the patient will be able to tolerate all procedures.
- Have chemical restraint prepared and waiting for at-risk patients; use before patient becomes aroused to promote efficacy, handler safety, and to reduce further advancement of patient fear.

Utilization of Counter-Conditioning

- A form of classical conditioning where an animal's reflexive negative emotional response (fear) to a stimulus (veterinary setting) is changed to a positive one (pleasure). Palatable

food is the easiest and most powerful means of establishing this association. • Prevents and/or treats established fear of handling and environment. • Most effective when food is first offered while the animal is relaxed and feels safe, then just before, during, and after the (aversive) procedure. Events may be aversive because they are painful (injections) or socially invasive (rectal temperature, nail trims). • Stressed animals may need to be fed the duration of handling to prevent escalation of fear and arousal. Utilize food that can be broken up into small pieces, or use sticky, smearable options. • Palatability must be high (meat baby food, liverwurst) to maximize the animal's interest in eating and increase the power of the positive emotional response. Petting and praise can be used additionally, but are far less powerful and may even be unpleasant for some pets. • Food serves as a “barometer” for patient stress; many won't eat even highly palatable food. Rejection should cue the handler to reassess patient comfort level, safety and handling plan.

Safe and Effective Restraint

Once the itinerary of procedures has been organized, a restraint plan should be coordinated for each procedure. Avoid the tendency to over-restrain animals. Stress often revolves around the restraint, rather than the procedure itself. When patients are CC with food, and stressors are mitigated through environmental management and non-threatening interactions with staff, less restraint is needed.

Guidelines for restraint

- Use the least restraint required to allow the specific procedure(s) to be performed properly (AVMA Restraint Policy). • When greater restraint is needed, provide firm, balanced pressure with global support around the patient. Prevent flailing by keeping control of head and rear end at all times. • Reserve lateral recumbency in dogs only for procedures that require it (ex. orthopedic exams). It is a threatening position for many. Most can be performed in a stand or sit position. Some dogs will assume this position when lured with a treat or asked to perform a “down.” If required, prevent flailing and hitting the head; move the patient slowly and steadily with full body support. • Reserve scruffing and/or stretching only for cats comfortable with this technique, and only when the procedure requires the cat to be in lateral recumbency. • Slide your hands along the patient's body, rather than releasing and grabbing when moving your hands or adjusting your position. • If the pet struggles longer than 3 sec., stop, reposition, and try again. Wait until relaxed, and preferably starts eating, before beginning the procedure. If after 2 or 3 attempts the patient does not relax and/or starts to get fractious, stop altogether and consider whether the procedure is

essential. • Essential: make a plan for chemical restraint. • Non-essential: send the animal home and create a plan for return.

Handling Tools

Designed to expedite veterinary procedures and increase safety. Handling tools also reduce the need for physical restraint and the stressful social interaction. The key is using them correctly, often, and early in the handling plan.

Pheromones

- An Adaptil diffuser for dogs and Feliway diffuser for cats in the reception area, examination rooms, and hospital wards may help to lower stress. • A pheromone spray or wipe can be used to reduce stress during travel, crating, on the examination table or in the clinic cages. Dogs might have the spray placed on a bandana around their neck prior to the visit, or can be fitted with an Adaptil collar at least one day in advance. • Never spray directly on the pet.

Muzzles

- Basket muzzle (plastic, metal):
 - Allows panting; safer for longer procedures and kennelled dogs. ◦ Food can easily be smeared along the inside of the muzzle, encouraging the dog to place its nose into the muzzle.
 - Increases safety so lightest restraint and CC can be used. ◦ Best if owner habituates and DS/CC to muzzle at home and have in place for arrival. ◦ If owner has not adapted pet to muzzle, first consider whether procedure can be postponed and client instructed to adapt to muzzle before the next visit. ◦ If staff must apply muzzle, safety is essential. Alternately, for short procedures or to facilitate an injection, a nylon slip-on muzzle might be easier to apply. [/sr1]
 - Feline muzzle (leather, plastic): Select a stiff leather or plastic option that covers both mouth and eyes. Provides handler safety and minimizes visual stimuli.

Elizabethan Collar

An alternative to the muzzle for conformation or intense fear of the muzzle this collar can be used to provide control of the head. For small dogs and cats a towel or blanket may be preferable.

Towels

- Towels or thick bedding can provide low-stress immobilization of cats and small dogs. • Provide head and body control, reduction of visual stimuli, and firm global pressure of handling; modifications can be made to gain access to the head. • Allow access for auscultation, abdominal palpation, and hind leg venipuncture. • Utilized to safely capture fleeing or fearful cats, remove from carrier or cage, and administer injections for chemical restraint; protect the cat from flailing and prevent bites and scratches.

Thunder Cap

- Limits visual stimuli; reduces anticipation of procedures, perception of handler posture, and known individual triggers (travel, dogs, strangers). • Utilize during travel, entering to

FEAR AND AGGRESSION IN VETERINARY VISITS

(CONTINUED)

the building, procedures, hospitalization, and after chemical restraint (to keep the patient under the plane of sedation). • A muzzle or towel that covers the eyes/head may have the same effect on cats.

Thundershirt

Swaddles the dog or cat, providing firm, balanced pressure around the chest and torso, reducing arousal, anxiety, and fear.

Classical Music (Through a Dog's Ear/Through a Cat's Ear)

- Increases behaviors associated with relaxation in animals and people.
- Source of noise cancellation, masking potentially stressful external sounds.
- Relaxes clients, reminds staff to work quietly and slowly.

Squeeze Cage

- For essential procedures on dogs that are not safe to muzzle; protected contact used to administer injection of chemical restraint.
- Alternative created with a chain-link panel that swings out from the wall or an existing door. Hold panel open at $\leq 90^\circ$ while the dog is walked in; pull the lead through the crevice at the hinge for head control. Gently close the panel towards the wall, securing the dog; quickly inject through the panel.

Clipnosis (Cats only)

- Pinch-based inhibition ("trance-like" state, semi-immobile, relaxed, without activation of stress response) using Clipnosis Gentle Calming Clips or other tools, such as binder clips.
- Produces firm, even pressure when placed on the scruff, provides a hands-free option to hand-scruffing, typically with more behavioral calming.
- Place on cats when calm and relaxed. Cats that are averse to pressure on the scruff or are fractious are not candidates.
- Some have reservations regarding the tool and its effects on behavioral inhibition through freezing vs. calming.

Cat Carriers

- Select type that allows the cat to easily exit on its own or have a removable top that allows the cat to remain in the bottom portion during exam.
- Allows the cat to remain in a familiar area, prevents fleeing, and promotes hiding.
- Soft-sided carriers useful for fractious cats in need of chemical restraint. Cat remains in the familiar carrier while the mesh panel is pressed up against the body to allow IM injection.
- Allow hospitalized cats to have their carrier in their cage. Provides familiarity, stress relief, and has been shown to encourage a faster return to eating.
- Carrier is a more effective tool if cats are conditioned to enter and travel in it comfortably.

EZ Nabber

- Mesh netting tightly secured to rectangular metal enclosure; opens and closes manually to allow for capture and quick restraint.
- Valuable for fractious cats who are fleeing or housed in a wall unit cage; 2 ft. distance between the handler and the cat.
- Use to administer IM chemical restraint through the mesh.
- Cover with a towel once the cat is

inside to reduce visual exposure and protect handler.

- Alternately a fish net might be used to cover or wrap the cat.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUG(S) OF CHOICE

Chemical Restraint

- Allows safe effective handling, blocking further distress. Avoid allowing patients to become fractious/agitated before considering; reduces the efficacy, allows learning to occur, advances fear responses.
- Desired plane of sedation—animal requires little to no restraint to accomplish all desired interactions, is unaware.
- Injectable forms of sedation IM are the most effective means of safely handling a fractious or highly fearful patient; protocol selection based on age, temperament, degree of health/disease.
- Manage environment to achieve and maintain desired sedation (white noise, music, dim lights, owner support, avoid triggers, Thunder cap, cotton balls in ears).
- Muzzle sedated patients for added safety.
- Oral administration of sedative/anxiolytic medication prior to arrival so experience is less fear-provoking, safer, and requires lower doses to achieve effect.

Injectable Chemical Restraint—Dogs

- For young fractious dogs—dexmedetomidine (10–20 $\mu\text{g}/\text{kg}$) + opioid (butorphanol* 0.2–0.4 mg/kg) IM \pm ketamine (3 mg/kg) IM.
- Alternative option—Telazol (tiletamine/zolazepam) 5–10 mg/kg IM (not practical for dogs > 20 kg due to high volume injection).
- For geriatric fractious dogs—acepromazine (0.05 mg/kg) OR dexmedetomidine (5 $\mu\text{g}/\text{kg}$) + opioid (butorphanol* 0.2–0.4 mg/kg) IM.
- Reverse dexmedetomidine with equivolume of atipamezole to volume of

dexmedetomidine administered IM/SC; in ketamine protocols wait 30–60 min to reverse.

*A full Mu opioid agonist, ex. morphine (0.2 mg/kg), hydromorphone (0.05–0.1 mg/kg), or oxymorphone (0.1 mg/kg) superior for pain management

Oral transmucosal—Dogs

- For healthy fractious dogs—dexmedetomidine (40 $\mu\text{g}/\text{kg}$) + morphine (1 mg/kg) OTM; reverse dexmedetomidine with half volume of atipamezole to volume of total dexmedetomidine IM or SC.
- Select dogs that: are pain sensitive, allow handling of mouth by owners or staff, have been DS/CC to placement of a syringe in cheek pouch.
- 1 hour to full effect; increased contact time with mucosa improves efficacy (avoid swallowing, spilling); slow application is key, increased viscosity (add honey, commercial agents) helps.
- Often requires additional IM dose of dexmedetomidine (10 $\mu\text{g}/\text{kg}$) + morphine (0.1–0.2 mg/kg); 15 min. to effect.
- Caution: commonly see vomiting.

Injectable Chemical Restraint—Cats

- For young fractious cats—dexmedetomidine (10–20 $\mu\text{g}/\text{kg}$) OR acepromazine (0.1 mg/kg) + ketamine (3–5 mg/kg) + opioid (butorphanol* 0.2 mg/kg or morphine 0.2 mg/kg) IM.
- Alternative option—Telazol (tiletamine/zolazepam) 5–10 mg/kg IM.
- For geriatric fractious cats—acepromazine (0.05 mg/kg) OR dexmedetomidine (5–10 $\mu\text{g}/\text{kg}$) + ketamine (3–5 mg/kg) + opioid (butorphanol* 0.2 mg/kg) IM.
- Reverse dexmedetomidine with half volume of atipamezole to volume of dexmedetomidine administered IM; in ketamine protocols wait 30–60 min to reverse.

*Full Mu opioid agonist, ex. morphine (0.2 mg/kg), hydromorphone (0.05–0.1 mg/kg), or oxymorphone (0.1 mg/kg) is superior for pain management.

Oral Transmucosal—Cats

- For healthy fractious cats—dexmedetomidine (40 $\mu\text{g}/\text{kg}$) + buprenorphine (0.02 mg/kg) OTM. Reverse dexmedetomidine with fourth-half volume of atipamezole to volume of total dexmedetomidine administered IM or SC.
- Additional IM injection may be required.

Protocols courtesy R. Bednarski, DVM, MS, DACVA

Oral Sedative/Anxiolytics

Administer 90 min. prior to travel to relieve mild to moderate fearful/fractious behavior or help patient cope with injectable sedation. Doses should be repeated Q8-12hr PRN for inpatients.

Dogs

- Trazodone: 4.0–18.0 mg/kg PO; not exceeding 300 mg per dose.

(CONTINUED)

FEAR AND AGGRESSION IN VETERINARY VISITS

F

- Clonidine: 0.01–0.05 mg/kg PO; can be combined with trazodone and/or benzodiazepines.
- Acepromazine: 0.55–2.2 mg/kg PO; best in combination with trazodone, gabapentin, or benzodiazepine; avoid as sole agent, doesn't provide anxiolysis.
- Lorazepam: 0.05–0.5 mg/kg PO.
- Diazepam: 0.5–2.2 mg/kg PO.
- Gabapentin: 20–40 mg/kg PO; can combine with trazodone, acepromazine, benzodiazepines.

Cats

- Acepromazine: 1.1–2.2 mg/kg PO.
- Lorazepam: 0.05–0.25 mg/kg PO; can combine with acepromazine.
- Gabapentin: 10–20 mg/kg PO; can combine with acepromazine.
- Buprenorphine: 0.01–0.03 mg/kg OTM.

CONTRAINDICATIONS

Cats—avoid oral diazepam; acute hepatic necrosis reported.

PRECAUTIONS

• Agitation, gastrointestinal upset, heavy sedation, changes in appetite are potential side effects of all of above oral medications. Always have client perform drug trial at home to determine response and ideal dose.

• Benzodiazepines—caution in fractious patients; disinhibition of aggression possible. Avoid in patients with a history of aggression in the home environment.

POSSIBLE INTERACTIONS

Avoid combining oral acepromazine with clonidine due to potential for serious fluctuations in blood pressure.

ALTERNATIVE DRUGS

Neutraceuticals: Harmonese, Anxitane, Zylkene, Composure. Additional medications likely required.

**FOLLOW-UP****PATIENT MONITORING**

Evaluate physiologic and behavioral parameters for evidence of stress response activation, and maintenance of normal physiologic and behavioral parameters. Long-term efficacy evidenced by reduced fear and increased affiliative behavior at subsequent visits (i.e., behavior improves with each handling bout).

PREVENTION/AVOIDANCE

- Prevention is key. It is more effective, less expensive, faster, and easier to

avoid problematic behavior.

- Client education—proper socialization of puppies and kittens, acclimate to a travel, DS/CC to handling.
- Refer clients to science-based humane written, online, and direct referrals.
- Low-stress handling and CC during all puppy and kitten sequential vaccination visits and adult visits.
- “Happy visits” (DS/CC) for puppies and kittens between sequential vaccine visits, and for adults after intense or multiple sick visits or hospitalization.
- Offer well-managed, positive puppy and kitten classes at your hospital.

POSSIBLE COMPLICATIONS

Animals with fearful and/or aggressive behavior are not able to effectively receive routine wellness care, diagnostic testing, advanced treatments or hospitalization, jeopardizing overall physical wellness.

EXPECTED COURSE AND PROGNOSIS
N/A**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Pets displaying fearful or fractious behavior in a veterinary setting often have comorbid behavioral problems in the home environment, including aggression to owners or strangers, leash reactivity, resource guarding, and anxiety disorders. Opening a dialog with clients, screening for these behavioral issues, and effectively triaging them will promote the patient's overall behavioral wellness and handling.

AGE-RELATED FACTORS

- Socialization period—3–12 wks (dogs), 2–7 wks (cats); this is the period where early exposure can minimize fear. A few sessions of exposure to the veterinary setting, staff, and restraint during this time paired with a positive experience (food) can lead to less fear and improved acceptance of future handling.
- Fear period—8–10 wks. of age and between 4 and 11 mo. of age (dogs; unknown for cats). Susceptible to single-event learning, highly sensitive to negative experiences. Single frightening veterinary visit during this time frame can result in fear of setting, handling, or personnel.
- Social maturity—reached at 2–4 y of age (dogs), 1–2 y (cats); period where animals develop mature social behaviors. Dogs who are fearful as puppies or adolescents often may not show first signs of aggression until this time. Essential to recognize signs

of fear in juvenile and/or adolescent so a plan to CC a positive emotional response to the veterinary clinic, handling, and procedures can be established before aggression develops.

ZOONOTIC POTENTIAL

Bite wounds and associated infections are a zoonotic potential.

PREGNANCY/FERTILITY/BREEDING

Fearful and aggressive temperaments may be heritable and predispose to veterinary clinic fear.

SYNONYMS

Fear-related aggression, defensive aggression, pain related aggression, phobic behavior, fearful behavior

FEARS, PHOBIAS, AND ANXIETIES—CATS

BASICS

DEFINITION

• Fear is the feeling of apprehension resulting from the nearness of some situation or object presenting an external threat. The response of the autonomic nervous system prepares the body for “freeze, fight, or flight.” As such, it is a normal behavior, essential for adaptation and survival. • Anxiety is the anticipation of dangers from unknown or imagined origins that results in physiologic reactions associated with fear. Anxiety may occur in the aftermath of a fear-producing event or as a result of unrelated environmental changes that are unpredictable. • A phobia is a persistent and excessive fear of a specific stimulus, such as a thunderstorm or separation from an attachment figure.

PATHOPHYSIOLOGY

• Stress responses become problematic when the individual is not able to control the stressful situation by his or her actions or escape from it through appropriate behavioral responses. • Chronic anxiety or fear can lead to secondary behavior problems, such as overgrooming, spraying, or intercat aggression, or predispose the cat to health problems owing to a compromised immune system.

SYSTEMS AFFECTED

- Behavioral—hypervigilance, avoidance behaviors, possible aggression if handling or restraint attempted.
- Cardiovascular—increased heart rate and blood flow to internal organs during fear-evoking incidents.
- Endocrine/Metabolic—glucose release into the bloodstream, release of glucocorticoids.
- Gastrointestinal—decreased appetite.
- Hemic/Lymphatic/Immune—chronic stress effects on immune function.
- Musculoskeletal—weight loss over time as response to chronic stress effects on appetite, decreased food intake due to hiding behavior.
- Neuromuscular—may see a decrease in activity due to avoidance and hiding. Fearful/anxious reaction may also include pacing, trembling, repetitive activity.
- Ophthalmic—dilated pupils in response to autonomic nervous system stimulation.
- Respiratory—increased respiratory rate when anxious or frightened.
- Skin/Exocrine—may show signs of secondary problem behavior such as overgrooming.

GENETICS

- Genetic component unknown but possible.
- Breed/coat color and paternal personality have been linked to individual personality traits in cats.

SIGNALMENT

Any age, sex, or breed

SIGNS

General Comments

- Signs of fear or anxiety can vary between individuals and with different stimuli. • In mild cases of anxiety or fear, the cat may become tense and more reactive to environmental stimuli. Some individuals may retreat to perceived safe hiding places or show little movement. Cats in a panic can become very aggressive or destructive in their attempts to get away from the thing they fear.
- Stimuli triggering anxious or fearful responses may be very specific (a particular individual, noise, or situation) or more generalized.

Historical Findings

- Obtain a clear description of the cat's body language, behavior, and events or situations that consistently trigger anxiety or fear. Information about specific triggers associated with anxious or fearful behavior may be helpful in setting up a behavioral modification and environmental management program.
- Body postures associated with fearful behavior include ears flattened to the back or to the side of the head, crouched body posture when resting or moving, lowered head, tail tucked alongside the body or held low, piloerection, “Halloween cat” silhouette.
- Pupils are often dilated; cat may be panting, shaking, drooling, or shedding hair.
- If the fear is intense, cat may lose bladder and bowel control, express its anal sacs.
- Vocalizations are usually minimal, unless the cat is showing defensive behavior in response to a perceived threat.
- The cat may pace, vocalize, and solicit attention from the owner.
- Urine spraying, destructive scratching may be seen in anxious cats.
- Details of the cat's early life, if known, may indicate a history of poor socialization and environmental exposure or possible genetic influences, feral ancestry.

Physical Examination Findings

Usually unremarkable unless the cat has injured itself trying to escape or while seeking shelter during its fright. Cats in veterinary clinics often show behavior markedly different from what is seen at home.

CAUSES & RISK FACTORS

Fearful behavior in cats can be related to the following factors:

- Genetic influences on temperament.
- Lack of positive early experience and socialization, observational learning from fearful mother, other adult cats.
- Learning from negative experiences.
- Social stress, population pressure.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

A thorough medical history and physical examination will help differentiate physical causes from behavioral.

CBC/BIOCHEMISTRY/URINALYSIS

May be indicated by information obtained in the history and physical examination, or as premedication screen.

OTHER LABORATORY TESTS

As indicated if physical causes are suspected.

IMAGING

May be indicated if history, physical, and laboratory tests suggest an organic cause for the cat's behavior.

TREATMENT

ACTIVITY

Normal interactions with owners encouraged, but contact/outgoing behavior should not be forced.

DIET

- Normal dietary routine.
- Placement of food, water, and litter box may need to be altered if anxious or fearful behavior is limiting access.

CLIENT EDUCATION

General Comments

- Discuss behavioral expectations. Owner expectations in regards to social interactions with him- or herself and with other cats may be contributing to the problem and could affect prognosis.
- A reasonable treatment plan involving case-tailored behavioral modification and environmental adjustments, and ancillary information such as handouts or articles, will help the owner better understand the situation and implement treatment.

Behavioral Therapy

- Identify the specific stimulus that provokes the fearful or anxious behavior.
- Avoid exposure to the fear-producing stimuli, if possible. Provide ways for the cat to manage the situation, by noting its “hideout” preferences and creating a “safe place” for the cat to go to if the situation cannot be avoided.
- If the cat must be handled while fearful, caution and physical restraint aids (cat muzzles, cat bags, towel wraps etc.) should be used to prevent injury and decrease stress for both cat and handler.
- Desensitization and counter-conditioning to help decrease reactivity to the fear-producing stimulus. Systematic desensitization is a program of slowly increasing exposure to the object or situation the cat fears. Counter-conditioning consists of enhancing an internal and external environment counter to one of fear, usually accomplished with food rewards or other pleasurable stimuli such as playing with toys. See the suggested reading list for references that provide greater detail.
- Address secondary problems such as strained social interactions subsequent to defensive aggression directed toward humans or other cats, or elimination problems that may be the result of fears or anxieties.

(CONTINUED)

FEARS, PHOBIAS, AND ANXIETIES—CATS**MEDICATIONS****DRUG(S)**

- Medication can be a helpful adjunct to behavioral modification, if the animal's fearful or anxious behavior is so intense that it interferes with learning or other normal behavioral activities.
- No drug is approved by the FDA for use in cats for fearful behavior; therefore, clients must be advised that information concerning efficacy, contraindications, and side effects is limited and often extrapolated from the human literature.
- If there are questions or concerns about a specific patient or medication, a consultation with a veterinary behaviorist may be helpful.

Selective Serotonin Reuptake Inhibitors

- Fluoxetine (Prozac) 0.5–1.0 mg/kg PO q24h.
- Side effects: decreased appetite and irritability.
- Paroxetine (Paxil) 0.5–1.0 mg/kg PO q24h.
- Side effects: decreased appetite, irritability, constipation.

Tricyclic Antidepressants

- Clomipramine 0.5 mg/kg q24h, 2.5–5.0 mg/cat PO q24h.
- Side effects: sedation, anticholinergic effects, possible cardiac conduction disturbances in predisposed animals.
- Amitriptyline 0.5–1.0 mg/kg PO q12–24h.
- Side effects: sedation, anticholinergic effects, possible cardiac conduction disturbances in predisposed animals.

Azapirone

- Buspirone 0.5–1.0 mg/kg q12h, 2.5–7.5 mg/cat PO q12h.
- Side effects: GI upset, mild sedation, disinhibition of aggressive behavior.

Benzodiazepines

- Alprazolam 0.125–0.25 mg/cat q12h.
- Side effects: sedation, disinhibition of aggression, increased appetite.

CONTRAINDICATIONS

- Use of buspirone, TCAs, and SSRIs not recommended in animals with seizures. SSRIs and TCAs should not be used together nor combined with MAOIs such as amitraz and selegiline. • Diazepam (Valium) is not recommended for use in cats due to rare reported cases of fatal idiopathic hepatic necrosis.

PRECAUTIONS

- Basic laboratory tests are strongly suggested before placing an animal on a psychotropic medication, to ensure that liver and kidney

functions are sufficient to metabolize the medication and to check for any physical condition that may be a contraindication to specific drugs. • Medicating cats can prove stressful, especially when the medication is not palatable, as are many of the above medications. Compounding medications in a more palatable form can ease administration, increasing consumption and effectiveness of the drug.

POSSIBLE INTERACTIONS

Discuss any questions on possible drug interactions with a veterinary behaviorist or a pharmacist.

ALTERNATIVE DRUG(S)

Pheromone therapy (Feliway), initially developed for urine marking cases, has been used as an aerosol spray and/or room diffuser to calm anxious and fearful cats, at home, during travel, and during hospitalization or clinic visits. Alternative medications such as herbal or dietary preparations including L-theanine have been suggested for anxious and fearful behaviors in animals; some have scientific studies showing efficacy for these conditions in cats. Concomitant use of some herbal remedies and psychotropic medications may lead to serious drug interactions, so clients should be questioned about over-the-counter remedies they are currently giving the cat.

**FOLLOW-UP****PATIENT MONITORING**

Frequent follow-up either in person or by telephone is necessary, especially during the first few months of treatment, to motivate the client and monitor the effectiveness of any adjunct drug treatment.

PREVENTION/AVOIDANCE

- Calm interactions and positive associations with socialization from 2–7 weeks stimuli may keep fear-based reactions to a minimum.
- Early socialization to people, places and things up to 7 weeks, and ongoing positive exposure during the first year may help prevent some later problems with fearful behavior.

POSSIBLE COMPLICATIONS

Secondary behavior problems may arise or persist after the fearful or anxious behavior has diminished and will need specific treatment.

EXPECTED COURSE AND PROGNOSIS

- Animals with shy personalities or poor socialization histories may show a minimal

response to treatment. • A realistic “end point” depends on the animal's background (socialization history, genetic and individual differences in personality), the home situation, and other confounding factors such as the frequency of natural exposure to fear-producing stimuli. • Medication may help improve but not totally ameliorate signs.

**MISCELLANEOUS****F****ASSOCIATED CONDITIONS**

- Stereotypic or compulsive disorders. • Urine marking, inappropriate elimination.
- Defensive aggression directed toward humans, other animals: may also make cat a target for aggression from other cats.

ZOONOTIC POTENTIAL

Fear-related aggression may lead to defensive biting or scratching and subsequent infections.

PREGNANCY/FERTILITY/BREEDING

Avoid use in pregnant animals.

FEARS, PHOBIAS, AND ANXIETIES—DOGS

BASICS

DEFINITION

Fear

An emotion consisting of a psychological and a physiologic response (i.e., stress response) to the presence of a dangerous stimulus (e.g., person, animal, situation, sound, object) inducing an adaptive, avoidance reaction.

F

Phobias

- A marked, irrational, and excessive fear of a stimulus (e.g., animal, situation, person, sound, object) consisting of a physiologic and psychological response resulting in a maladaptive reaction.
- Most common—noises (e.g., thunderstorms or firecrackers).

Anxiety

Reaction consisting of a physiologic and psychological response triggered by the anticipation of future danger or memory of past dangers. The original fear-inducing stimulus does not have to be present to cause the response.

PATHOPHYSIOLOGY

- Information about a fear-inducing stimulus is conducted from sensory organs to the central nucleus (CN) of the amygdala. The CN sends output to the central grey matter (musculoskeletal response), the lateral hypothalamus (ANS response), and the stria terminalis (hormonal response), mounting a physiologic stress response.
- The physiologic stress response is graded based on the animal's perceived level of control, coping strategy, and perceived level of difficulty.
- Any neutral stimulus in the environment can be paired with physiologic stress response until the stimulus causes the physiologic response.
- Certain stress hormones enhance learning, memory consolidation, and retrieval.
- There is evidence that while frightening memories can be significantly reduced, they cannot be "erased."

SYSTEMS AFFECTED

- Behavioral—immobility, restlessness, pacing, circling, hyperattachment, escape, avoidance, defensiveness, destructiveness, vocalization, aggression.
- Cardiovascular—tachycardia.
- Endocrine/Metabolic—alterations in the HPA axis, increased blood glucose.
- Gastrointestinal—inappetence, hypersalivation, vomiting, diarrhea, defecation.
- Hemic/Lymphatic/Immune—stress leukogram.
- Musculoskeletal—self-injury.
- Neuromuscular—increased motor activity, trembling, decreased pain perception, catatonia.
- Ophthalmic—episcleral injection, mydriasis.
- Renal/Urologic—urination.
- Respiratory—tachypnea.
- Skin/Exocrine—traumatic injury, acral lick dermatitis (ALD).

GENETICS

Heredity influences the development of fears and phobias, although it is unclear at this

time to what extent specific fears (e.g., noise) are heritable.

INCIDENCE/PREVALENCE

Unknown for fears, anxieties, and phobias.

SIGNALMENT

No age, breed, or sex is overrepresented.

SIGNS

General Comments

Hypervigilance, ANS arousal, catatonia, increased motor activity, elimination, destruction, excessive vocalization, hypersalivation, panting, hiding, trembling, escape behaviors, fearful body language.

Historical Findings

Traumatic experience, inadequate socialization, fearful/anxious dam or sire, history of inability to escape stimulus (e.g., locked in crate), or exposure while alone.

Physical Examination Findings

Usually unremarkable; self-induced injuries possible.

CAUSES

- Inadequate socialization, traumatic event, hereditary, CDS, previous learning.
- Illnesses or painful physical conditions may increase anxiety and contribute to the development of fears, phobias, and anxieties.

RISK FACTORS

General—existing fears, anxieties, and phobias; inadequate socialization, rehoming, anxious/fearful/physically ill dam, traumatic event—especially when alone.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Behavioral—CDS, unruly behavior, incomplete housetraining, urine/fecal marking, attention-seeking behavior, lack of stimulation, territorial behavior.
- Medical—neoplasia (e.g., intracranial mass), endocrine disease (e.g., hepatomegaly, diabetes, hypothyroidism), cystitis, pyelonephritis, diabetes, gastrointestinal disease (e.g., colitis, parasites, food allergies, IBD, IBS), neurologic disease (e.g., seizures, neuritis), dermatologic (e.g., ALD, atopy, flea allergy dermatitis, food allergies), toxicity (e.g., lead, recreational drugs).

CBC/BIOCHEMISTRY/URINALYSIS

- Should be normal.
- Perform before initiating drug treatment.

OTHER LABORATORY TESTS

- Adrenal tests if indicated by history, signalment, physical examination, and laboratory tests.
- Assess thyroid status before initiating drug treatment.

IMAGING

CT or MRI to rule out structural brain disorder may be indicated. Other imaging as

necessary to diagnose and treat underlying medical disorders.

DIAGNOSTIC PROCEDURES

- Thorough behavioral history and observation of the patient (video of behavior is helpful).
- Screen patients for aggression.
- Exposure to stimulus if safe.
- Appropriate diagnostic procedures to evaluate any concurrent medical diseases.

TREATMENT

APPROPRIATE HEALTH CARE

- Typically outpatient.
- Inpatient (dayboarding/daycare)—fear-/anxiety-/phobia-inducing stimulus unavoidable, patient is causing self-injury, medication is not yet effective, owner is unable to complete treatment, hospitalization to stabilize patient on medication.
- Treatment includes owner education, safety, behavior modification to change emotional state of patient, environmental modification to facilitate avoidance and distract patient during episodes, and reduction of anxiety.
- Diagnose and treat any medical conditions that may cause pain, discomfort, or changes in mood as well as any injuries.

Safety

• Owner—should not physically manipulate the patient when frightened or hiding, as this can result in owner-directed aggression. Instead, attempt to move the dog with food or a toy.

• Patient—if intense escape attempts or self-injury is present, avoid crating and limit the dog's access to windows, doors, electrical wiring, and water lines. Consider dayboarding.

• Public—if the dog has shown aggression when fearful/anxious, owner should avoid provocative situations and use appropriate control devices (e.g., Head halter, basket muzzle).

Behavior Modification

- Avoid stimulus for 2–8 weeks depending on the severity of reaction while teaching coping skills to the patient (e.g., sit, watch, look at that, leave it, relaxation) and setting up a safe spot.
- Structured interactions with the owner (e.g., sit for all interactions).
- Independence exercises—down/stay with a food toy.
- Punishment (e.g., shock/choke collar correction, yelling, hitting) is contraindicated.
- Client should distract dog and redirect to play or a food toy when frightened or anxious.
- Desensitization and counter-conditioning—begin after coping tools have been taught. Should be attempted with supervision as it can sensitize the animal to the stimulus, causing the behavior disorder to progress.

Environmental Modification

- Create a safe spot where exposure to the fear-producing stimulus can be limited.
- Consider dayboarding/daycare.
- Limit use

(CONTINUED)

FEARS, PHOBIAS, AND ANXIETIES—DOGS

of a crate until the dog readily goes there, and does not panic when confined. • Rotate toys.

NURSING CARE

Behavior treatment appointments can be scheduled with veterinary technicians.

ACTIVITY

Increased exercise will act as environmental enrichment for the patient but will not by itself significantly lower anxiety/fear disorders.

CLIENT EDUCATION

- Advise owners that patient is not spiteful or guilty; may be a long course of treatment; will most likely be managed, not cured. • Help the client understand the subtlety of the signs involved and learn to recognize the signs associated with physiologic stress.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Should always be prescribed with a complete treatment plan in order to be compliant with the standard of care.
- Most treatment will be long-term, possibly years; minimum treatment is generally 6 months with concurrent behavior modification. If the dog has significantly improved in 6 months, try slow weaning by reducing the dose by 25–50% every 14 days.
- Situational, mild-PRN drug indicated (e.g., benzodiazepine, SARI) either alone if stimulus is occasional and predictable or more commonly concurrent with SSRI or TCA prior to event.

◦ Works best if administered before any signs of anxiety, fear, or panic; minimally 30–90 minutes before the anticipated provocative stimulus.

◦ Benzodiazepines: diazepam 0.50–2.2 mg/kg PO up to q4; clorazepate 0.50–2.2 mg/kg PO up to q4; alprazolam 0.01–0.1 mg/kg PO up to q4.

◦ SARI: trazodone 2.0–10.0 mg/kg PO up to q8h.

◦ Alpha2 agonist: clonidine 0.01–0.05 mg/kg PO up to q12h.

- Generalized, stimulus unavoidable or severe—daily administered drug indicated.

◦ Selective serotonin reuptake inhibitors, tricyclic antidepressants. Both TCAs and SSRIs can take up to 6 weeks to take effect. Patients should be started at the low end of the dosing range and then slowly increased in 2- to 4-week increments based on response to avoid side effects.

◦ TCA: clomipramine 1.0–3.0 mg/kg PO q12h.

◦ SSRI: sertraline 1.0–3.0 mg/kg PO q24; fluoxetine 0.5–2.0 mg/kg PO q24.

PRECAUTIONS

- All listed medications are extra-label except for clomipramine and fluoxetine for the treatment of separation anxiety in dogs in the

United States—follow Health and Human Services recommendations. • Cardiac conduction anomalies—use caution and monitoring when giving TCAs. • Use caution when prescribing drugs to geriatric patients or patients with hepatic or renal compromise—review metabolism and elimination of medication before prescribing. • Clients should receive drug information handouts with potential side effects listed.

• Mood-altering medications have the potential to increase agitation, fear, and aggression.

POSSIBLE INTERACTIONS

- Use caution when prescribing multiple medications concurrently that have the same mode of action. Review drug monographs for each drug before prescribing. • Do not use SARIs, SSRIs, or TCAs with MAOIs including but not limited to selegiline, Preventic collars, and Amitraz Dip. • Do not use SSRIs and TCAs together—possible risk of serotonin syndrome, which can be fatal.

ALTERNATIVE DRUGS**Supplements**

- Anxitane—as directed on label. Flavored—do not use in patients on elimination diets.
- Melatonin—< 5 kg → 1.0 mg; 5–12 kg → 1.5 mg; > 12 kg → 3.0–6.0 mg. All doses PO, up to q12h. • Zylkene—as directed on label. • SAMe—10–20 mg/kg PO q24h.
- Royal Canin Calm Diet (alpha-casozepine and tryptophan supplemented).

**FOLLOW-UP****PATIENT MONITORING**

- Clients should contact the veterinarian at 2-week intervals for the first 6–8 weeks of treatment. Typically the treatment plan will have to be altered possibly including medication dosing or medication changes.
- CBC, biochemistry, urinalysis, T₄, fT₄ q12 months for animals < 8 years on daily administered medications; senior dogs may require more frequent reassessment based on age and health.

PREVENTION/AVOIDANCE

- Proper socialization—8–12 weeks, including puppy classes starting at 8 weeks.
- Structured relationship with owner (sit for all interactions). • Basic obedience. • Treat traumatic experiences immediately.

POSSIBLE COMPLICATIONS

If left untreated or treated with medication only, progression is likely.

EXPECTED COURSE AND PROGNOSIS

- Course of treatment depends on response to medication, suitability of the environment, and client's ability to perform behavior modification. • Treatment duration varies from 2 to 12 months depending on severity

and number of problems. Only dogs who respond well to behavior modification and environmental management can be expected to be able to be weaned off medication.

- Typically, treatment will continue to some extent throughout the dog's life.

**MISCELLANEOUS****AGE-RELATED FACTORS**

CDS can present as non-specific fear.

PREGNANCY/FERTILITY/BREEDING

Most of the listed drugs are either not evaluated in or contraindicated in pregnant animals.

SYNONYMS

- Generalized anxiety • Neophobia • Specific anxiety

ABBREVIATIONS

- ALD = acral lick dermatitis • ANS = autonomic nervous system • CDS = cognitive dysfunction syndrome • CN = central nucleus • CT = computed tomography • HPA = hypothalamic-pituitary-adrenal • IBD = inflammatory bowel disease • IBS = irritable bowel syndrome • MAOI = monoamine oxidase inhibitor • MRI = magnetic resonance imaging • SARI = serotonin reuptake inhibitor/antagonist • SSRI = selective serotonin reuptake inhibitor • T₄ = thyroxine • TCA = tricyclic antidepressant

FELINE CALICIVIRUS INFECTION

BASICS

DEFINITION

A common viral respiratory disease of domestic and exotic cats characterized by upper respiratory signs, oral ulceration, pneumonia, and occasionally arthritis, or a highly fatal systemic hemorrhagic disease.

F

PATHOPHYSIOLOGY

Rapid cytolysis of infected cells with resulting tissue pathology and clinical disease.

SYSTEMS AFFECTED

- Gastrointestinal—ulceration of the tongue common; occasional ulceration of the hard palate and lips; infection occurs in intestines; usually no clinical disease.
- Hemic/Lymphatic/Immune—hemorrhage.
- Musculoskeletal—acute arthritis.
- Ophthalmic—acute serous conjunctivitis without keratitis or corneal ulcers.
- Respiratory—rhinitis; interstitial pneumonia; ulceration of the tip of the nose.

GENETICS

None

INCIDENCE/PREVALENCE

- Persistent infection common.
- Clinical disease—common in multicat facilities, shelters, and breeding catteries.
- Routine vaccination—reduced incidence of clinical disease; has not decreased the prevalence of the virus.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

Cat

Breed Predilections

None

Mean Age and Range

- Young kittens > 6 weeks old—most common.
- Cats of any age may show clinical disease.

Predominant Sex

None

SIGNS

General Comments

May present as an upper respiratory infection with eye and nose involvement, as an ulcerative disease primarily of the mouth, as pneumonia, as an acute arthritis, as a systemic hemorrhagic disease, or any combination of these.

Historical Findings

- Sudden onset.
- Anorexia.
- Ocular or nasal discharge, usually with little or no sneezing.
- Ulcers on the tongue, hard palate, lips, tip of nose, or around claws.
- Dyspnea from pneumonia.
- Acute, painful lameness.

Physical Examination Findings

- Generally alert and in good condition.
- Fever.
- Ulcers may occur without other signs.
- Systemic hemorrhage.

CAUSES

- A small, non-enveloped single-stranded RNA virus, feline calicivirus.
- Numerous strains exist in nature, with varying degrees of antigenic cross-reactivity.
- More than 1 serotype.
- Relatively stable and resistant to many disinfectants.

RISK FACTORS

- Lack of vaccination or improper vaccination
- Multi-cat facilities
- Concurrent infections with other pathogens (e.g., FHV-1 or FPV)
- Poor ventilation

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Feline viral rhinotracheitis
- Chlamydiosis
- *Bordetella bronchiseptica*

CBC/BIOCHEMISTRY/URINALYSIS

No characteristic or consistent findings

OTHER LABORATORY TESTS

Serologic testing on paired serum samples—detect a rise in neutralizing antibody titers against the virus.

IMAGING

Radiographs of the lungs—a consolidation of lung tissue in cats with pneumonia.

DIAGNOSTIC PROCEDURES

- Cell cultures to isolate the virus—oral pharynx; lung tissue; feces; blood; secretions from the nose and conjunctiva.
- PCR.
- Immunofluorescent assays of lung tissue—viral antigen.

PATHOLOGIC FINDINGS

- Gross—upper respiratory infection; ocular and nasal discharge; pneumonia with consolidation of large portions of individual lung lobes; possible ulcerations on the tongue, lips, and hard palate; systemic hemorrhages.
- Histopathologic—interstitial pneumonia of large portions of individual lung lobes; ulcerations on epithelium of the tongue, lips, and hard palate; mild inflammatory reactions in the nose and conjunctiva; systemic hemorrhages.

TREATMENT

APPROPRIATE HEALTH CARE

Outpatient, unless severe pneumonia or hemorrhages occur

NURSING CARE

- Clean eyes and nose as indicated
- Provide soft foods
- Oxygen—with severe pneumonia

ACTIVITY

Patients should be restricted from contact with other cats to prevent transmission of the causative virus.

DIET

- No restrictions.
- Special diets—perhaps to entice anorectic cats to resume eating.
- Soft foods—if ulcerations restrict eating.

CLIENT EDUCATION

Discuss the need for proper vaccination and the need to modify the vaccination protocol in breeding catteries to include kittens before they become infected (often at 6–8 weeks of age) from a carrier queen.

SURGICAL CONSIDERATIONS

None

MEDICATIONS

DRUG(S) OF CHOICE

- No specific antiviral drugs that are effective.
- Broad-spectrum antibiotics—usually indicated (e.g., amoxicillin at 22 mg/kg PO q12h).
- Secondary bacterial infections of affected cats are not nearly as important as with FHV-1 infections.
- Antibiotic eye ointments—to reduce secondary bacterial infections of the conjunctiva.
- Appropriate pain medication—for transient arthritis pain.

CONTRAINdicATIONS

None

PRECAUTIONS

None

POSSIBLE INTERACTIONS

None

ALTERNATIVE DRUG(S)

None

FOLLOW-UP

PATIENT MONITORING

- Monitor for sudden development of dyspnea associated with pneumonia.
- No specific laboratory tests.

PREVENTION/AVOIDANCE

- All cats should be vaccinated at the same time they are vaccinated against FHV-1 and FPV; routine vaccination with either MLV or inactivated vaccines should be done as early as 6 weeks of age and repeated every 3–4 weeks until at least 16 weeks of age.

(CONTINUED)

- Breeding catteries—respiratory disease is a problem; vaccinate kittens at an earlier age, either with an additional vaccination at 4–5 weeks of age or with an intranasal vaccine at 10–14 days of age; follow-up vaccinations every 3–4 weeks until 16 weeks of age.
- American Association of Feline Practitioners—classifies FHV, FPV, and calicivirus as core vaccines; vaccinate all cats with these three agents on the initial visit as early as 6 weeks of age, repeat every 3–4 weeks until 16 weeks of age, and 1 year after the last kitten vaccine; revaccinate for calicivirus every 3 years.
- Vaccination will not prevent virus infection in a subsequent exposure but will prevent serious clinical disease caused by most strains.

POSSIBLE COMPLICATIONS

- Interstitial pneumonia—most serious complication; can be life-threatening.
- Secondary bacterial infections of the lungs or upper airways.
- Oral ulcers and the acute arthritis usually heal without complications.
- Systemic hemorrhagic disease may be severe and fatal.

EXPECTED COURSE AND PROGNOSIS

- Clinical disease—usually appears 3–4 days after exposure.
- Once neutralizing antibodies appear, about 7 days after exposure, recovery is usually rapid.
- Prognosis excellent, unless severe pneumonia or systemic hemorrhagic disease develops.
- Recovered cats—persistently infected for long periods; will continuously shed small quantities of virus in oral secretions.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Affected cats may also be concurrently infected with FHV-1, especially in multi-cat and breeding facilities.

AGE-RELATED FACTORS

Usually occurs in young kittens whose maternally derived immunity has waned.

ZOONOTIC POTENTIAL

None

PREGNANCY/FERTILITY/BREEDING

Generally no problem, because most cats have been exposed or vaccinated before becoming pregnant.

SYNONYMS

Feline picornavirus infection—FCV originally classified as a picornavirus; older literature refers to the infection by this name; no known picornavirus that infects cats.

SEE ALSO

Chlamydiosis—Cats

ABBREVIATIONS

- FCV = feline calicivirus
- FHV = feline herpesvirus
- FPV = feline parvovirus
- MLV = modified live virus
- PCR = polymerase chain reaction

Client Education Handout available online

F

FELINE FOAMY VIRUS INFECTION (FFV)

BASICS

OVERVIEW

- A complex retrovirus in the Spumaretrovirinae subfamily that infects cats, apparently with little or no pathogenic effect.
- Found worldwide; estimated prevalences, 10–70% or greater.
- Present in some non-domestic feline populations.
- Infection linked statistically with chronic progressive polyarthritis; disease has not been reproduced by experimental infection.
- Experimentally infected cats have subclinical glomerulonephritis and interstitial pneumonia.
- Some strains infect lymphoblastoid cells and induce apoptosis—suggests potential impact on immune function in cats.
- Research—disease potential low; nuisance when using feline-origin tissue culture cells; test cats and remove from study if FFV-positive.
- Potential for use as a gene therapy or vaccine vector is under investigation.

SIGNALMENT

- Cats—free-roaming more than multi-cat households or catteries.
- Prevalence of virus—low in kittens; increases with age.
- No clear sex predilection—some early studies found that males were more likely than females to be infected, but a study of Australian cats found no difference between rates of infection in males and females.
- Chronic progressive polyarthritis (possibly from immune complex formation) occurs predominantly in males aged 1.5–5 years.

SIGNS

- Most affected cats healthy.
- Statistical links with myeloproliferative disease and chronic progressive polyarthritis—may actually reflect co-infection with FIV, FeLV or other pathogens.
- Chronic progressive polyarthritis—swollen joints; abnormal gait; lymphadenomegaly.

CAUSES & RISK FACTORS

- Transmission—somewhat controversial; possibly through bites; free-roaming cats at greater risk of infection.
- Co-infections with FIV and FeLV—fairly common, possibly because of shared transmission modes and risk factors; FFV

co-infection does not enhance early pathogenesis of FIV infections.

- Transmitted efficiently from infected queens to their offspring, probably *in utero*.
- The high prevalence of infection in some cat populations suggests casual contact may play a role in transmission; this has not been demonstrated experimentally.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Signs of chronic progressive polyarthritis—test for FIV, FeLV, and septic joint disease.

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal

OTHER LABORATORY TESTS

- Serologic testing—for FFV antibodies and virus isolation; not readily available; not particularly useful because correlation between FFV infection and disease is so tenuous.
- Qualitative real-time PCR—for detection of viral nucleic acids; available commercially; may be useful for establishing FFV-negative cat colonies and monitoring biologic products or vaccines.
- Virus isolation from peripheral blood lymphocytes or buffy coat cells.

DIAGNOSTIC PROCEDURES

- Joint fluid cytology—with chronic progressive polyarthritis; may reveal high numbers of neutrophils and large mononuclear cells.
- Histology—lymphocytic, plasmocytic infiltrates common with joint disease; osteoporosis with periarticular periosteal proliferation or periarticular erosions and joint deformities may be seen.

TREATMENT

None, except for treatment of chronic progressive polyarthritis.

MEDICATIONS

DRUG(S)

Chronic progressive polyarthritis—immunosuppressive doses of prednisone and

cyclophosphamide (see Immune-Mediated Polyarthritis for more information).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Immunosuppressive drugs—take care when using in patients co-infected with FIV or FeLV.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

- Infection with FFV alone—adverse consequences unlikely.
- Chronic progressive polyarthritis—often difficult to control; poor prognosis for long-term recovery.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Chronic progressive polyarthritis
- Co-infections with FIV and FeLV

ZOONOTIC POTENTIAL

No evidence of zoonotic transmission, although studies are limited.

SYNOMYMS

- Feline syncytial virus
- Feline syncytium-forming virus

SEE ALSO

Immune-Mediated Polyarthritis

ABBREVIATIONS

- FeLV = feline leukemia virus
- FFV = feline foamy virus infection
- FIV = feline immunodeficiency virus
- PCR = polymerase chain reaction

FELINE HERPESVIRUS INFECTION

BASICS

DEFINITION

Causes an acute disease in domestic and many exotic species of cats, which is characterized by sneezing, fever, rhinitis, conjunctivitis, and ulcerative keratitis.

PATHOPHYSIOLOGY

FHV-1—causes an acute cytopathic infection of respiratory or ocular epithelium after oral, intranasal, or conjunctival exposure. This intracellular virus travels from cell to cell and does not stimulate a strong immune response from the host.

SYSTEMS AFFECTED

- Integumentary—herpes dermatitis may occur near the nasal openings.
- Ophthalmic—often conjunctivitis with serous or purulent ocular discharge; ulcerative keratitis or panophthalmitis can occur.
- Reproductive—*in utero* infection owing to infection of pregnant queens may result in severe herpetic infections in neonates.
- Respiratory—rhinitis with sneezing and serous to purulent nasal discharge; tracheitis may occur; chronic sinusitis may be a sequela.
- Neurologic—latent virus found in optic nerve, ciliary ganglion, brainstem, cerebellum, and olfactory bulb.

GENETICS

N/A

INCIDENCE/PREVALENCE

- Common, especially in multi-cat households or other facilities housing large numbers of cats, due to ease of transmission. Catteries and shelters are the source of most infections.
- Perpetuated by latent carriers that harbor the virus in nerve ganglia, especially in the trigeminal ganglion.

GEOGRAPHIC DISTRIBUTION

Found worldwide

SIGNALMENT

Species

Affects all domestic and many exotic cats.

Breed Predilections

- None.
- Brachycephalic breeds have more severe corneal disease and are more likely to have corneal sequestra.

Mean Age and Range

- Cats of all ages
- Kittens most susceptible

Predominant Sex

N/A

SIGNS

Historical Findings

- Acute onset of paroxysmal sneezing.
- Blepharospasm and ocular discharge.
- Anorexia—from high fever, general malaise, or inability to smell.

- Recurrent signs—carriers.
- Abortion.

Physical Examination Findings

- Fever—up to 106°F (41°C).
- Rhinitis—serous, mucopurulent, or purulent nasal discharge.
- Conjunctivitis—serous, mucopurulent, or purulent ocular discharge.
- Chronic rhinitis/sinusitis—chronic purulent nasal discharge; presence of sinusitis cannot be determined without radiographs.
- Keratitis—ulceration, descemetocele, or panophthalmitis.

CAUSE

FHV-1, of which there is only 1 serotype.

RISK FACTORS

- Lack of vaccination for FHV-1 although vaccines do not bestow sterilizing immunity.
- Multiple cat facilities with overcrowding, poor ventilation, poor sanitation, poor nutrition, or physical or psychological stress.
- Pregnancy and lactation.
- Concomitant disease, especially owing to immunosuppressive organisms or other respiratory organisms.
- Kittens born to carrier queens—infected at about 5 weeks of age.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Feline calicivirus infection—less sneezing, conjunctivitis, ulcerative keratitis; may cause ulcerative stomatitis, pneumonia.
- Feline *Chlamydophila* infection—more chronic conjunctivitis, which may be unilateral; pneumonitis; intracytoplasmic inclusions in conjunctival scrapings; responds to tetracyclines or chloramphenicol.
- Bacterial infection (*Bordetella*, *Haemophilus*, or *Pasteurella*)—less nasal and ocular involvement; often respond to antibiotics.

CBC/BIOCHEMISTRY/URINALYSIS

- Not diagnostic.
- Transient leukopenia followed by leukocytosis may occur.

OTHER LABORATORY TESTS

- PCR testing from pharyngeal and conjunctival swabs will identify presence of the virus; more sensitive than other diagnostic modalities. May be transiently positive following MLV FHV-1 vaccination.
- Immunofluorescent assay—nasal or conjunctival scrapings; viral detection.
- Viral isolation—pharyngeal swab sample.
- Stained conjunctival smears—detect intranuclear inclusion bodies.

IMAGING

Radiography—open mouth ventrodorsal and rostrocaudal (skyline) views of the skull reveal presence of chronic disease in the nasal cavity

and frontal sinuses; infection cannot be reliably distinguished from neoplasia and inflammatory polyps; no abnormal radiographic findings with acute disease. CT provides a more accurate assessment of disease in the nasal cavity and frontal sinus when compared to radiographs. In many cats, it can differentiate neoplasia from inflammation based on the amount of bony destruction.

DIAGNOSTIC PROCEDURES

N/A

F

PATHOLOGIC FINDINGS

- Gross—ocular and nasal discharge; mucosal edema of upper airway epithelium; tracheitis; sinusitis; ulcerative keratitis; panophthalmitis.
- Microscopic—submucosal edema; inflammatory cell infiltrates of upper respiratory and conjunctival tissues; chronic sinusitis; intranuclear inclusion bodies in epithelial cells.

TREATMENT

APPROPRIATE HEALTH CARE

Inpatient—nutritional and fluid support to anorectic cats; prevent contagion.

NURSING CARE

- Outpatient—keep patient indoors to prevent environmentally induced stress, which may lengthen the course of the disease.
- Fluids—intravenous or subcutaneous; to correct and prevent dehydration; to keep nasal secretions thin.

ACTIVITY

Isolate affected cats during the acute phase, because they are contagious.

DIET

- Outpatient—entice food consumption to avoid anorexia, which induces a cascade of negative consequences; offer foods with appealing tastes and smells.
- Inpatient—forced enteral feeding for anorectic cats; remove nasal secretions (so nasal breathing can occur) before starting orogastric tube feeding; avoid nasoesophageal tubes because of rhinitis.

CLIENT EDUCATION

- Inform client of the contagious nature of the disease.
- Discuss proper vaccination protocols and early vaccination of cats in multi-cat facilities and households.
- Inform client that early weaning and isolation from all other cats except littermates may prevent infections.

SURGICAL CONSIDERATIONS

Surgically implanted feeding tubes (esophagostomy tube, gastrostomy tube) may be needed when prolonged anorexia occurs.

FELINE HERPESVIRUS INFECTION

(CONTINUED)

MEDICATIONS

DRUG(S) OF CHOICE

- Broad-spectrum antibiotics—ampicillin (20–40 mg/kg PO q8h; 10–20 mg/kg IV, IM, SC q6–8h) or amoxicillin (10–40 mg/kg q8–12h PO, IM, SC) for secondary bacterial infections.
- Antibiotic combinations—ampicillin or amoxicillin and a fluoroquinolone (enrofloxacin [2.5 mg/kg PO, IM, IV q12h], orbifloxacin [2.5–7.5 mg/kg PO q24h], marbofloxacin [2.75–5.55 mg/kg PO q24h]), pradofloxacin [7.5 mg/kg] for secondary bacterial infections.
- Lysine-lactoferrin (500 mg PO q12h) more effective than lysine alone for treatment.
- Lysine (500 mg PO q12h) may have some virucidal effect.
- Ophthalmic antibiotics—for keratitis.
- Ophthalmic antivirals in order of efficacy—trifluridine, cidofovir, idoxuridine, ganciclovir, aciclovir; for herpetic ulcers; must be instilled q2h for significant effect except for cidofovir which can be given q12h.
- There is some evidence that administration of an intranasal vaccine 2–6 days prior to exposure will result in lessening of clinical signs. This may be helpful in an outbreak in a multi-cat setting.

CONTRAINDICATIONS

- Iodoxuridine ophthalmic may be painful in some cats; discontinue medication.
- Trifluridine, idoxuridine, acyclovir—toxic if given systemically.
- Systemic corticosteroids—may induce relapse in chronically infected cats.
- Ophthalmic corticosteroids—may predispose to ulcerative keratitis.
- Nasal decongestant drops—0.25% oxymetazoline HCl; decrease nasal discharge; contraindicated because some cats object and some experience rebound rhinorrhea.

PRECAUTIONS

Death is usually the result of inadequate nutritional and fluid support or immunosuppression due to FeLV or FIV.

ALTERNATIVE DRUG(S)

- Penciclovir—effectively inhibits FHV-1, doses unknown at this time.
- Famciclovir—early reports indicate efficacy at 15 mg/kg PO q8–12h.

FOLLOW-UP

PATIENT MONITORING

Monitor appetite closely; hospitalize for forced enteral feeding if anorexia develops.

PREVENTION/AVOIDANCE

Ammonia-based cleaners effectively kill the virus.

Vaccines

- Routine vaccination with an MLV or inactivated virus vaccine—prevents development of severe disease; does not prevent infection and local viral replication with mild clinical disease and virus shedding.
- Vaccinate at 8–10 weeks of age, at 12–14 weeks of age, and 16–18 weeks of age and with annual boosters for reasonable protection, especially in high-risk populations.
- Endemic multi-cat facilities or households—vaccinate kittens with a dose of an intranasal vaccine at 10–14 days of age, then parenterally at 6, 10, and 14 weeks of age; isolate the litter from all other cats at 3–5 weeks of age; then use kitten vaccination protocol to prevent early infections.

POSSIBLE COMPLICATIONS

- Chronic rhinitis or rhinosinusitis with long-term sneezing and nasal discharge.
- Herpetic ulcerative keratitis.
- Corneal sequestrum that must be removed surgically.
- Permanent closure of the nasolacrimal duct with chronic ocular discharge.

EXPECTED COURSE AND PROGNOSIS

- Usually 7–10 days before spontaneous remission, if secondary bacterial infections do not occur.
- Prognosis generally good, if fluid and nutritional therapy are adequate.
- Correlation between severity of acute signs and degree of latent infection.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Simultaneous viral or bacterial respiratory diseases.

AGE-RELATED FACTORS

More severe in young kittens

ZOONOTIC POTENTIAL

None

PREGNANCY/FERTILITY/BREEDING

Pregnant cats that develop disease may transmit FHV-1 to kittens *in utero*, resulting in abortion or neonatal disease.

SYNONYMS

- Coryza
- Feline Rhinotracheitis
- Rhino

SEE ALSO

available online

FELINE HYPERESTHESIA SYNDROME

BASICS

OVERVIEW

- Idiopathic disorder of cats characterized by paroxysmal agitation, focal epaxial muscle spasms, vocalization, and intense biting or licking of the back, tail, and pelvic limbs.
- Also known as neurodermatitis, rolling skin disease, neuritis, psychomotor epilepsy, and pruritic dermatosis of Siamese.
- Pathophysiology is unknown. • Organ systems affected include: behavioral, nervous, neuromuscular, and skin/exocrine.

SIGNALMENT

Species

Cat

Breed Predilections

Can be seen in any breed, but Siamese, Abyssinian, Burmese, and Himalayan cats may be predisposed.

Mean Age and Range

- Signs can occur at any age • Most common at 1–5 years

SIGNS

- Episodes of twitching of the skin over the lumbar area, violent swishing of the tail, vocalizing, and biting or licking of the flank and pelvic region. • Pupils often dilate, and cats can become aggressive or appear agitated and run wildly about the environment.
- Episodes are several seconds to several minutes in length. Cats are typically normal between episodes but may be intolerant of being stroked along the back. • General physical examination often reveals no abnormalities aside from possible alopecia and broken hair over the lumbar area from self-mutilation. Many cats resent palpation of the thoracolumbar musculature, and manipulation of the area may elicit an episode. No neurologic deficits are present.

CAUSES & RISK FACTORS

- It is not known whether this syndrome is a manifestation of an underlying behavioral problem, a focal seizure disorder, or a localized sensory neuromyopathy causing hyperesthesia. It has been speculated that the cause is multifactorial, or that the syndrome is not a distinct entity with a single cause but rather can develop from a variety of different factors. • Cats that tend to be nervous or hyperexcitable have been described as having an increased risk; environmental stressors may serve as a trigger.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Dermatologic conditions causing pruritus—parasitic (e.g., flea, *Notoedres*,

Cheyletiella), fungal (e.g., dermatophytosis), or allergic (e.g., parasitic, inhalant, dietary); evaluate for underlying dermatitis; skin scrapings and fungal cultures can help confirm diagnosis. • Diseases of the vertebral column causing spinal pain—degenerative (intervertebral disc disease), inflammatory (discospondylitis, local meningitis), neoplastic, or traumatic; radiography of the vertebral column is helpful in evaluating for abnormalities; further diagnostics (e.g., spinal imaging, serologic testing for infectious agents, CSF analysis) may be necessary. • Forebrain disease causing behavioral changes and/or seizures—metabolic (hepatic encephalopathy), infectious/inflammatory (feline leukemia virus, feline immunodeficiency virus, feline infectious peritonitis, cryptococcosis, toxoplasmosis), neoplastic, vascular; complete diagnostic evaluation including bile acid tolerance, serologic testing for infectious causes, CSF analysis, and brain imaging may be indicated. • Behavioral condition—compulsive disorder; exclusion diagnosis.

CBC/BIOCHEMISTRY/URINALYSIS

- Frequently normal. • Increased globulin levels have been reported in some cats.

OTHER LABORATORY TESTS

None required

IMAGING

None required aside from that necessary to exclude differential diagnoses.

DIAGNOSTIC PROCEDURES

- Diagnosis is based on characteristic history and clinical findings, and by excluding other diseases that can cause similar signs. • There is no test or group of tests that support a definitive diagnosis. • EMG—evidence of abnormal spontaneous activity in the thoracolumbar epaxial muscles in one study of affected cats. • Muscle biopsy—if EMG changes; may reveal vacuoles within the epaxial muscles, with antibody labelling characteristics similar to those described with inclusion body myositis/myopathy in humans.

TREATMENT

- Outpatient. • Eliminate environmental changes that can precipitate episodes.
- Behavioral modification has been successful in reducing clinical manifestations in some cats. • In severe cases of self-mutilation, an Elizabethan collar or tail bandaging may be necessary.

MEDICATIONS

DRUG(S)

- Several pharmacologic agents

recommended, based on suspected underlying cause.

- Prednisolone is indicated if pruritic dermatitis is suspected.
- Antiepileptic drugs are often utilized. Phenobarbital (1–2 mg/kg PO q12h) is most effective but does not successfully control the episodes in all cats. Gabapentin (5–10 mg/kg PO q12h) can be used for both its antiepileptic properties as well as its analgesic effect in neuropathic pain.
- Selective serotonin reuptake inhibitors (fluoxetine 0.5–2.0 mg/kg PO q24h), tricyclic antidepressants (clomipramine 0.5–1.0 mg/kg PO q24h), or benzodiazepines (lorazepam 0.125–0.50 mg PO q8–24h) are recommended when a primary behavioral disorder is suspected.
- Carnitine and coenzyme Q10—if underlying myopathy.
- Treatment response is variable. In cats that respond, therapy is often life-long as episodes tend to resume after medication is discontinued.

F

CONTRAINdicATIONS/POSSIBLE INTERACTIONS

Fluoxetine inhibits the cytochrome P450 system and should be used cautiously with other drugs that undergo extensive hepatic metabolism including phenobarbital, benzodiazepines, and tricyclic antidepressants.

FOLLOW-UP

PATIENT MONITORING

Cats placed on phenobarbital—check serum drug concentrations in 2–3 weeks and adjust dosage as needed to maintain levels of 20–30 µg/mL (85–130 µmol/L); CBC and biochemistry profile at 6- to 12-month intervals to monitor for adverse effects.

PREVENTION/AVOIDANCE

Avoid any known environmental stressors.

EXPECTED COURSE AND PROGNOSIS

Prognosis depends on whether underlying cause is identified, response to medication, and frequency and severity of episodes.

MISCELLANEOUS

ABBREVIATIONS

- CSF = cerebrospinal fluid • EMG = electromyography

FELINE IDIOPATHIC LOWER URINARY TRACT DISEASE

BASICS

DEFINITION

The terms "feline urologic syndrome" and "FUS" have been misused by the veterinary profession as diagnostic terms to describe disorders of domestic cats characterized by hematuria, dysuria, pollakiuria, perioria, and partial or complete urethral obstruction, because varying combinations of these signs may be associated with any cause of feline lower urinary tract disease. The similarity of clinical signs with diverse causes is not surprising since the feline urinary tract responds to various diseases in a limited and predictable fashion. Fortunately, with improved understanding of the causes and consequences of feline lower urinary tract disorders, these terms have been abandoned. At the time of this writing, the names idiopathic lower urinary tract disease (iLUTD) and feline idiopathic cystitis (FIC) have come into common use. However, these terms represent exclusionary diagnoses established only after known causes have been eliminated.

PATOPHYSIOLOGY

- Refer to specific chapters describing diseases listed in the "Differential Diagnosis" section.
- Initial episodes of idiopathic lower urinary tract diseases usually occur in the absence of significant numbers of detectable bacteria and pyuria. Prospective diagnostic studies of male and female obstructed and non-obstructed cats identified bacterial urinary tract infections in < 3% of young to middle-age adults and ~ 10% of geriatric adults. • The etiopathogenesis of iLUTD is uncertain. Proposed mechanisms include dysfunction of the urothelial barrier, neurogenic cystitis, mast-cell-induced neuroimmune disease, and systemic psychoneuroendocrine dysfunction.
- Experimental and clinical studies have implicated viruses, especially caliciviruses, as potential etiologic agents in some cats. • Some cats with lower urinary tract diseases exhibit findings similar to those observed in humans with interstitial cystitis, a non-malignant neuro-inflammatory disorder characterized by decreased urine concentrations of glycosaminoglycans and increased urinary bladder permeability, which is associated with damage to the glycosaminoglycan layer that covers the luminal surface of the urinary tract. These similarities prompted the hypothesis that some lower urinary tract diseases are analogous to human interstitial cystitis.
- Clinical observations suggest that stress may play a role in precipitating or exacerbating signs associated with idiopathic cystitis.

SYSTEMS AFFECTED

- Renal/Urologic—lower urinary tract.
- Persistent urethral outflow obstruction results in post-renal azotemia.

INCIDENCE/PREVALENCE

- The incidence of hematuria, dysuria, and/or urethral obstruction in domestic cats in the United States and Great Britain has been previously reported to be ~ 0.5–1% per year.
- The hospital proportional morbidity rate for iLUTD in cats with lower urinary tract signs is ~ 65%.

SIGNALMENT

Species

Cat

Mean Age and Range

- May occur at any age, but is most commonly recognized in young to middle-aged adults (mean 3.5 years).
- Uncommon in cats < 1 and > 10 years old.

SIGNS

Historical Findings

- Dysuria • Hematuria • Pollakiuria
- Perioria—urinating in inappropriate locations • Outflow obstruction

Physical Examination Findings

Thickened, firm, contracted bladder wall

CAUSES

- See "Pathophysiology" • Non-infectious diseases, including idiopathic cystitis
- Viruses implicated

RISK FACTORS

Stress—may play a role in precipitating or exacerbating signs; an unlikely primary cause.

DIFFERENTIAL DIAGNOSIS

- Metabolic disorders including various types of uroliths/urethral plugs. • Infectious agents including bacteria, mycoplasma/ureaplasma, fungal agents, and parasites. • Trauma.
- Neurogenic disorders including reflex dyssynergia, urethral spasm, and hypotonic or atonic bladder (primary or secondary).
- Iatrogenic disease including reverse flushing solutions, indwelling and post-surgical urethral catheters (especially open systems), and urethrostomy complications. • Anatomic abnormalities including urachal anomalies and acquired urethral strictures. • Neoplasia (benign and malignant). • Clinical signs may be confused with constipation.

CBC/BIOCHEMISTRY/URINALYSIS

- Hematuria and proteinuria without significant pyuria or bacteriuria—usually present. • If urethral obstruction persists, serum chemistry profiles reveal azotemia, hyperphosphatemia, hyperkalemia, and reduced TCO₂.

OTHER LABORATORY TESTS

- Absence of bacteriuria—verify by quantitative urine culture; collect urine specimens by cystocentesis to avoid contamination with bacteriuria that normally inhabit the distal urinary tract.
- Transmission electron microscopy has revealed calicivirus-like particles in some urethral plugs.

IMAGING

- Survey radiography—may exclude radiopaque uroliths or urethral plugs.
- Positive-contrast retrograde urethrocystography or antegrade cystography—may exclude urethral strictures, vesicourachal diverticula, and neoplasia.
- Double-contrast cystography—may exclude small or radiolucent uroliths, blood clots, and thickening of the bladder wall due to inflammation or neoplasia.
- Ultrasonography—may exclude uroliths.

DIAGNOSTIC PROCEDURES

- Cystoscopy—may exclude uroliths and diverticula. • Biopsies obtained with urinary catheters, cystoscopes, or via surgery—may permit morphologic characterization of inflammatory or neoplastic lesions; not routinely needed.

PATHOLOGIC FINDINGS

- Cystoscopy may reveal petechial hemorrhages (also called glomerulations) of the mucosal surface of the urinary bladder.
- Mucosal ulceration, congestion, submucosal edema, hemorrhage, and fibrosis; inflammatory cells may not be prominent, unless secondary bacterial urinary tract infections have resulted from catheterization or perineal urethrostomy.

TREATMENT

APPROPRIATE HEALTH CARE

- Patients with non-obstructive lower urinary tract diseases—typically managed as outpatients; diagnostic evaluation may require brief hospitalization. • Patients with obstructive lower urinary tract diseases—usually hospitalized for diagnosis and management.

DIET

- Appropriate dietary management recommended for persistent crystalluria associated with matrix-crystalline urethral plugs. • Empirical observations suggest that recurrence of signs may be minimized by feeding moist rather than dry foods. The goal is to promote the flushing action of increased urine volume, and increased dilution of toxins, chemical irritants, inflammatory mediators, and urolith-promoting constituents.

CLIENT EDUCATION

- Hematuria, dysuria, and pollakiuria—often self-limiting; subside within 4–7 days, but signs often recur unpredictably. • A lack of controlled studies demonstrate efficacy of most drugs used to treat this disorder symptomatically. • Males should be monitored for signs of urethral obstruction.
- Reduce environmental stress by minimizing impact of changes in the home, and maintaining a constant diet. Environmental

(CONTINUED)

FELINE IDIOPATHIC LOWER URINARY TRACT DISEASE

enrichment for indoor-housed cats consists of provision of necessary resources (food, water, litter boxes, space, play), providing a safe place to hide, refinement of cat-owner interactions, and management of conflict.

- Provide proper litter box hygiene.

SURGICAL CONSIDERATIONS

- We do not recommend cystotomy to lavage and debride the bladder mucosa as a form of treatment.
- Do not perform perineal urethrostomies to minimize recurrent urethral obstruction without localizing obstructive disease to the penile urethra by contrast urethrography.

MEDICATIONS

DRUG(S) OF CHOICE

- Tolteridine may be considered as an anticholinergic and antispasmodic to minimize hyperactivity of the bladder detrusor muscle and urge incontinence; suggested empirical dose is 0.05 mg/kg PO q12h. However, there have been no reports of controlled studies to evaluate its safety or efficacy.
- Amitriptyline, a tricyclic antidepressant and anxiolytic drug (with anticholinergic, antihistaminic, anti- α -adrenergic, anti-inflammatory, and analgesic properties)—empirically advocated to treat cats with severe recurrent or persistent signs; suggested empirical dosage is 5–10 mg/cat q24h given at night. We do not recommend amitriptyline for treatment of acute, self-limiting episodes of iLUTD.
- Butorphanol, buprenorphine, and fentanyl—have been empirically recommended for short-term analgesia in cats with idiopathic cystitis. However, there have been no reports of controlled studies to evaluate their safety or efficacy.
- Phenoxybenzamine—may be used to minimize reflex dyssynergia and functional urethral outflow obstruction; suggested empirical dosage is 0.5 mg/kg PO q12h.
- Prazosin—may be used to minimize reflex dyssynergia and functional urethral outflow obstruction; suggested empirical dosage is 0.25–0.5 mg/cat PO q12–24h.
- Pentosan polysulfate sodium, a semisynthetic glycosaminoglycan—empirically recommended to help repair the glycosaminoglycan coating of the mucosa of the urinary tract. Results of controlled clinical studies have not demonstrated any beneficial effects of pentosan polysulfate on reducing the severity or frequency of clinical signs in cats with iLUTD.
- Oral glucosamine alone or in combination with oral chondroitin sulfate has been

empirically recommended to help repair the damaged GAG layer coating the urothelium. Results of controlled clinical studies have not demonstrated any beneficial effects of glucosamine on reducing the severity or frequency of clinical signs in cats with iLUTD.

- Corticosteroids—no detectable effect on remission of acute clinical signs demonstrated; predispose to bacterial urinary tract infections, especially in cats with indwelling transurethral catheters.
- Nonsteroidal anti-inflammatory drugs—empirically recommended by some because of their anti-inflammatory and analgesic properties. However, the safety of NSAIDs in the treatment of idiopathic cystitis has not been evaluated by controlled clinical trials.
- Dimethylsulfoxide (DMSO)—no detectable effect on remission of clinical signs demonstrated.
- Antibiotics and methenamine—no detectable effect on remission of clinical signs in cats demonstrated.

CONTRAINdications

- Phenazopyridine—a urinary tract analgesic used alone or in combination with sulfa drugs; may result in methemoglobinemia and irreversible oxidative changes in hemoglobin resulting in formation of Heinz bodies and anemia.
- Methylene blue—a weak antiseptic agent; may cause Heinz bodies and severe anemia.
- Bethanechol—a cholinergic drug used to manage hypotonic urinary bladders; do not use in patients with urethral obstruction.

PRECAUTIONS

- Cats with urethral obstruction and post-renal azotemia are at increased risk for adverse drug events, especially with drugs and anesthetics that depend on renal elimination or metabolism.
- Indwelling transurethral catheters, especially when associated with fluid-induced diuresis, predispose patients to bacterial urinary tract infections.

FOLLOW-UP

PATIENT MONITORING

Monitor hematuria by urinalysis; cystocentesis may cause iatrogenic hematuria, so naturally voided samples are preferred.

PREVENTION/AVOIDANCE

- Empirical observations suggest that recurrence of signs may be minimized by feeding moist foods.
- Reduce environmental stress.

POSSIBLE COMPLICATIONS

- Indwelling transurethral catheters—cause trauma; predispose to ascending bacterial

urinary tract infections.

- Perineal urethrostomies—predispose to bacterial urinary tract infections and urethral strictures.

EXPECTED COURSE AND PROGNOSIS

Hematuria, dysuria, and pollakiuria often are self-limiting in patients with most idiopathic lower urinary tract diseases, subsiding within 4–7 days. These signs often recur unpredictably; the frequency of recurrence appears to decline with advancing age.

F

MISCELLANEOUS

AGE-RELATED FACTORS

Frequency of recurrence appears to decline with advancing age.

SYNONYMS

- Feline idiopathic cystitis

FELINE IMMUNODEFICIENCY VIRUS INFECTION (FIV)

BASICS

DEFINITION

A complex retrovirus that causes an immunodeficiency disease in domestic cats; same genus (*Lentivirus*) as HIV, the causative agent of AIDS in humans.

PATHOPHYSIOLOGY

- Infection disrupts immune system function; immune dysfunction occurs due to cytokine alterations, non-specific hyperactivation of B- and T-lymphocytes, immunologic anergy, and apoptosis of T-cells.
- Pathogenicity can be strain or subtype dependent; subtypes A and B are most common in the United States.
- Acute infection—virus spreads from the site of entry to the lymph tissues and thymus via dendritic cells, first infecting T-lymphocytes, then macrophages.
- Primary receptor is feline CD134; uses chemokine receptor CXCR4 as co-receptor.
- CD4⁺ and CD8⁺ cells—both can be infected lytically in culture; virus selectively and progressively decreases CD4⁺ (T-helper) cells; inversion of the CD4⁺:CD8⁺ ratio (from ~2:1 to <1:1) develops slowly; an absolute decrease of CD4⁺ T-cells is seen after several months of infection.
- Early infection and activation of CD4⁺ CD25⁺ regulatory T-cells may limit effective immune response to FIV infection.
- Patients are clinically asymptomatic until cell-mediated immunity is disrupted—decline is associated with decreased Th1 cytokines; humoral immune function—perturbed in advanced stages of infection.
- Macrophages—main reservoir of virus in affected cats; transport virus to tissues throughout the body; defects in function (e.g., increased production of TNF).
- Astrocyte and microglial cells in the brain and megakaryocytes and mononuclear bone marrow cells may be infected; neuronal loss may occur.
- Co-infection with FeLV may increase the expression of FIV in many tissues, including kidney, brain, and liver.

SYSTEMS AFFECTED

- Gastrointestinal—panleukopenia-like syndrome.
- Hemic/Lymphatic/Immune—loss of CD4⁺ T-cells; lymphocytic/plasmacytic infiltrates in tissues (especially gingiva, lymphoid tissues); lymphomas, mast cell tumors.
- Nervous—alterations in astrocyte function and neurotransmitter expression.
- Ophthalmic—anterior uveitis.
- Renal/Urologic—nephropathy.
- Reproductive—fetal death or perinatal infections.
- Other body systems—secondary infections.

GENETICS

- No predisposition for infection.
- May play a role in progression and severity.

INCIDENCE/PREVALENCE

United States and Canada—1.5–3% in the healthy cat population; 9–15% in cats with signs of clinical illness.

GEOGRAPHIC DISTRIBUTION

Worldwide; seroprevalence rates vary greatly.

SIGNALMENT

Species

Cat

Mean Age and Range

- Prevalence of infection increases with age.
- Mean age—5 years at time of diagnosis.

Predominant Sex

Male—more aggressive; roaming

SIGNS

General Comments

- Diverse owing to immunosuppressive nature of infection.
- Associated disease cannot be clinically distinguished from FeLV-associated immunodeficiencies.

Historical Findings

Recurrent minor illnesses, especially with upper respiratory and gastrointestinal signs.

Physical Examination Findings

- Depend on occurrence of opportunistic infections.
- Lymphadenomegaly—mild to moderate.
- Gingivitis, stomatitis, periodontitis (25–50% of cases).
- Upper respiratory tract—rhinitis; conjunctivitis; keratitis (30% of cases); often associated with feline herpesvirus and calicivirus infections.
- Chronic renal insufficiency—immune-mediated glomerulonephritis.
- Persistent diarrhea (10–20% of cases); bacterial or fungal overgrowth, parasite-induced inflammation; direct effect of FIV infection on the gastrointestinal epithelium.
- Chronic, non-responsive, or recurrent infections of the external ear and skin—from bacterial infections or dermatophytosis.
- Fever and wasting—especially in later stage; possibly from high levels of TNF.
- Ocular disease—anterior uveitis; pars planitis; glaucoma.
- Lymphoma or other neoplasia.
- Neurologic abnormalities—disruption of normal sleep patterns; behavioral changes (pacing and aggression); motor and neurocognitive deficits; peripheral neuropathies.

CAUSES

- Cat-to-cat transmission; usually by bite wounds.
- Occasional perinatal transmission.
- Sexual transmission uncommon, although FIV has been detected in semen.

RISK FACTORS

- Male
- Free-roaming

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Primary bacterial, parasitic, viral, or fungal

infections.

- Toxoplasmosis—neurologic and ocular manifestations may be the result of *Toxoplasma* infection, FIV infection, or both.
- Non-viral neoplastic diseases.

CBC/BIOCHEMISTRY/URINALYSIS

- Hemogram may be normal.
- Anemia, lymphopenia or neutropenia—may be seen; neutrophilia may occur in response to secondary infections.
- Urinalysis and serum chemistry profile—high serum protein from hypergammaglobulinemia.

OTHER LABORATORY TESTS

Serologic Testing

- Detects antibodies to FIV.
- ELISA—routine screening test; kits for in-house use to microtiter plates for diagnostic laboratory use; confirm positive results with additional testing, especially in healthy, low-risk cats or when diagnosis would result in euthanasia.
- Western blot (immunoblot)—confirmatory testing of ELISA-positive samples.
- Kittens—when <6 months old may test positive owing to passive transfer of antibodies from an FIV-positive queen; a positive test does not indicate infection; retest at 8–12 months to determine infection.
- Vaccinated cats will test positive for FIV antibodies.

Others

- Virus isolation or detection—other methods occasionally available on an experimental basis.
- RT-PCR—useful in vaccinated cats or kittens with maternal antibody; use is hampered by inconsistent results between laboratories.
- CD4⁺:CD8⁺ evaluation—helps determine extent of immunosuppression.

PATHOLOGIC FINDINGS

- Lymphadenopathy—associated with follicular hyperplasia and massive paracortical infiltration of plasmacytes; later, may see a mixture of follicular hyperplasia and follicular depletion or involution; in terminal stages, lymphoid depletion is predominant finding.
- Lymphocytic and plasmacytic infiltrates—gingiva, lymph nodes and other lymphoid tissues, spleen, kidney, liver, and brain.
- Perivascular cuffing, gliosis, neuronal loss, white matter vacuolization, and occasional giant cells in the brain.
- Intestinal lesions similar to those seen with feline parvovirus infection (feline panleukopenia-like syndrome).

TREATMENT

APPROPRIATE HEALTH CARE

- Outpatient sufficient for most patients.
- Inpatient—with severe secondary infections until condition is stable.

(CONTINUED)

FELINE IMMUNODEFICIENCY VIRUS INFECTION (FIV)

F**NURSING CARE**

- Primary consideration—manage secondary and opportunistic infections.
- Supportive therapy—parenteral fluids and nutritional supplements, as required.

ACTIVITY

Normal

DIET

- Normal.
- Diarrhea, kidney disease, or chronic wasting—special diet, as needed.

CLIENT EDUCATION

- Inform client that the infection is slowly progressive and healthy antibody-positive cats may remain healthy for years.
- Advise client that cats with clinical signs will have recurrent or chronic health problems that require medical attention.
- Discuss the importance of keeping cats indoors to protect them from exposure to secondary pathogens and to prevent spread of FIV.

SURGICAL CONSIDERATIONS

- Oral treatment or surgery—frequently required; dental cleaning, tooth extraction, gingival biopsy.
- Biopsy or removal of neoplastic lesions.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Zidovudine (Retrovir) 5–15 mg/kg PO q12h: direct antiviral agent; most effective against acute infection; monitor for bone marrow toxicity.
- Immunomodulatory drugs—may alleviate some clinical signs; hr α -interferon (Roferon A) diluted in saline at 30 units/day PO for 7 days every other week; may increase survival rates and improve clinical status; high-dose recombinant feline omega-interferon (Virbagen Omega) at 1 million units/kg/day SC daily for 5 days at 3 intervals (d0–4, d14–18, d60–64) or lower-dose oral protocols may be effective; also try *Propionibacterium acnes* (Immunoregulin) at 0.5 mL/cat IV, once or twice weekly, or acemannan (Carrisyn) at 100 mg/cat PO daily.
- Gingivitis and stomatitis—may be refractory to treatment.
- Antibacterial or antimycotic drugs—useful for overgrowth of bacteria or fungi; prolonged therapy or high dosages may be required; for anaerobic bacterial infections use metronidazole at 7–15 mg/kg PO q8–12h or clindamycin at 11 mg/kg PO q12h.
- Corticosteroids or gold salts—judicious but aggressive use may help control immune-mediated inflammation.
- Anorexia—short-term appetite stimulation: diazepam at 0.2 mg/kg IV or oxazepam at 2.5 mg/cat PO.
- Topical corticosteroids—for anterior uveitis; long-term response may be incomplete or

poor; pars planitis often regresses spontaneously and may recur.

- Glaucoma—standard treatment.
- Yearly vaccination for respiratory and enteric viruses with inactivated vaccines is recommended.

CONTRAINdications

- Griseofulvin—avoid or use with extreme caution in FIV-positive cats; may induce severe neutropenia; neutropenia is reversible if the drug is withdrawn early enough but secondary infections associated with the condition can be life threatening.
- MLV vaccines—although unlikely, potential to cause disease in immunosuppressed cats.

PRECAUTIONS

Systemic corticosteroids—use with caution; may lead to further immunosuppression.

POSSIBLE INTERACTIONS

See "Contraindications"

**FOLLOW-UP****PATIENT MONITORING**

Varies according to secondary infections and other manifestations of disease.

PREVENTION/AVOIDANCE

- Prevent contact with FIV-positive cats.
- Quarantine and test incoming cats before introducing into multi-cat households.

Vaccine

- Dual subtype (A and D), inactivated whole virus plus infected cells vaccine (Fel-O-Vax FIV, Fort Dodge Animal Health).
- 0–100% efficacy after 3 doses, depending on study design and strain of challenge virus.
- Cannot distinguish between vaccinated and FIV-infected cats with antibody assays; virus detection by PCR is inconsistent.

EXPECTED COURSE AND PROGNOSIS

- Within the first 2 years after diagnosis or 4.5–6 years after the estimated time of infection, about 20% of cats die but > 50% remain asymptomatic.
- In late stages of disease (wasting and frequent or severe opportunistic infections), life expectancy is \leq 1 year.
- Overall survival time and quality of life for many FIV-positive cats will be similar to uninfected cats.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- Secondary bacterial, viral, fungal, and parasitic disease
- Lymphoid tumors
- Immune-mediated disease

AGE-RELATED FACTORS

Kittens (up to 4–6 months old) may test positive because of passive antibody transfer.

ZOONOTIC POTENTIAL

- None known; evidence against FIV transmission to humans is compelling but cannot be considered conclusive owing to the relatively short time the virus has been studied.
- Macaques susceptible to experimental infection; evidence of CD4⁺ T-cell decline.
- Potential transmission of secondary pathogens (e.g., *Toxoplasma gondii*) to immunocompromised humans.

PREGNANCY/FERTILITY/BREEDING

FIV-positive queens—reported abortions and stillbirths; transmission to kittens is infrequent if the queen is antibody-positive before conception; rate of transmission may be subtype or strain-dependent (> 90% for experimental infections with some strains).

SYNONYMS

Feline immunodeficiency syndrome

SEE ALSO

Individual chapters on secondary infectious diseases, ocular disease, gingivitis, and stomatitis.

ABBREVIATIONS

- AIDS = acquired immune deficiency syndrome
- ELISA = enzyme-linked immunosorbent assay
- FeLV = feline leukemia virus
- FIV = feline immunodeficiency virus
- HIV = human immunodeficiency virus
- hr α -interferon = human recombinant α -interferon
- MLV = modified live virus
- PCR = polymerase chain reaction
- RT-PCR = reverse transcriptase polymerase chain reaction
- TNF = tumor necrosis factor

FELINE INFECTIOUS PERITONITIS (FIP)

BASICS

DEFINITION

A systemic, immune-mediated, viral disease of domestic and exotic cats characterized by insidious onset, persistent non-responsive fever, pyogranulomatous tissue reaction, accumulation of exudative effusions in body cavities, and high mortality.

F

PATHOPHYSIOLOGY

- FIP virus replicates locally in epithelial cells of the upper respiratory tract, oropharynx, and intestinal tract.
- Immune-mediated disease—antiviral antibodies are produced, and the virus/antibody complex is taken up by macrophages.
- The virus is transported within monocytes/macrophages throughout the body; localizes at various vein wall and perivascular sites.
- Local perivascular viral replication and subsequent pyogranulomatous tissue reaction produce the classic lesion.

SYSTEMS AFFECTED

- Multisystemic—pyogranulomatous or granulomatous lesions in the omentum, on the serosal surface of abdominal organs (e.g., liver, kidney, and intestines), within abdominal lymph nodes, and in the submucosa of the intestinal tract.
- Nervous—vascular lesions can occur throughout the CNS, especially in the meninges.
- Ophthalmic—lesions may include uveitis and chorioretinitis.
- Respiratory—lesions on lung surfaces; pleural effusion in the wet form.

INCIDENCE/PREVALENCE

- Prevalence of antibodies against FCoV—high in most populations, especially in multi-cat facilities.
- Incidence of clinical disease—low in most populations, especially in single-cat households.
- Because of the difficulty in diagnosis, control, and prevention, outbreaks within breeding catteries may be catastrophic; in endemic catteries, the risk of an FCoV antibody-positive cat eventually developing FIP is usually < 10%.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

Cats—domestic and exotic

Breed Predilections

Some families or lines of cats appear more susceptible. Cheetahs are particularly susceptible.

Mean Age and Range

- Highest incidence—in kittens 3 months to 2 years of age.
- Incidence decreases sharply after cats reach 2 years of age.
- Geriatric cats may have slightly increased incidence.

SIGNS

General Comments

- A wide range, depending on the virulence of the strain, effectiveness of the host immune response, and organ system affected.
- Two classic forms—wet or effusive form, targets the body cavities; dry or non-effusive form, targets a variety of organs.

Historical Findings

- Insidious onset.
- Gradual weight loss and decrease in appetite.
- Stunting in kittens.
- Gradual increase in the size of the abdomen, giving a potbellied appearance.
- Persistent fever—fluctuating; antibiotic unresponsive.

Physical Examination Findings

- Depression.
- Poor condition.
- Stunted growth.
- Weight loss.
- Dull, rough hair coat.
- Icterus.
- Abdominal and/or pleural effusion.
- Palpation of the abdomen—abdominal masses (granulomas or pyogranulomas) within the omentum, on the surface of viscera (especially the kidney), and within the intestinal wall; mesenteric lymph nodes may be enlarged.
- Ocular—anterior uveitis; keratic precipitates; color change to the iris; and irregularly shaped pupil.
- Neurologic—brain stem, cerebrocortical, or spinal cord.

CAUSES

- Feline coronavirus—two genomic types.
- FCoV-1 (causes perhaps 85% of infections).
- FCoV-2 (similar to canine coronavirus).
- Distinguishing between forms—there has been great effort to distinguish between the low virulent or avirulent enteric strains (FECV) and the virulent strains (FIPV), but FECV and FIPV occur in both type 1 and type 2 forms; within each type is a spectrum from avirulent viruses that produce asymptomatic infections to those that produce fatal FIP.

RISK FACTORS

- Contact with an FCoV antibody-positive cat
- Breeding catteries or multi-cat facilities
- Less than 2 years of age
- FeLV infection

DIAGNOSIS

- Wet form—relatively easy to diagnose clinically.
- Dry form—difficult to diagnose accurately.
- No single diagnostic laboratory Test.

DIFFERENTIAL DIAGNOSIS

- Fever of unknown origin—when other causes of fever are ruled out.
- Cardiac disease causing pleural effusion—effusion has low specific gravity and cell count.
- Lesions of lymphoma, especially in the kidney, on palpation.
- CNS tumors—most cats test positive for FeLV; for FeLV-negative cats, biopsy the lesion (if accessible) for

histopathology and immunohistochemistry for FCoV.

- Respiratory disease—FCV, FHV, chlamydiosis, or various bacteria.

- Pansteatitis (yellow fat disease)—classic feel and appearance of fat within the abdominal cavity; pain on abdominal palpation; often a fish-only diet.
- Panleukopenia producing enteritis—leukopenia; positive fecal canine parvovirus antigen assay.

CBC/BIOCHEMISTRY/URINALYSIS

- Leukopenia—common early in the infection; later leukocytosis with neutrophilia and lymphopenia.
- Mild to moderate anemia may occur.
- High total plasma globulin common.
- Often hyperbilirubinemia and hyperbilirubinuria.

OTHER LABORATORY TESTS

- Serum antibody tests—immunoassays, viral neutralization assays; detect antibodies against FCoV; positive tests not diagnostic, indicate only previous infection; correlation between height of titer and eventual confirmation of infection not high.
- PCR assays—detect viral antigen; accuracy of positive tests correlating with clinical disease is still being evaluated.

- Immunohistochemistry (immunoperoxidase) assays detect FCoV within specific cells of biopsy samples or histopathologic sections of tissues from cats with fatal diseases; excellent for confirming cause of specific lesions, especially inflammatory abdominal disease, which often is not diagnosed as FIP.

IMAGING

- Generally not required.
- May confirm abdominal and pleural effusions.
- May detect granulomatous lesions.

DIAGNOSTIC PROCEDURES

- Fluid obtained via thoracocentesis and abdominocentesis—pale to straw colored; viscous; flecks of white fibrin often seen; will clot upon standing; specific gravity usually high (1.030–1.040).
- Laparoscopy—to observe specific lesions of the peritoneal cavity; to obtain a biopsy sample for histopathology or immunohistochemistry confirmation.
- Exploratory laparotomy—may be indicated for difficult-to-diagnose patients if laparoscopy is not available.

PATHOLOGIC FINDINGS

Gross

- Vary depending on the organs or tissues involved.
- Patient will be emaciated, with a rough hair coat.

Wet Form

- Abdomen and/or thoracic cavity—may contain thick, viscous exudates.
- White, rough, pyogranulomatous plaques—may be on serosal surface of abdominal organs and the omentum.
- Granulomatous lumps—may protrude from the surface of the kidney.
- Granulomas—may be in the intestinal wall.

(CONTINUED)

FELINE INFECTIOUS PERITONITIS (FIP)

- Fibrous strands—may extend between organs.
- Liver—may have focal, pale lesions.
 - Iris—may be discolored.
 - Cornea—may see keratic precipitates.
 - CNS—may see lesions in the brain and/or the spinal cord.

Histopathologic

- Granulomas or pyogranulomas in any affected tissue.
- Lesions—start around veins; increase in size, involving large portions of tissue; microscopic appearance suggests the diagnosis.

**TREATMENT****APPROPRIATE HEALTH CARE**

Inpatient or outpatient, depending on stage and severity of disease and owner's willingness and ability to provide good supportive care.

NURSING CARE

- Therapeutic paracentesis—to relieve pressure from excessive ascites or pleural effusions.
- Important to encourage the affected cat to eat.

ACTIVITY

Restrict to prevent exposure of other cats, although greatest degree of virus shed occurs before the patient shows signs.

DIET

Any food that will entice the patient to eat.

CLIENT EDUCATION

- Discuss the various aspects of disease, including the grave prognosis; once clinical FIP is confirmed, nearly 100% of cats will eventually die of the disease.
- Inform client of the high prevalence of FCoV infection but low incidence of actual clinical disease; < 10% of FCoV antibody-positive cats < 2 years of age eventually develop clinical disease.

SURGICAL CONSIDERATIONS

- Generally none.
- Rarely, inflammatory abdominal disease from FCoV may present with intestinal obstruction; abdominal surgery may be required.

**MEDICATIONS****DRUG(S) OF CHOICE**

- No treatment routinely effective.
- Patients with generalized and typical signs almost invariably die.
- Most FCoV-positive cats have subclinical infection or mild, localized granulomatous disease that is not diagnosed as FIP.
- Immunosuppressive drugs (e.g., prednisolone and cyclophosphamide)—limited success.
- Corticosteroids (subconjunctival injection)—may help ocular involvement.

- Interferons—effective in vitro; limited success in vivo; a recombinant interferon reported to have some success in Japan.
- Antibiotics—ineffective because generally not associated with secondary bacterial infections.

ALTERNATIVE DRUG(S)

No antiviral drugs proven to be efficacious.

**FOLLOW-UP****PATIENT MONITORING**

Monitor for development of large quantities of pleural effusion.

PREVENTION/AVOIDANCE

- MLV intranasal vaccine—available against FIPV; efficacy low; cannot rely on vaccination alone for control; will produce antibody-positive cats, complicating monitoring in catteries or colonies; FIP vaccine is not generally recommended by the American Association of Feline Practitioners vaccine guidelines.
- Mother/offspring—main method of transmission appears to be from asymptomatic carrier queens to their kittens at 5–7 weeks of age, after maternally derived immunity wanes; break cycle of transmission by early weaning at 4–5 weeks of age and isolating litter from direct contact with other cats, including the queen.
- Routine disinfection—premises, cages, and water/food dishes; readily inactivates virus; reduces transmission.
- Introduce only FCoV antibody-negative cats to catteries or colonies that are free of virus.
- Restrict household cats to indoor environments.

POSSIBLE COMPLICATIONS

- Pleural effusion may require thoracocentesis.
- Intestinal obstruction from inflammatory abdominal disease.
- Neurologic disease from CNS lesions.

EXPECTED COURSE AND PROGNOSIS

- Clinical course—a few days to several months.
- Prognosis grave once typical signs occur; mortality nearly 100%.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

FeLV-positive cats—more prone to develop clinical disease.

PREGNANCY/FERTILITY/BREEDING

FIP virus can infect fetuses, resulting in fetal death or neonatal disease.

SYNOMYS

- Feline coronaviral polyserositis
- Feline coronaviral vasculitis
- Feline coronavirus infection

ABBREVIATIONS

- CNS = central nervous system

FELINE ISCHEMIC ENCEPHALOPATHY

BASICS

DEFINITION

- Seasonal neurologic disease that occurs in outdoor cats or those with access to the outdoors in North America during late spring, summer, and early fall; usually results in sudden onset of seizures, circling, altered mentation, and/or blindness.
- Aberrant migration of a *Cuterebra* larva in the brain of a cat that often causes thrombosis or vasospasm of the middle cerebral artery with ensuing ischemic necrosis; degeneration of the superficial layers of the cerebral cortex and parenchymal destruction associated with the physical migration of the larva in the brain parenchyma.
- Must be differentiated from other causes of vascular diseases affecting the brains of cats as well as other neurologic diseases of cats.

PATOPHYSIOLOGY

- In FIE, the *Cuterebra* larva enters the nasal passage of the cat, migrates through the cribriform plate into the olfactory bulb of the brain, then along the olfactory peduncle and sometimes continues in the parenchyma of the brain or alternatively in the subarachnoid space; the parasite then, if still alive, migrates caudally, where it may compromise the MCA physically through the spines on the larvae's body, or possibly via a chemical agent secreted by the parasite causing vasospasm to the vessel; or the vasospasm may be secondary to the hemorrhage caused by the parasite; the parasite may then die in the SAS or within the parenchyma.
- The adult botfly lays eggs by the entrance of a rodent's den. The eggs hatch into the L1 stage of the larva, which attaches to the hair of the mouse or rabbit and enters the body through a normal orifice (mouth, nose, eye, or anus) and migrates into the associated tissues (nasopharynx, trachea, thoracic cavity, diaphragm, abdominal cavity). Then the larva continues its migration to reach a subcutaneous site in the inguinal or thoracic region where it matures first to the L2 stage and then within the warble to the L3 larval stage, emerges through the skin, drops off the host, pupates in the soil over the winter, and then emerges in the spring as the adult botfly; when the cat hunts near the rodent's den, the L1 larva attaches to the cat's hair and gains access to the nasal passage of the cat and begins the catastrophic pathway of feline ischemic encephalopathy.
- Occasionally the larva does not migrate through the cribriform plate but embeds in the nasal passage or respiratory tract of the cat, causing focal respiratory signs. The larva has also been found in the eye and oropharyngeal region.

SYSTEMS AFFECTED

- Brain and less commonly spinal cord.
- Larvae can also be found in the skin, nasal passage, pharynx, larynx, eye, trachea, and thorax of cats.

GENETICS

None

INCIDENCE/PREVALENCE

Not known

GEOGRAPHIC DISTRIBUTION

- North America only.
- Same distribution as the *Cuterebra* botfly.
- Disease is not recognized in locations that do not have the *Cuterebra* botfly, such as Australia and Japan.

SIGNALMENT

Breed Predilections

None

Mean Age and Range

- Median age—2 years old
- Range—1–7 years old

Predominant Sex

None

SIGNS

- Sudden onset of neurologic signs.
- Often preceded by upper respiratory signs 1–3 weeks prior to the neurologic signs (due to the migration of the parasite in the nasal passage).
- Often prosencephalic signs.
- Most commonly—seizures, circling, altered mentation, blindness.
- Sometimes multifocal neurologic signs.
- Rarely spinal cord signs.

CAUSES

Cuterebra larvae

RISK FACTORS

- Outdoor cats; access to outdoors
- July, August, and September in the northeast United States and southeast Canada. Can be found in May and June, in the southeast United States
- Hunting cats

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of vascular accidents in the brain such as renal disease with hypertension.
- External trauma.
- Tumors—progressive rather than sudden in onset.
- Infectious/inflammatory diseases—such as those caused by *Cryptococcus* sp., *Toxoplasma gondii*, feline infectious peritonitis virus, and feline immunodeficiency virus.

CBC/BIOCHEMISTRY/URINALYSIS

- Usually normal
- CBC—occasionally neutrophilia, leukocytosis, or eosinophilia

- Chemistry—occasionally elevated globulins or hyperglycemia

OTHER LABORATORY TESTS

- Serology for FeLV, FIV, FIP—negative
- Cryptococcal antigen titers—negative
- Toxoplasma IgG and IgM—negative

IMAGING

- MRI—diagnostic modality of choice; detect track lesion extending from the cribriform plate into the olfactory bulb and frontal, parietal, and temporal lobes best recognized on dorsal sequences; may also see area of ischemic infarction; if performed soon after onset of signs, increased signal intensity on T2-WI, PD-WI, and FLAIR images associated with ischemia of the superficial layers of the cerebral cortex, or the area supplied by the MCA; scant parenchymal enhancement in the area of infarction after administration of contrast. If MRI is done more than 2–3 weeks after onset of signs, may find loss of overlying gray matter in the region supplied by the MCA and associated hydrocephalus ex vacuo. MRA (time of flight or post-contrast) may be of some utility in some cases.
- CT—limited value.

DIAGNOSTIC PROCEDURES

Cerebrospinal fluid—normal or non-suppurative inflammation with macrophages, lymphocytes, or eosinophils.

PATHOLOGIC FINDINGS

- Local areas of malacia and hemorrhage involving the olfactory bulbs and peduncles and brain transverse sections. Thorough examination of the cribriform plate, olfactory bulbs, and peduncles, as well as the remaining parenchyma, meninges, and overlying calvaria, may reveal the larva, which is approximately 5–10 mm in length (stage 2 larva), tan and with concentric rings of spines along the length of the body.
- Histopathologic features may include necrosis and hemorrhage of the parasitic track or less specific findings such as superficial laminar cerebrocortical necrosis, cerebral infarction, subependymal rarefaction, and astrogliosis and subpial astroglioses.

TREATMENT

APPROPRIATE HEALTH CARE

N/A

NURSING CARE

- Padded cage may be necessary if the cat is having seizures.
- Swivel IV line can be used if the patient exhibits propulsive circling or loss of balance.

ACTIVITY

N/A

DIET

N/A

(CONTINUED)

FELINE ISCHEMIC ENCEPHALOPATHY

F

CLIENT EDUCATION

- Only occurs in outdoor cats and those with access to the outdoors; strictly indoor cats do not develop FIE.
- Only occurs in summer months with the majority of patients seen during July, August, and September in the northeast United States and southeast Canada.
- May not occur in major metropolitan areas that do not have the normal appropriate hosts such as the cottontail rabbit.

SURGICAL CONSIDERATIONS

Successful removal of the parasite from the brain/spinal cord has not been reported in cats but may be possible if neuroimaging is available early after onset of clinical signs.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Supportive care including antiepileptic drugs and appropriate fluid supplementation, which may include thiamine administration and additional potassium intravenously depending on the nutritional status of the patient; typically phenobarbital is used at a maintenance dose of 7.5–15 mg PO, IM, or IV q12h/cat; in addition phenobarbital can be loaded at a total loading dose of 16 mg/kg IV, PO, or IM; this dose is usually divided over 24–48 hours (e.g., 4 mg/kg q12h for 2 days); then maintenance dose is started; diazepam can be used at 2.5–5 mg IV to stop cluster seizures or status epilepticus. Other anticonvulsants, such as levetiracetam, may also be utilized.
- A cocktail treatment has been proposed for recently affected cats—diphenhydramine IM at 4 mg/kg, 1–2 hours before giving ivermectin SC at 200–500 µg/kg and prednisolone sodium succinate at 30 mg/kg IV; treatment is repeated 24 and 48 hours after the first injection of ivermectin; in addition patients receive prednisone at 5 mg/cat q12h PO for 14 days and enrofloxacin at 22.7 mg PO q12h for 14 days; ivermectin is not approved for use against *Cuterebra* larva so appropriate client permission must be obtained prior to administration; the above cocktail treatment is not for patients with clinical signs > 1 week as the parasite is likely already dead.

CONTRAINDICATIONS

Do not use ivermectin in cats with known sensitivity.

PRECAUTIONS

No adverse effects from ivermectin have been noted; however, an anaphylactic or allergic reaction could occur if the *Cuterebra* larva suddenly dies and releases possible foreign antigens.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

Can use dexamethasone instead of prednisone.

**FOLLOW-UP****PATIENT MONITORING**

Sequential neurologic evaluations

PREVENTION/AVOIDANCE

- Keep cat indoors.
- Use of monthly fipronil, imidacloprid, selamectin or ivermectin has been suggested to prevent infections with the parasite.

POSSIBLE COMPLICATIONS

- May continue to have uncontrolled seizures.
- May continue to circle compulsively.
- May have behavioral changes such as aggression.

EXPECTED COURSE AND PROGNOSIS

After initial onset, many patients improve and become acceptable pets; there may be persistent deficits, seizures, circling, and undesirable behavior such as aggression; persistent clinical signs depend on damage caused by the infarction and parasitic migration.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

None

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

None; however, aberrant *Cuterebra* larva migration has been reported in humans, most commonly as an ocular form in children.

PREGNANCY/FERTILITY/BREEDING

N/A

SYNONYMS

CNS cuterebriasis

FELINE LEUKEMIA VIRUS INFECTION (FELV)

BASICS

DEFINITION

A simple retrovirus (*Gammaretrovirus* genus) that causes immunodeficiency and neoplastic disease in domestic cats.

PATHOPHYSIOLOGY

- Four subgroups of FeLV—A, B, C, and T; FeLV-A is most transmissible and is present in all isolates; FeLV-B arises from recombination of FeLV-A *env* gene with endogenous retroviral sequences (50% of isolates); FeLV-C (1% of isolates) arises from a mutation in *env* gene sequences; FeLV T infects only T-cells.
- Early infection consists of five stages—(1) viral replication in tonsils and pharyngeal lymph nodes; (2) infection of a few circulating B-lymphocytes and macrophages that disseminate the virus; (3) replication in lymphoid tissues, intestinal crypt epithelial cells, and bone marrow precursor cells; (4) release of infected neutrophils and platelets from the bone marrow into the circulatory system; and (5) infection of epithelial and glandular tissues, with subsequent shedding of virus into the saliva and urine.
- If virus replication is terminated at stage 1, with no detectable viremia, the infection is considered to be *abortive*.
- If an adequate immune response stops progression at stage 2 or 3 (4–8 weeks after exposure) and forces the virus into latency after a transient viremia, it is called a *regressive* or nonproductive infection.
- If the immune response is not effective, persistent viremia (stages 4 and 5) usually develops 4–6 weeks after infection but may take 12 weeks, and the cat has a *progressive* or productive infection.
- Tumor induction—occurs when the DNA provirus integrates into cat chromosomal DNA in critical regions (oncogenes).
- Virus integration near the cellular gene *c-myc* or near genes influencing the expression of *c-myc*—often results in thymic lymphosarcoma.
- Feline sarcoma viruses—mutants of FeLV; arise by recombination between the genes of FeLV and host; virus-host fusion proteins are responsible for the efficient induction of fibrosarcomas.

SYSTEMS AFFECTED

- Hemic/Lymphatic/Immune—anemia; blood cell dyscrasias; bone marrow neoplasias; neuroendocrine dysfunction and immunosuppression; absolute decrease in CD4⁺ and CD8⁺ subsets of T-cells; decreased CD4⁺: CD8⁺ ratio.
- Nervous—degenerative myopathy, neoplasias.
- All other body systems—immunosuppression with secondary infections or development of neoplastic disease.

GENETICS

No genetic predisposition

INCIDENCE/PREVALENCE

- Prevalence in United States—2–3% in the healthy cat population; worldwide infection rate of 1–8% in healthy cats; 3–4 times greater in cats exhibiting signs of clinical illness.
- Decline in US prevalence since 1980s—attributed to test and removal programs, possibly vaccination programs.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

Cat

Mean Age and Range

- Prevalence highest between 1 and 6 years of age
- Mean—3 years

Predominant Sex

Male:female ratio—1.7:1

SIGNS

General Comments

- Onset of FeLV-associated disease—usually occurs over a period of months to years after infection.
- Associated diseases—non-neoplastic or neoplastic; most of the non-neoplastic or degenerative diseases result from immunosuppression.
- Regressive infections may be associated with conditions such as cardiomyopathies, lymphomas and leukemias, anemia, other infectious diseases.
- Clinical signs of FeLV-induced immunodeficiency cannot be distinguished from those of FIV-induced immunodeficiency.

Historical Findings

- Patient allowed outdoors
- Member of a multi-cat household

Physical Examination Findings

- Depend on the type of disease (neoplastic or non-neoplastic) and occurrence of secondary infections.
- Lymphadenomegaly—mild to severe.
- Fever and wasting.
- Upper respiratory tract—rhinitis, conjunctivitis, and keratitis.
- Persistent diarrhea—bacterial or fungal overgrowth; parasite-induced inflammation; direct effect of infection on crypt cells.
- Gingivitis; stomatitis; periodontitis.
- Chronic, non-responsive, or recurrent infections of the external ear and skin; abscesses.
- Lymphoma—most common associated neoplastic disease (risk increased by 62-fold in FeLV-infected cats); thymic and multicentric lymphomas highly associated; miscellaneous lymphomas (extranodal origin) most frequently involve the eye and nervous system.
- Erythroid and myelomonocytic leukemias—predominant non-lymphoid leukemias.
- Fibrosarcomas—in patients co-infected with mutated sarcoma virus; most frequently in young cats.
- Peripheral neuropathies; progressive ataxia.

CAUSES

- Cat-to-cat transmission—close casual contact (grooming); shared dishes or litter

pans; bites.

- Perinatal transmission—fetal and neonatal death of kittens from 80% of affected queens; transplacental and transmammary transmission in at least 20% of surviving kittens from infected queens.

RISK FACTORS

- Age—kittens much more susceptible to infection than adults.
- Male—result of behavior.
- Free-roaming.
- Multi-cat household.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- FIV
- Other infections—bacterial, parasitic, viral, or fungal
- Non-viral neoplastic diseases

CBC/BIOCHEMISTRY/URINALYSIS

- Anemia—often severe; most often nonregenerative; regenerative anemias usually associated with *Mycoplasma haemofelis* or *M. haemominutum* co-infections.
- Lymphopenia or lymphocytosis.
- Neutropenia—sometimes cyclic; may be in response to secondary infections or immune-mediated disease.
- Thrombocytopenia and immune-mediated hemolytic anemia—may occur secondary to immune complex formation.
- Urinalysis and serum chemistry profile findings—depend on system affected and type of disease.

OTHER LABORATORY TESTS

- IFA—identify FeLV p27 antigen in leukocytes and platelets in fixed smears of whole blood or buffy coat preparations; positive result indicates a productive infection in bone marrow cells; 97% of IFA-positive cats remain persistently infected and viremic for life; p27 antigen usually detected by 4 weeks after infection but may take up to 12 weeks for positive test; for leukopenic cats, use buffy coat smears rather than whole blood smears.
- ELISA—detect soluble FeLV p27 antigen in whole blood, serum, plasma, saliva, or tears; more sensitive than IFA at detecting early or transient infections; a single positive test cannot predict which cats will be persistently viremic; retest in 12 weeks; false-positive results more common when whole blood rather than serum or plasma is used; positive tests with saliva or tears should be checked with whole blood (IFA) or serum (ELISA).
- A few cats have persistently discordant ELISA-positive and IFA-negative tests or test positive only sporadically; this may be due to atypical local viral replication in tissues such as bladder or eyes (*focal* infection); demonstrates infection despite no detectable cell-associated viremia.
- FeLV vaccination does not interfere with testing—tests detect antigen, not antibody.

IMAGING

Thymic atrophy (fading kittens)

(CONTINUED)

FELINE LEUKEMIA VIRUS INFECTION (FeLV)

DIAGNOSTIC PROCEDURES

Bone marrow aspiration or biopsy—with erythroblastopenia (nonregenerative anemia), bone marrow often hypercellular owing to an arrest in differentiation of erythroid cells; true aplastic anemia with hypocellular bone marrow may be seen; some cases of anemia result from myeloproliferative disease.

PATHOLOGIC FINDINGS

- Lesions—depend on type of disease; bone marrow hypercellularity often accompanies neoplastic disease.
- Lymphocytic and plasmacytic infiltrates of gingiva, lymph nodes, other lymphoid tissues, spleen, kidney, and liver.
- Intestinal lesions similar to those seen with feline parvovirus infection (feline panleukopenia-like syndrome).

TREATMENT

APPROPRIATE HEALTH CARE

- Outpatient for most cats.
- Inpatient—may be required with severe secondary infections, anemia, or cachexia until condition stable.
- Blood transfusions—emergency support; multiple transfusions may be necessary; passive antibody transfer reduces level of FeLV antigenemia in some cats; thus, immunization of blood donor cats with FeLV vaccines is useful.

NURSING CARE

- Management of secondary and opportunistic infections—primary consideration.
- Supportive therapy (e.g., parenteral fluids and nutritional supplements) may be useful.

ACTIVITY

Normal

DIET

- Normal.
- Diarrhea, kidney disease, or chronic wasting—may require special diet.

CLIENT EDUCATION

- Discuss importance of keeping cats indoors and separated from FeLV-negative cats to protect them from exposure to secondary pathogens and to prevent spread of FeLV.
- Discuss good nutrition and routine husbandry for control of secondary bacterial, viral, and parasitic infections.

SURGICAL CONSIDERATIONS

- Biopsy or removal of tumors.
- Oral treatment or surgery—dental cleaning, tooth extraction, gingival biopsy.

MEDICATIONS

DRUG(S) OF CHOICE

- Zidovudine (Retrovir, 5–15 mg/kg PO q12h)—clinical improvement but does not clear virus.

- Immunomodulatory drugs—may alleviate some clinical signs; hr α -interferon (Roferon A, diluted in saline, 30 U/day PO for 7 days every other week) may increase survival rates and improve clinical status; *Propionibacterium acnes* (Immunoregulin, 0.5 mL/cat IV once or twice weekly); acemannan (Carrisyn, 100 mg/cat/day PO).

- *Mycoplasma haemofelis* infection—suspect in all cats with regenerative hemolytic anemia (see chapter, Hemotropic Mycoplasmosis (also Hemoplasmosis or Haemobartonellosis)).

- Lymphoma—management with standard combination chemotherapy protocols; periods of remission average 3–4 months; some cats may remain in remission for much longer.

- Myeloproliferative disease and leukemias—more refractory to treatment; for anemia, try erythropoietin (EpoGen, 35–100 IU/kg SC q48h); for neutropenia, try rhG-CSF (Neupogen, 5 μ g/kg SC q24h).

- Yearly vaccination for respiratory and enteric viruses with inactivated vaccines recommended.

CONTRAINdications

MLV vaccines—potential for disease in immunosuppressed cats.

PRECAUTIONS

Systemic corticosteroids—use with caution because of the potential for further immunosuppression.

FOLLOW-UP

PATIENT MONITORING

Varies according to the secondary infections and other manifestations of disease.

PREVENTION/AVOIDANCE

- Prevent contact with FeLV-positive cats.
- Quarantine and test incoming cats before introduction into multiple-cat households.

Vaccines

- Most commercial vaccines induce virus-neutralizing antibodies specific for gp70; reported efficacy ranges from < 20% to almost 100%, depending on the trial and challenge system; inactivated whole virus vaccines tend to be best (canarypox-FeLV recombinant vaccine has similar efficacy without adjuvant).
- Test cats for FeLV before initial vaccination; if prevaccination testing is not done, advise clients that the cat may already be infected.
- Vaccinate kittens at 8–9 weeks and 12 weeks of age; boost at 1 year of age; revaccinate every 2–3 years.

EXPECTED COURSE AND PROGNOSIS

Persistently viremic cats—> 50% succumb to related diseases within 2–3 years after infection.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Secondary bacterial, viral, fungal, and parasitic disease
- Lymphoid tumors
- Fibrosarcomas
- Immune-mediated disease

AGE-RELATED FACTORS

- Neonatal kittens—most (70–100%) susceptible to progressive infection.
- Older kittens—< 30% susceptible to progressive infection by 16 weeks of age but may develop regressive infections.

ZOONOTIC POTENTIAL

Probably low, but controversial—studies report conflicting results of antibodies to FeLV in humans and of correlation between certain human leukemias and exposure to cats.

PREGNANCY/FERTILITY/BREEDING

- Abortions, stillbirths, and fetal resorptions common in FeLV-positive queens.
- Transmission from queen to kittens—in at least 20% of live births.

SYNONYMS

FeLV-AIDS—a mutated FeLV that causes immunodeficiency disease to develop rapidly.

SEE ALSO

Individual chapters on neoplasia, secondary infectious diseases, ocular disease, and gingivitis/stomatitis.

ABBREVIATIONS

- AIDS = acquired immune deficiency syndrome
- ELISA = enzyme-linked immunosorbent assay
- FeLV = feline leukemia virus
- FIV = feline immunodeficiency virus
- hr α -interferon = human recombinant α -interferon
- IFA = immunofluorescent antibody
- MLV = modified live virus
- rhG-CSF = recombinant human granulocyte colony-stimulating factor

FELINE PANLEUKOPENIA

BASICS

DEFINITION

An acute, enteric, viral infection of cats characterized by sudden onset, depression, vomiting and diarrhea, severe dehydration, and a high mortality.

PATHOPHYSIOLOGY

The causative virus, feline parvovirus, infects only mitotic cells, causing acute cell cytolysis of rapidly dividing cells.

SYSTEMS AFFECTED

- Gastrointestinal—intestinal crypt cells of the jejunum and ileum destroyed; acute enteritis with vomiting and diarrhea; shortened blunt villi with poor absorption of nutrients, dehydration, and secondary bacteremia.
- Hemic/Lymphatic/Immune—severe panleukopenia; atrophy of the thymus.
- Nervous and Ophthalmic—in neonatal kittens rapidly dividing granular cells of the cerebellum and retinal cells of the eye destroyed; cerebellar hypoplasia with ataxia and retinal dysplasia.
- Reproductive—*in utero* infection in non-immune queens leading to fetal death, fetal resorption, abortion, stillbirth, or fetal mummification.

GENETICS

N/A

INCIDENCE/PREVALENCE

- Unvaccinated populations—the most severe and important feline infectious disease.
- Routine vaccination—almost total control of this disease.
- Extremely contagious.
- Extremely stable virus, surviving for years on contaminated premises.

GEOGRAPHIC DISTRIBUTION

Worldwide in unvaccinated populations

SIGNALMENT

Species

- Felidae—all, domestic and exotic.
- Canidae—susceptible to the closely related canine parvovirus; some exotic canids may be susceptible to FPV infection.
- Mustelidae—especially mink; may be susceptible.
- Procyonidae—raccoon and coatiundi; susceptible.

Breed Predilections

None

Mean Age and Range

- Unvaccinated and previously unexposed cats of any age can become infected once passively transferred maternal immunity has been lost.
- Kittens 2–6 months of age—most

susceptible to develop severe disease.

- Adults—often mild or subclinical infection.

Predominant Sex

N/A

SIGNS

Historical Findings

- History of recent exposure (e.g., adoption shelter).
- Newly acquired kitten.
- Kitten 2–4 months old from a premises with a history of FP.
- No vaccination history or last vaccinated when < 16 weeks of age.
- Sudden onset, with vomiting, diarrhea, depression, and complete anorexia.
- Owner may suspect poisoning.
- Cat may have disappeared or hid for 1 day or more before being found.
- Owner may report cat hangs head over water bowl or food dish but does not eat or drink.

Physical Examination Findings

- Depression—may be mild to severe.
- Typical “panleukopenia posture”—sternum and chin resting on floor, feet tucked under body, and top of scapulae elevated above the back.
- Dehydration—appears rapidly; may be severe.
- Vomiting and diarrhea may occur.
- Body temperature—usually mild to moderately elevated or depressed in the early stages of disease; becomes severely subnormal as affected cat becomes moribund.
- Abdominal pain—may be elicited on palpation.
- Small intestine—either turgid and hose-like or flaccid.
- Subclinical or mild infections with few or no clinical signs common, especially in adults.
- Ataxia from cerebellar hypoplasia—kittens infected *in utero* or neonatally; signs evident at 10–14 days of age and persist for life: hypermetria; dysmetria; incoordination with a base-wide stance and an elevated “rudder” tail; alert, afebrile, and otherwise normal; retinal dysplasia sometimes seen.

CAUSES

Feline Parvovirus

- Small, single-stranded DNA virus.
- Single antigenic serotype.
- Considerable antigenic cross-reactivity with canine parvovirus Type 2 and mink enteritis virus.
- Extremely stable against environmental factors, temperature, and most disinfectants.
- Requires a mitotic cell for replication.

Canine Parvovirus Types 2a, 2b, and 2c

- CPV-2a, CPV-2b, and CPV-2c can produce FP in domestic and/or exotic cats.
- Properties of CPV like those for FPV.

RISK FACTORS

- Anything that increases the mitotic activity of the small intestinal crypt cells—intestinal

parasites; pathogenic bacteria. • Secondary or co-infections—viral upper respiratory infections. • Age—kittens 2–6 months of age tend to be more severely affected.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Panleukopenia-like syndrome of FeLV infection—chronic infection; chronic enteritis; chronic panleukopenia; often anemia; patient positive for FeLV antigen in the blood and/or saliva.
- Salmonellosis—usually subclinical infection; severe gastroenteritis; total WBC counts usually high.
- Acute poisoning—similar to acute or fulminating disease; severe depression; subnormal temperature; total WBC count not severely depressed.
- Many diseases of cats can cause mild clinical signs that are hard to differentiate from mild FP; total WBC count is always low during the acute infection with FP, even in subclinical infections.

CBC/BIOCHEMISTRY/URINALYSIS

- Panleukopenia—most consistent finding; leukocyte counts usually between 500 and 3,000 cells/dL during the acute disease.
- Biochemical findings usually non-specific.

OTHER LABORATORY TESTS

- CPV antigen fecal immunoassay (Cite Canine Parvovirus Test Kit, IDEXX Labs)—not licensed for feline panleukopenia; detects FPV antigen in feces.
- Chromatographic test strip—feces for FPV and CPV.
- Serologic testing—paired serum samples (acute and convalescent); detects rising antibody titer.

DIAGNOSTIC PROCEDURES

- Viral isolation from feces or affected tissues (e.g., thymus, small intestine, spleen).
- Electron microscopy of feces—detects parvovirus particles, presumably FPV.

PATHOLOGIC FINDINGS

Gross

- Rough hair coat.
- Severe dehydration.
- Evidence of vomiting and diarrhea.
- Weight loss.
- Edematous and turgid small intestine.
- Petechial or ecchymotic hemorrhages on the serosal and/or mucosal surfaces of the jejunum and ileum.
- Thymic atrophy.
- Gelatinous or liquid bone marrow.
- In utero* or neonatal infection—gross hypoplasia of the cerebellum.

Microscopic

- Dilated small intestinal crypts with sloughing of epithelial cells.
- Shortened and

(CONTINUED)

blunt intestinal villi. • Absence of lymphocytic infiltrates in all tissues. • Lymphocytic depletion of follicles of lymph nodes, Peyer's patches, and spleen. • Neonatal and fetal infection—disorientation and depletion of the granular and Purkinje cells of the cerebellum. • Eosinophilic intranuclear inclusions in affected tissues during early stages of infection; not usually observed on routine histopathologic examination of formalin-fixed tissues.

TREATMENT

APPROPRIATE HEALTH CARE

- Main principles of treatment—rehydration; reestablishment of electrolyte balance; supportive care until the patient's immune system produces antiviral antibodies that neutralize the virus. • Inpatient—severe cases; hydration and replacement electrolyte therapy. • Outpatient—mild cases.

NURSING CARE

- Fluid therapy—essential in severe cases; with electrolyte replacement and intravenous nutrient support may well make the difference between survival and death. • Whole blood transfusions—if plasma protein falls < 4 g/dL or if total WBC counts fall < 2,000 cells/dL.

ACTIVITY

Keep patient indoors during the acute disease—prevent contamination of the environment; prevent the cat from going into hiding.

DIET

Temporarily withhold food until the acute gastroenteritis is controlled.

CLIENT EDUCATION

- Inform client that all current and future cats in the household must be vaccinated against FPV before exposure. • Inform client that the virus will remain infectious on the premise for years unless environment can be adequately disinfected with household bleach.

SURGICAL CONSIDERATIONS

None

MEDICATIONS

DRUG(S) OF CHOICE

Broad-spectrum antibiotics—counter secondary bacteremia from intestinal bacteria.

CONTRAINDICATIONS

Oral medications until gastroenteritis has been controlled.

ALTERNATIVE DRUG(S)

None

FOLLOW-UP

PATIENT MONITORING

- Monitor hydration and electrolyte balance closely. • Monitor CBC daily or at least every 2 days until recovery. • Recovered cats are immune against FPV infection for life and do not require further vaccination.

PREVENTION/AVOIDANCE

- Contaminated environments (e.g., cages, floors, food and water dishes) should be disinfected with a 1:32 dilution of household bleach. • FPV resistant to most commercial disinfectants.

Vaccines

- FP vaccines are core vaccines—to be given to all cats. • FP completely preventable by routine vaccination of kittens. • MLV or inactivated parenteral vaccines. • MLV intranasal vaccine. • Immunity—long duration, perhaps even for life. • Kittens—vaccinate as early as 6 weeks of age, then every 3–4 weeks until 16 weeks of age; Recent American Association of Feline Practitioners vaccine guideline recommendations have changed the last kitten vaccine to be given when kitten is at least 16 weeks of age, instead of 12 weeks of age; maternally derived immunity in some kittens may not have waned until 16 weeks of age. • Boosters—1 year after last kitten vaccine; then repeat not more frequently than every 3 years. • Do not use MLV vaccines in pregnant cats.

POSSIBLE COMPLICATIONS

- Chronic enteritis—fungal or other cause. • Teratogenic effects (cerebellar hypoplasia resulting in ataxia for life)—virus infection of fetus. • Shock and other complications—severe dehydration and electrolyte imbalance.

EXPECTED COURSE AND PROGNOSIS

- Most cases acute, lasting only 5–7 days. • If death does not occur during the acute disease, recovery is usually rapid and uncomplicated; it may take several weeks for the patient to regain weight and body condition.
- Prognosis is guarded during the acute disease, especially if the total WBC count is < 2,000 cells/dL.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Viral upper respiratory diseases, including feline viral rhinotracheitis and feline calicivirus infection.

AGE-RELATED FACTORS

- Clinical—generally a disease of kittens
- Subclinical—usually adults

FELINE PANLEUKOPENIA

ZOONOTIC POTENTIAL

None

PREGNANCY/FERTILITY/BREEDING

- Unvaccinated pregnant cats are at great risk of infection. • Fetuses almost always become infected with fatal or teratogenic effects, even when the dam has a subclinical infection.
- Fetal resorption, abortion, fetal mummification, stillbirth, or birth of weak, fading kittens. • Kittens may show ataxia from cerebellar hypoplasia when they become ambulatory.

F

SYNOMYNS

- Feline distemper • Feline parvovirus infection • Feline viral enteritis

ABBREVIATIONS

- CPV = canine parvovirus • FeLV = feline leukemia virus • FP = feline panleukopenia
- FPV = feline parvovirus • MLV = modified live virus • WBC = white blood cell

FELINE PARANEOPLASTIC ALOPECIA

BASICS

OVERVIEW

- Rare condition characterized by cutaneous lesions which serve as markers of internal neoplasia.
- Most affected cats have pancreatic adenocarcinoma with metastases to liver, lungs, pleura, and/or peritoneum; also reports of bile duct and hepatocellular carcinoma.
- The link between internal malignancies and cutaneous lesions is unknown; may involve cytokines producing atrophy of the hair follicles.

F

SIGNALMENT

- Domestic shorthair cats only reported cases
- Median age—13 years; range of 7–16 years

SIGNS

- Decrease in appetite followed by rapid weight loss and excessive shedding.
- Pruritus—variable; sometimes with excessive grooming.
- Hair loss—rapidly progressive.
- Some affected cats may be reluctant to walk, owing to painful fissuring of the footpads.
- Hairs epilate easily.
- Severe alopecia—ventral neck, abdomen, and medial thighs.
- Stratum corneum may “peel,” leading to a glistening appearance to the skin.
- Alopecic skin is shiny, inelastic, and thin, but not fragile.
- Gray lentigines may develop in alopecic areas.
- Footpads may be fissured and/or scaly; often painful.

CAUSES & RISK FACTORS

- Majority of cases are associated with underlying pancreatic adenocarcinoma.
- Internal carcinomas, such as bile duct and hepatocellular, possible causes.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hyperadrenocorticism—polyuria, polydipsia, and skin fragility.
- Hyperthyroidism—polyphagia.
- Hypothyroidism—spontaneous condition rare in cats; not associated with glistening skin.
- Feline symmetrical alopecia—hair loss self-induced; not associated with easy epilation.
- Thymoma—skin is thick, scaly and fissured, lymphocytic interface dermatitis; radiographs reveal thoracic mass.

- Demodicosis—mites not associated with paraneoplastic alopecia.
- Dermatophytosis—hair loss often associated with breakage, not spontaneous shedding; inappetence and weightloss rare.
- Alopecia areata—rarely involves the entire ventral surface; inappetence and weight loss rare.
- Telogen effluvium—not associated with miniaturization of hair follicles.
- Skin fragility syndrome—fragile skin not associated with paraneoplastic alopecia.
- Superficial necrolytic dermatitis—not associated with marked exfoliation and miniaturization of hair follicles.

CBC/BIOCHEMISTRY/URINALYSIS

No consistent abnormalities; may be helpful in ruling out other differentials.

OTHER LABORATORY TESTS

- Endocrine (thyroid profiles and a dexamethasone suppression test)—rule out endocrine disease.
- Skin scrapings—rule out demodicosis.
- KOH examination of hairs and/or fungal culture—rule out dermatophytosis.
- Skin cytology—possible secondary *Malassezia* infection (causing pruritus).

IMAGING

- Ultrasonography—pancreatic mass and/or nodular lesions in the liver or peritoneal cavity; failure to demonstrate nodules does not exclude the diagnosis, neoplasia may be too small for detection.
- Thoracic radiographs—metastatic lesions in the lungs or pleural cavity.

DIAGNOSTIC PROCEDURES

- Skin biopsy.
- Laparoscopy or exploratory laparotomy—identify primary and metastatic tumors.

PATHOLOGIC FINDINGS

- Histopathologic examination of the skin*—non-scarring alopecia; severe atrophy of hair follicles and adnexa; miniaturization of hair bulbs; mild to severe acanthosis; variable absence of stratum corneum; variable mixed superficial perivascular infiltrates of neutrophils, eosinophils, and mononuclear cells; some have secondary *Malassezia* infections.
- Primary tumor—usually pancreatic adenocarcinoma, rarely primary bile duct or hepatocellular carcinomas.
- Metastatic nodules—common in the liver, lungs, pleura, and peritoneum.

TREATMENT

- Removal of tumor via partial pancreatectomy may be curative; however,

prognosis is guarded, as majority of cases have metastatic disease.

- Chemotherapy or other medications—no reported response.
- Affected animals rapidly deteriorate; euthanasia should be suggested as a humane intervention.
- Supportive care—only if owners refuse to consider euthanasia; feed highly palatable, nutrient-dense foods and/or tube feed.

MEDICATIONS

DRUG(S)

N/A

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

- Progressive deterioration.
- Supportive care—ultrasonography and thoracic radiographs may demonstrate progression of metastatic disease.
- Death most often occurs within 2–20 weeks after onset of skin lesions.

MISCELLANEOUS

FELINE SYMMETRICAL ALOPECIA

BASICS

OVERVIEW

- Alopecia in a symmetrical pattern with no gross changes in the skin.
- Common clinical presentation in cats.
- Manifestation of several underlying disorders.

SIGNALMENT

No age, breed, or sex predilection reported

SIGNS

- Total to partial hair loss; most often symmetrical but can occur in a patchy distribution.
- Areas of the body commonly affected: ventrum, caudal dorsum, and lateral and caudal thighs.
- Patchy areas of hair loss (unsymmetrical) on the distal extremities or body.

CAUSES & RISK FACTORS

- Cutaneous hypersensitivity—flea allergic dermatitis, food, atopy.
- Ectoparasites—flea bite dermatitis, Cheyletiellosis, *Otodectes cynotis*.
- Infection—dermatophytosis.
- Neurologic or behavioral—"psychogenic alopecia." (uncommon as primary cause of symptoms.)
- Stress or metabolic—telogen effluvium.
- Neoplasia—pancreatic neoplasia (paraneoplastic alopecia).
- Hyperadrenocorticism.
- Alopecia areata.
- Hyperthyroidism (early sign).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

See "Causes & Risk Factors"

CBC/BIOCHEMISTRY/URINALYSIS

Eosinophilia in some allergic cats

OTHER LABORATORY TESTS

Serum thyroxine—hyperthyroidism

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Flea combing—identify fleas, flea excrement, or both.
- Microscopic examination of hair—self-induced hair loss results in broken blunt shafts; endogenous hair loss results in tapered ends (telogen hairs).
- Fecal examination—excess hair, mites, and ova (*Cheyletiella*), tapeworm, or fleas.
- Food elimination diet trial—adverse reactions to food.
- Intradermal tests—atopy.
- Skin biopsy—confirm presence of underlying cause (e.g., hypersensitivity dermatitis, psychogenic, or rarely, systemic disease).
- Cytology of papules or crusts, if present, may have large numbers of eosinophils.
- Microscopic examination of skin scrapings—ectoparasites.
- Hair plucks—dermatophyte arthrospores or *Demodex* mites adjacent to hair shafts.

PATHOLOGIC FINDINGS

- Histopathologic findings—vary depending on the cause.
- Feline psychogenic alopecia—hair follicles and skin normal.
- High numbers of mast cells, eosinophils, lymphocytes, or macrophages suggest allergic dermatitis.
- Alopecia areata—lymphocytic inflammation that encircles the bulb portions of the hair follicles; rare.

TREATMENT

- Management of the underlying cause.
- Inform the owner of the diagnostic plan and the time it could take to see a response (hair coat regrowth).

MEDICATIONS

DRUG(S)

- Antihistamines—e.g., chlorpheniramine 0.5 mg/kg PO q8h
- Glucocorticosteroids: Prednisolone 0.5 mg/kg PO, alternate-day therapy
- Amitriptyline 1–2 mg/kg PO daily

- Clomipramine hydrochloride 0.5 mg/kg q24h
- Cyclosporine, modified (Atopica) 5–7 mg/kg PO daily

CONTRAINdications/POSSible INTERACTIONS

- Glucocorticosteroids—can cause alopecia, diabetes mellitus, polydipsia, polyuria, polyphagia, and weight gain; can suppress pruritus, making it difficult to determine the underlying cause.
- Withdraw antipruritic medications (including glucocorticosteroids) as the diagnostic tests near completion (e.g., restricted-ingredient food trials).

FOLLOW-UP

- Frequent examinations are essential in confirming the differential diagnoses.
- Successful identification of the underlying cause offers the best prognosis, if the cause can be controlled (e.g., flea bites or food hypersensitivity).

Consulting Editor Alexander H. Werner

FEVER

BASICS

DEFINITION

Higher than normal body temperature because of a changed thermoregulatory set point in the anterior hypothalamus; normal body temperature in dogs and cats is 100.2–102.8°F (37.8–39.3°C). Fever of unknown origin (FUO)—at least 103.5°F (39.7°C) on at least four occasions over a 14-day period and illness of 14 days in duration without an obvious cause.

PATHOPHYSIOLOGY

Exogenous or endogenous pyrogens cause release of endogenous substances that reset the hypothalamic thermoregulatory center to a higher temperature, activating a physiologic responses to raise the body temperature to this new set point. Physiologic consequences include increased metabolic demands, muscle catabolism, bone marrow suppression, heightened fluid and caloric requirements, and possibly DIC and shock.

SYSTEMS AFFECTED

- Cardiovascular—tachycardia
- Hemic/Lymphatic/Immune—bone marrow depression and DIC
- Nervous—cerebral edema, depression

GEOGRAPHIC DISTRIBUTION

Incidence of infections varies significantly.

SIGNALMENT

Species

Dog and cat

Breed Predilections

Some breed-associated conditions may result in FUO (e.g., shar-pei fever).

Mean Age and Range

Any age

Predominant Sex

Any sex

SIGNS

General Comments

- Fever lowers bacterial division and increases immune competence.
- Prolonged fever > 105°F (> 40.5°C) leads to dehydration and anorexia.
- Fever > 106°F (> 41.1°C) may lead to cerebral edema, bone marrow depression, heart arrhythmia, electrolyte disorders, multiorgan damage, and DIC.

Historical Findings

- Clinical history (e.g., contact with infectious agents, lifestyle, travel, recent vaccination, drug administration, insect bites, previous illness, allergies) and physical examination (including retinal examination) may help identify an underlying disease condition.
- Fever patterns of fever (e.g., sustained, intermittent) is rarely helpful.

Physical Examination Findings

- Hyperthermia
- Lethargy
- Inappetence

- Tachycardia
- Tachypnea
- Hyperemic mucous membranes
- Dehydration
- Shock

CAUSES

Infectious Agents (Most Common)

- Viruses—FeLV, FIV, parvovirus, distemper, herpes, calicivirus
- Bacteria—Gram-positive and Gram-negative endotoxins, *Mycoplasma*, *Bartonella*
- Systemic fungi—*Histoplasma*, *Blastomyces*, *Coccidioidomycetes*, *Cryptococcus*
- Rickettsiaceae—*Rickettsia rickettsii* (Rocky Mountain spotted fever)
- Anaplasmataceae*—*Ehrlichia canis*, *Anaplasma phagocytophila*, *Neorickettsia helminthoeca*
- Parasites and protozoa—*Babesia*, *Toxoplasma*, aberrant larva migrans, *Dirofilaria* thromboemboli, *Leishmania*, *Cytauxzoon*, *Hepatozoon*, *Neospora*
- Leptospira* spp
- Borrelia burgdorferi* (Lyme disease)

Immune-Mediated Processes

Systemic lupus erythematosus, immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, pemphigus, polyarthritis, polymyositis, rheumatoid arthritis, vasculitis, hypersensitivity reactions, transfusion reaction, and infection secondary to inherited or acquired immune defects.

Endocrine and Metabolic

Hyperthyroidism, hypoadrenocorticism (rare), pheochromocytoma, hyperlipidemia, and hypernatremia

Neoplasia

Lymphoma, myeloproliferative disease, plasma cell neoplasm, mast cell tumor, malignant histiocytosis, metastatic disease, necrotic tumor, and solid tumor, particularly in liver, kidney, bone, lung, and lymph nodes.

Other Inflammatory Conditions

Cholangiohepatitis, hepatic lipidosis, toxic hepatopathy, cirrhosis, inflammatory bowel disease, pancreatitis, peritonitis, pleuritis, granulomatous diseases, portosystemic shunting, thrombophlebitis, infarctions, pansteatitis, panosteitis panniculitis, hypertrophic osteodystrophy, blunt trauma, cyclic neutropenia, intracranial lesions, and pulmonary thromboembolism.

Drugs and Toxins

Tetracycline, sulfonamide, penicillins, nitrofurantoin, amphotericin B, barbiturates, iodine, atropine, cimetidine, salicylates (high dosages), antihistamines, procainamide, and heavy metals.

FUO—Dogs

- Infection (28%)—discospondylitis, blastomycosis, and other fungal infections, valvular endocarditis, soft tissue or parenchymal abscesses, bacteremia, septic arthritis, septic meningitis, pyothorax, pulmonary foreign body/abscess, stump pyometra, bronchopneumonia, osteomyelitis, peritonitis, prostatitis, pancreatitis, pyelonephritis, osteomyelitis, sepsis secondary to immunodeficiency, leptospirosis, leishmaniasis, toxoplasmosis, Lyme disease,

infection with *Ehrlichia*, *Anaplasma*, *Bartonella* • Immune-mediated disease (27%)—immune-mediated polyarthritis, meningitis, vasculitis, others • Bone marrow disease, including neoplasia (16%)

- Neoplasia (7%) • Miscellaneous (10%)—hypertrophic osteodystrophy, meningitis, lymphadenitis, panosteitis, portosystemic shunting, drug reaction, toxin, shar-pei fever • Undiagnosed (12%)

FUO—Cats

- Most are virally mediated (e.g., FeLV, FIV, FIP, less commonly parvovirus, herpes, and calicivirus).
- Persistent occult bacterial infection with atypical bacteria, sometimes secondary to bite wounds (e.g., *Yersinia*, *Mycobacteria*, *Nocardia*, *Actinomycetes*, and *Brucella*).
- Pyothorax common.
- Additional causes—pyelonephritis, blunt trauma, penetrating intestinal lesion, dental abscess, systemic mycoses (e.g., *Histoplasma*, *Blastomyces*, *Coccidioides*), lymphoma, and solid tumors.
- Immune disorders are rare, as are endometritis, discospondylitis, pneumonia, and endocarditis.

RISK FACTORS

- Recent travel
- Exposure to biologic agents
- Immunosuppression
- Very young or old animals

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

True fever must be differentiated from hyperthermia. Stress in the hospital may cause a mild temperature rise. Temperatures up to 103°F (39.4°C) may be caused by stress or illness. Temperatures > 104°F (> 40°C) are almost always important. Temperatures > 107°F (> 41.7°C) are usually not fever, more likely to be primary hyperthermia.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC and blood smear—leukopenia or leukocytosis, left shift, moncytosis, lymphocytosis, thrombocytopenia, or thrombocytosis, spherocytes, organisms.
- Biochemistry profile and urinalysis vary with the organ system involved.

OTHER LABORATORY TESTS

- If infectious disease is suspected, attempt to culture an organism—urine culture, blood cultures (i.e., three anaerobic and three aerobic cultures, taken during a rise in temperature or 20 minutes apart; try to use as much volume as possible to increase diagnostic yield; consider using resin vials that bind antibiotics), fungal and CSF cultures, synovial and prostatic fluid, and biopsy specimens.
- FeLV and FIV test, Snap 4DX test, serologic tests or PCR for *Toxoplasma*, *Borrelia*, *Mycoplasma*, *Bartonella*, *Anaplasma*, *Ehrlichia*, *Rickettsia*, FIP, systemic mycoses.
- Fecal examination if gastrointestinal signs.

(CONTINUED)

FEVER**F**

- Tracheal wash or bronchoalveolar lavage if respiratory involvement.
- Occult heartworm test if pulmonary embolism suspected.
- If immune disorders suspected—cytologic examination of synovial fluid; Coombs' test, RF (anticanuclear antibody titer and rheumatoid factor test are often unrewarding).
- PLI level • T_4 to rule out hyperthyroidism in cats.

IMAGING**Radiography**

- Abdominal radiographs to scan for tumors and effusion.
- Thoracic radiographs to rule out pneumonia, neoplasia, and pyothorax.
- Survey skeletal radiographs for bone tumors, multiple myeloma, osteomyelitis, discospondylitis, panosteitis, hypertrophic osteopathy, and hypertrophic osteodystrophy.
- Dental and skull radiographs to look for tooth root abscess, sinus infections, foreign bodies, and neoplasia.
- Contrast radiography (e.g., gastrointestinal and excretory urography) to look for evidence of neoplasia or infection.

Ultrasonography

- Abdominal (plus directed aspirate or biopsy, if indicated) to look for abdominal neoplasia and abscess or other site of infection (e.g., pyelonephritis, pancreatitis, pyometra).
- Echocardiography if endocarditis suspected.

Nuclear Imaging

- Radionuclide scanning procedures to evaluate for bone tumors, osteomyelitis, and pulmonary embolism.
- Computed tomography or MRI if indicated.
- Image fusion (combination of positron emission tomography using radioactively labeled fluorodeoxyglucose and CT).

DIAGNOSTIC PROCEDURES

- Arthrocentesis (culture and cytology).
- Bone marrow aspirate and biopsy if malignancy or myelodysplasia suspected.
- Lymph node, skin, or muscle biopsy if clinically indicated.
- Examination of fine-needle aspirate or biopsy of any mass or abnormal organ.
- CSF tap if neurologic signs suggest brain tumor or meningitis.
- Endoscopy and biopsy if gastrointestinal signs.
- Exploratory laparotomy—last resort if all other diagnostic tests fail to determine the cause and the patient is not improving.

**TREATMENT****APPROPRIATE HEALTH CARE**

- Goals of treatment:
 - Reset the thermoregulatory set point to a lower level
 - Remove the underlying cause.

NURSING CARE

- Fluid administration (IV) often lowers body temperature.
- If the patient is dehydrated, initiate isotonic crystalloids.
- Topical cooling

if fever is severe (convection cooling with fans, evaporative cooling with isopropyl alcohol on foot pads, axilla, and groin). • Only use antipyretic treatment when fever is prolonged and life-threatening ($> 106^\circ\text{F}$, $> 41.1^\circ\text{C}$) and topical cooling is unsuccessful. Impaired patients (e.g., those with heart failure, seizures, or respiratory disease) require antipyretic treatment earlier. Antipyretic treatment may preclude elucidation of the cause, delay correct treatment, and complicate patient monitoring (e.g., reduction of fever is an important indication of response to treatment).

DIET

Febrile patients are in a hypercatabolic state and require high caloric intake.

CLIENT EDUCATION

Work-up of patients with FUO often extensive, expensive, and invasive, and may not result in a definitive diagnosis.

SURGICAL CONSIDERATIONS

Surgery may be necessary in some animals with underlying infectious (e.g., pyometra, peritonitis, pyothorax, and liver abscess) or localized.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Selection depends on the diagnosis.
- Do not use broad-spectrum (i.e., "shotgun") treatment in place of a thorough diagnostic workup unless the patient's status is critical and deteriorating rapidly.

Antibiotics

- Based on results of bacterial culture or serology.
- In emergency situations, combination antibiotic therapy can be started after culture specimens have been obtained (e.g., cephalothin, 20 mg/kg IV q6–8h; combined with enrofloxacin 10 mg/kg IV q24h). Additional antimicrobials depend on the main clinical suspicion based on preliminary laboratory and clinical evidence.
- Do not give antibiotics longer than 1–2 weeks if ineffective.

Antipyretics

- Dipyrrone—dogs, 25 mg/kg IV
- Aspirin—dogs, 10 mg/kg PO q12h; cats, 6 mg/kg PO q48h
- Deracoxib—dogs, 1–2 mg/kg/day
- Meloxicam 0.1 mg/kg/d, flunixin meglumine—dogs, 0.25 mg/kg SC once (give IV fluids).

Glucocorticoids

- Block acute phase response. Do not use unless infectious causes have been ruled-out.
- May mask clinical signs, may lead to immunosuppression, and are not recommended for use as antipyretics; administration of corticosteroids to cats with intractable FUO after ruling out infectious diseases may promote a favorable response.

- Primarily indicated for fever associated with immune-mediated disease and certain steroid-responsive tumors (e.g., lymphoma).

Phenothiazines

Depress normal thermoregulation center and cause peripheral vasodilation. Use with caution due to sedative and hypotensive effects.

PRECAUTIONS

Side effects of antipyretics include emesis, diarrhea, gastrointestinal ulceration, renal damage, hemolysis, hepatotoxicity (acetaminophen, particularly dangerous in cats), and muscle stiffness (flunixin meglumine).

POSSIBLE INTERACTIONS

Combination of NSAIDs and steroids raises the risk of gastrointestinal hemorrhage.

**FOLLOW-UP****PATIENT MONITORING**

- Body temperature at least q12h.
- If the cause of the fever continues to elude the clinician, repeat the history and physical examination along with screening laboratory tests.
- If fever develops or worsens during hospitalization, consider nosocomial infection or superinfection.

EXPECTED COURSE AND PROGNOSIS

Vary with cause; in some patients (more commonly in cats), an underlying cause cannot be determined.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- Young animals—infectious disease more common; prognosis better than in old animals.
- Old animals—common causes are neoplasia and intra-abdominal infection; signs tend to be more non-specific; prognosis often guarded.

FIBER-RESPONSIVE LARGE BOWEL DIARRHEA

BASICS

OVERVIEW

- A type of chronic idiopathic large bowel diarrhea that occurs in dogs that respond favorably to dietary fiber supplementation.
- Exclusion diagnosis that requires eliminating known causes of chronic large bowel diarrhea and clinical response to dietary fiber supplementation.
- No pathophysiologic studies have been performed.
- Only 3 reports in dogs comprising 83 cases.
- May overlap with a stress-associated poorly defined syndrome that has been called irritable bowel syndrome, also referred to as nervous colitis, spastic colon, or mucus colitis.

F

SIGNALMENT

- Dogs of all ages (0.5–14 years); median 6 years.
- Many breeds, including mixed breeds; common breeds include German shepherd dog, miniature schnauzer, cocker spaniel, and miniature or toy poodle.

SIGNS

- Chronic diarrhea (soft to liquid) with classic large bowel characteristics; tenesmus, excess fecal mucus, hematochezia, increased frequency (median 3.5 times/day), and urgency.
- Diarrhea usually episodic alternating with periods of normal stool; diarrhea may be continuous in approximately 25% of dogs.
- Less common signs include occasional vomiting, decreased appetite during episodes of diarrhea, abdominal pain, and anal pruritus.
- Weight loss rare.
- Stress factors or abnormal personality traits in approximately 35% of dogs; visitation, travel, moving, construction, invisible fence, recent adoption or considered nervous, high-strung, sensitive, noise phobia, aggressive, anxiety or depressive disorders.
- Physical examination reveals no significant findings related to the gastrointestinal tract.

CAUSES AND RISK FACTORS

Unknown; stress or abnormal personality traits may play a role in some.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Chronic idiopathic large bowel diarrhea has been diagnosed in approximately 25% of dogs undergoing colonoscopy.
- Dietary indiscretion.
- Highly digestible diet-responsive diarrhea.
- Hypoallergenic diet-responsive diarrhea.
- Whipworms.
- *Clostridium perfringens*-associated diarrhea.
- Lymphocytic plasmacytic colitis.
- Eosinophilic colitis.
- Miscellaneous types of colitis.
- Irritable bowel syndrome.

- Colonic neoplasia (adenocarcinoma, lymphoma, and adenoma are most common).
- Cecal inversion.

CBC/BIOCHEMISTRY/URINALYSIS

No consistent or specific abnormalities, although can recognize peripheral eosinophilia occasionally in dogs with colonic whipworms, eosinophilic colitis, and food allergy.

OTHER LABORATORY TESTS

Multiple fecal floatations by zinc sulfate; negative for whipworms and other parasites.

IMAGING

- Abdominal radiographs within normal limits.
- Abdominal ultrasound within normal limits.

DIAGNOSTIC PROCEDURES

- Highly digestible diet trial for 2–4 weeks; no improvement in stool quality.
- Elimination or hypoallergenic diet trial for 2–4 weeks; no improvement in stool quality.
- *Clostridium perfringens* enterotoxin fecal ELISA negative.
- Therapeutic deworming for whipworms (fenbendazole 50 mg/kg PO q24h for 5 days; no improvement).
- Colonoscopy usually within normal limits or only mild nonspecific findings such as slight increases in granularity or friability.

PATHOLOGIC FINDINGS

- Histopathologic evaluation of colonic biopsy samples within normal limits.
- Multiple biopsy samples should be evaluated from throughout the colon from the cecum to the rectum.

TREATMENT

- Health care can be provided on an outpatient basis and consists of dietary fiber supplementation.
- Activity level does not have to be modified.
- A highly digestible "GI" diet should initially be supplemented with 1–3 tbsp daily of psyllium hydrophobic mucilloid (Metamucil 10.2 g psyllium/tbsp).
- Psyllium is a soluble fiber that adsorbs water, improving fecal consistency, promotes bacterial fermentation and production of volatile fatty acids, which act as an energy source for colonic epithelial cells.
- Median dose is 2 tbsp/day, or 0.13 tbsp/kg/day, or 1.3 g psyllium/kg/day.
- Initial response to lower amounts of fiber supplementation or the use of other types of fiber is not as successful.
- After 2–3 months without diarrhea, the amount of fiber can be slowly reduced successfully in approximately 50% of dogs.
- After resolution of diarrhea with psyllium supplementation, owners may attempt to switch to a commercial high fiber (insoluble fiber) diet that may be more convenient to feed; however diarrhea may

return in 50% of dogs.

- After resolution of diarrhea with psyllium supplementation, owners may be able to switch from the highly digestible "GI" diet to a high-quality maintenance dog food.
- Lack of initial response to fiber supplementation suggests that the chronic idiopathic large bowel diarrhea may be due to irritable bowel syndrome and pharmacologic management of that disorder should be instituted.

MEDICATIONS

None indicated

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

No known interactions of fiber supplementation with commonly used drugs.

FOLLOW-UP

- Patient monitoring requires periodic assessment of the stool quality, performed during recheck office examinations or via telephone interviews.
- If stresses were initially identified, stress reduction should be attempted.
- If abnormal personality traits were initially identified, they should be modified.
- Dietary soluble fiber supplementation can occasionally produce excessive flatulence, which can be managed by reduction in the fiber dosage.
- Prognosis is very favorable as approximately 85% of dogs have an excellent or very good long-term response to fiber supplementation.

MISCELLANEOUS

- There are no known associated conditions.
- Age does not play a role in diagnosis or treatment.
- There is no known zoonotic potential.
- There are no special considerations regarding pregnancy, fertility or breeding.

FIBROCARTILAGINOUS EMBOLIC MYELOPATHY

BASICS

DEFINITION

Acute ischemic necrosis of the spinal cord caused by fibrocartilaginous emboli.

PATHOPHYSIOLOGY

- Emboli—found in spinal cord arteries, veins, or both; source is possibly intervertebral disc material or marrow of vertebral body.
- Exact mechanism of entry into the spinal vasculature unknown.

SYSTEMS AFFECTED

Nervous

GENETICS

N/A

INCIDENCE/PREVALENCE

- Common cause of spinal cord disease in non-chondrodystrophic breeds of dogs.
- Not reported in chondrodystrophic breeds.
- Rare in cats.

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Dog and cat

Breed Predilections

- Giant- and large-breed dogs—highest prevalence.
- Miniature schnauzers and Shetland sheepdogs—overrepresented; hyperlipoproteinemia and resultant hyperviscosity common in these breeds; may contribute to spinal cord infarction without fibrocartilaginous emboli.

Mean Age and Range

- Most patients 3–5 years old
- Range 16 weeks–10 years

Predominant Sex

Slight male predominance

SIGNS

Historical Findings

- Mild trauma or vigorous exercise at the onset of signs common.
- Sudden onset.
- Affected dog typically cries in pain; pain subsides in minutes to hours (at most).
- Signs of paresis or paralysis develop over a matter of seconds, minutes, or hours.
- Condition stabilizes within 12–24 hours.

Physical Examination Findings

N/A

Neurologic Examination Findings

- Deficits—usually lateralized; unaffected side usually mildly affected or normal; symmetrically distributed in a few patients.
- Pain—at onset of signs and then generally absent; usually subsided by the time patient is

examined; may be felt for a few hours in severely affected patients.

- Any level of the spinal cord can be affected, depending on the distribution of the embolic material.
- Mild ataxia to paralysis.
- Upper or lower motor neuron deficits.
- Spinal cord injury—unilateral; or only the dorsal or ventral aspect of the spinal cord, causing an ipsilateral limb deficit with sensory loss but muscle tone and motor function preserved (or vice versa); other odd combinations possible in patients with focal quadrant injuries.
- If signs progress beyond 24 hours, consider other diseases.

CAUSES

Unknown

RISK FACTORS

- Vigorous exercise may trigger the incident
- Hyperlipoproteinemia

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Acute, non-progressive, asymmetric, and non-painful spinal cord disease—presence of these characteristics greatly helps in the diagnosis.
- Back and neck pain with symmetrical signs—intervertebral disc disease; discospondylitis; vertebral tumor; fracture and luxation; survey radiography, MRI, CT, and/or myelography help confirm the diagnosis.
- Parenchymal spinal cord hemorrhage secondary to bleeding diathesis (e.g., caused by anticoagulant rodenticide ingestion, thrombocytopenia, or disseminated intravascular coagulation)—rule out by examining for evidence of hemorrhage, performing platelet count, and determining blood clotting times.
- Focal myelitis—differentiate on progressive history and CSF analysis.

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal

OTHER LABORATORY TESTS

N/A

IMAGING

- Survey spinal radiograph—usually normal.
- Myelography and CT myelography—in acute stage often demonstrates focal intramedullary swelling at the embolic site; later, often normal or shows an area of cord atrophy.
- MRI—ideal diagnostic technique; on T2-weighted images, at site of lesion, there may be decreased signal intensity of disc and increased signal intensity of spinal cord parenchyma.

DIAGNOSTIC PROCEDURES

CSF Analysis

- Results depend on location (e.g., lumbar vs. cerebello-medullary cistern) and time of collection in relation to onset of clinical signs.
- Acute stage—increased RBC and neutrophils may be seen; a few days later, may see only mild increase in protein.
- Sometimes normal.

PATHOLOGIC FINDINGS

- Gross—focal spinal cord swelling with hemorrhage.
- Microscopic—emboli of fibrocartilage in arteries and veins of spinal cord and meninges; hemorrhagic necrosis and malacia in gray and white matter.

TREATMENT

APPROPRIATE HEALTH CARE

In-patient—for immediate medical treatment and diagnostic procedures.

NURSING CARE

- Keep recumbent patients on padded surface; turn frequently to prevent pressure sores.
- Assist and encourage patients to ambulate as soon as possible.
- Assist bladder emptying several times a day if needed by expression or catheterization to prevent bladder over distension and detrusor muscle injury.
- Hydrotherapy in pool or underwater treadmill—very helpful in rehabilitation.
- The use of a light weight chest harness with a dorsally located handle designed for the use by search and rescue dogs such as a Ruff Wear Web Master Dog Harness (www.ruffwear.com) can be very helpful for managing nursing care at home during recovery.

ACTIVITY

- Restrict until diagnosis is made in case of vertebral column instability from other causes such as intervertebral disc herniation or fracture/luxation.
- Once fibrocartilaginous embolic myelopathy is confirmed, activity should be encouraged, not restricted.

DIET

Normal unless hyperlipidemia is present, then feed a low fat diet such as Hill's Prescription Diet r/d.

CLIENT EDUCATION

- Inform client that recovery from paresis or paralysis is slow and gradual, when it occurs.
- Inform client that most patients need considerable home care during recovery.

SURGICAL CONSIDERATIONS

N/A

FIBROCARTILAGINOUS EMBOLIC MYELOPATHY

(CONTINUED)

MEDICATIONS

DRUG(S) OF CHOICE

Methylprednisolone sodium succinate—may be beneficial only if given within the first 8 hours after the onset of signs according to studies of acute spinal cord injury caused by spinal cord impact; 30 mg/kg IV as first treatment; then 15 mg/kg at 2 and 6 hours and every 6 hours thereafter for a total treatment period of 24–48 hours; give each dose slowly over 10–15 minutes; too rapid injection can cause vomiting. Controversial and may not be effective.

F

CONTRAINDICATIONS

Non-steroidal analgesics—do not administer with methylprednisolone sodium succinate; increases probability of gastrointestinal ulceration.

PRECAUTIONS

- Methylprednisolone sodium succinate—no benefit with longer treatment (> 24–48 hours) and dramatically increases adverse effects (e.g., gastrointestinal ulceration).
- High-fiber and low fat diet such as Hill's Prescription Diet r/d during and after steroid treatment reduces gastrointestinal ulceration.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

N/A

FOLLOW-UP

PATIENT MONITORING

- Sequential neurologic evaluations—during the first 12–24 hours after the initial examination.
- Neurologic status—at 2, 3, and 4 weeks after onset of clinical signs.

- Urinary incontinence—urinalysis and culture and sensitivity to detect urinary tract infection.

PREVENTION/AVOIDANCE

- Recurrence highly unlikely but possible.
- No known method of prevention in most cases.
- If hyperlipidemia, feed a low fat diet (< 10%) and oral omega-3 fish oils 10–30 mg/kg q24h.

POSSIBLE COMPLICATIONS

- Fecal and urinary incontinence
- Urinary tract infection
- Urine scalding and pressure sores

EXPECTED COURSE AND PROGNOSIS

- Pain perception present and upper motor neuron signs—prognosis for marked improvement good.
- Loss of pain perception—prognosis poor.
- Areflexia of limbs or sphincters—almost no chance of recovery.
- Reduced purposeful movements and reflexes—functional recovery common; some degree of permanent deficit likely.
- Progression of clinical signs from upper to lower motor neuron and an enlarging area of sensory loss indicate ascending or descending myelomalacia and a hopeless prognosis; consider euthanasia.
- Neurologic status—little change in the first 14 days after onset; most improvement occurs between days 21 and 42; remyelination is complete in most patients within 6–12 weeks after onset; if no improvement after 21–30 days, recovery is unlikely.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Disorders that lead to a compromise in circulatory function may predispose or mimic fibrocartilaginous embolic

myelopathy—hyperadrenocorticism; hypothyroidism; high systemic blood pressure; hyperviscosity syndrome; hyperlipidemia; bleeding diathesis; bacterial endocarditis.

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

N/A

PREGNANCY/FERTILITY/BREEDING

High-dose corticosteroid administration—may cause premature delivery.

ABBREVIATIONS

- CSF = cerebrospinal fluid
- CT = computed tomography
- MRI = magnetic resonance imaging
- RBC = red blood cell

FIBROSARCOMA, BONE

BASICS

OVERVIEW

- Primary bone fibrosarcoma arises from stromal elements within the marrow cavity and is characterized by malignant spindle cells that produce varying amounts of collagen but not any osteoid or cartilage.
- In dogs, FSA accounts for <5% of all primary bone tumors with the metaphysis or diaphysis of long bones affected most commonly.
- In cats, FSA has been reported to be the second most common bone tumor in cats and can involve the maxilla, mandible, humerus, scapula, carpus, digits, ribs, and sacrum.

SIGNALMENT

- Dog and cat.
- No obvious breed or gender predilections in dog or cats.
- Reported age ranges 1.5–12 years in dogs and 9–13 years in cats.

SIGNS

Historical Findings

Appendicular FSA

- Lameness, usually progressive but occasionally acute if there is a pathologic fracture.
 - A palpable swelling may be present.
- Axial FSA**
- Localized swelling with or without pain is common.
 - Tumors arising from the mandible or maxilla can be associated with halitosis, dysphagia, pain on opening the mouth, or nasal discharge.
 - Vertebral tumors may induce neurologic deficits secondary to spinal cord compression.
 - Rib tumors are rarely associated with respiratory signs unless large and causing space-occupying effects.

Physical Examination Findings

Appendicular FSA

- Lameness of variable severity, ranging from minimal to non-weight-bearing.
- A palpable swelling may be present.

Axial FSA

- Variable physical examination findings.
- Depending on the size and location of the tumor, a mass may be visible or palpable.

CAUSES & RISK FACTORS

Unknown

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other primary bone tumors (osteosarcoma, chondrosarcoma, hemangiosarcoma).

- Metastatic bone tumors (transitional cell, prostatic, mammary, thyroid, apocrine gland anal sac carcinomas).

- Tumors that locally invade adjacent bone (nasal carcinoma; oral squamous cell carcinoma, melanoma, fibrosarcoma, ameloblastoma; synovial sarcoma; histiocytic sarcoma; digital squamous cell carcinoma, melanoma).
- Hematopoietic tumors (myeloma, lymphoma).
- Bacterial or fungal osteomyelitis.

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal

IMAGING

- Radiographs of the primary lesion show features of an aggressive bone lesion (bone lysis, cortical destruction, non-homogenous bone formation, ill-defined zone of transition).
- Thoracic radiographs are recommended to screen for pulmonary metastasis.
- CT is recommended for axial tumors to more accurately stage local disease and plan for surgery and/or radiation therapy.

DIAGNOSTIC PROCEDURES

- Histopathology is needed for a definitive diagnosis.
- Primary bone FSA has been reported to metastasize to a variety of locations: lungs, regional lymph nodes, other bones, skin, pericardium, and myocardium. Consider additional diagnostic evaluation as indicated to rule out metastasis to these or other locations.

TREATMENT

- Amputation is recommended for appendicular tumors.
- For axial tumors, wide surgical excision is recommended whenever possible. If surgical excision is incomplete, adjuvant radiation therapy might help improve local control.
- Stereotactic radiation therapy provides effective local control for canine osteosarcoma and might be an alternative to surgery for patients with FSA.
- Palliative analgesic therapy is recommended for patients with nonresectable local disease or gross metastasis, or when definitive therapy is declined.

MEDICATIONS

DRUG(S)

- Nonsteroidal anti-inflammatory drugs.
- Tramadol (2–5 mg/kg PO q6–12h).

- Gabapentin (3–10 mg/kg PO q8–24h).

- Intravenous aminobisphosphonates (pamidronate, zoledronate) might alleviate bone pain and attenuate bone resorption.
- Adjuvant chemotherapy has not been evaluated, but given the high metastatic risk, doxorubicin as a single agent or alternating with cisplatin or carboplatin might be reasonable; consult a veterinary oncologist for current recommendations.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

None

F

FOLLOW-UP

PATIENT MONITORING

Physical examination and thoracic radiographs every 2–3 months.

EXPECTED COURSE AND PROGNOSIS

- There is limited information regarding long-term prognosis.
- Complete excision of the primary tumor can potentially provide long-term control.
- Up to half of patients will develop metastasis. Metastasis has been identified as long as 19 months after amputation.

MISCELLANEOUS

FIBROSARCOMA, GINGIVA

BASICS

OVERVIEW

- Fibrosarcoma is a mesenchymal tumor characterized by malignant spindle cells that produce varying amounts of collagen.
- Oral FSA arises most commonly in the gingiva; it occasionally involves the lips and rarely the tongue.
- In dogs, FSA is the third most common oral malignancy (20% of all oral tumors).
- In cats, FSA is the second most common oral malignancy (5–15% of all oral tumors).

F

SIGNALMENT

- Dogs: overall, large-breed dogs are predisposed. Golden retrievers are overrepresented specifically for the histologically low-grade but biologically high-grade FSA variant (see "Pathologic Findings"). Median age is 7 years (range, 1–16 years).
- Cats: no breed predilections. Median age 10 years (range 1–21 years).

SIGNS

Historical Findings

- Visible mass arising within the oral cavity.
- Halitosis, hypersalivation, dysphagia, and/or bloody oral discharge.
- Oral pain—head-shy behavior and/or decreased food intake despite showing interest in food.

Physical Examination Findings

- A firm, smooth mass is seen most commonly.
- The overlying mucosa usually is intact, although trauma and ulceration from the occlusal teeth is common with larger tumors.
- Halitosis, hypersalivation, and/or oral bleeding.
- Difficulty or pain when opening the mouth and/or facial deformity.
- Ipsilateral mandibular lymphadenopathy.
- Nasal discharge, epistaxis, or decreased air flow through the nares (maxillary tumors).

CAUSES & RISK FACTORS

None identified

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other oral tumors including melanoma, squamous cell carcinoma, and epulis (ameloblastoma or periodontoma)

- Tooth root abscess
- Osteomyelitis
- Dentigerous cyst
- Craniomandibular osteopathy

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal

IMAGING

- Skull or dental radiographs recommended to evaluate for bone involvement (present in 60–70%).
- CT imaging can more accurately stage local disease and is useful for planning surgery and/or radiation therapy. It is especially helpful for maxillary tumors and large or caudal mandibular tumors.

DIAGNOSTIC PROCEDURES

- Histopathology is required to reach a definitive diagnosis.
- Cytology or histopathology of the ipsilateral mandibular lymph node recommended to screen for metastasis.

PATHOLOGIC FINDINGS

Histologically low-grade yet biologically high-grade tumors have been described, particularly in golden retrievers and other large-breed dogs. Initially, on histopathology these tumors were classified as benign lesions (nodular fasciitis, chronic inflammatory nodules, granulation tissue) or low-grade FSA. However, aggressive biologic behavior including bone destruction (75%), lymph node metastasis (20%), and pulmonary metastasis (12%) is present in affected dogs.

TREATMENT

- Surgical excision—removal of the mass and adjacent bone (maxillectomy or mandibulectomy) with a margin of at least 2–3 cm is recommended whenever possible.
- If excision is incomplete, adjuvant radiation therapy is recommended to improve local control.
- Radiation therapy can be considered as a sole local treatment modality when surgery is not possible or declined.
- Palliative care focuses on pain control.

MEDICATIONS

DRUG(S)

- Nonsteroidal anti-inflammatory drugs.
- Tramadol (2–5 mg/kg PO q6–12h).

- Gabapentin (3–10 mg/kg PO q8–24h).
- Empiric antibiotic therapy can be considered for secondary bacterial infections.

CONTRAINDICATIONS/POSSIBLE

INTERACTIONS

Use NSAIDs cautiously in all cats and in dogs with renal insufficiency.

FOLLOW-UP

PATIENT MONITORING

Physical examination every 2–3 months and thoracic radiographs every 3–4 months.

EXPECTED COURSE AND PROGNOSIS

- Most patients die or are euthanized due to local disease.
- Overall metastatic rate is 20–30% (regional lymph nodes and lungs).
- With surgery alone, individual prognosis depends on tumor size, tumor location, and surgical resectability, with reported median survival varying 9–24 months, and long-term control is possible with complete excision.
- Combining surgery (incomplete excision) with radiation therapy, median survival is 18 months.
- With radiation therapy alone, median progression-free survival is 45 months for tumors < 2 cm, 31 months for tumors 2–4 cm, and 7 months for tumors > 4 cm.
- There is limited information for cats, but prognosis likely is more guarded due to the difficulty of complete surgical excision.

MISCELLANEOUS

ABBREVIATIONS

- CT = computed tomography
- FSA = fibrosarcoma

Suggested Reading

Frazier SA, Johns SM, Ortega J, et al. Outcome in dogs with surgically resected oral fibrosarcoma (1997–2008). Vet Comp Oncol 2013, 10(1):33–43.

Consulting Editor Timothy M. Fan

FIBROSARCOMA, NASAL AND PARANASAL SINUS

BASICS

OVERVIEW

- Fibrosarcoma is a malignant tumor of spindle cells that produce varying amount of collagenous (fibrous) stroma.
- In dogs, FSA accounts for up to 5% of all canine sinonasal tumors and is the second most common nasal sarcoma.
- Nasal FSA is uncommon in cats.

SIGNALMENT

- In dogs, no breed or gender predilections have been identified. Median age 9 years (range 1–16 years).
- Uncommon in cats—no obvious predilections.

SIGNS

Historical Findings

- Unilateral or bilateral epistaxis and/or mucopurulent discharge.
- Sneezing, stertorous breathing, and/or facial deformity.
- Decreased appetite and/or halitosis secondary to oral cavity invasion.
- Seizures, behavior changes, and/or obtundation secondary to cranial invasion.

Physical Examination Findings

- Epistaxis and/or nasal discharge (unilateral or bilateral).
- Decreased nasal air flow (unilateral or bilateral).
- Pain on nasal or paranasal sinus palpation or percussion.
- Facial deformity, decreased retropulsion of the eyes or exophthalmia, and epiphora.
- Visible mass effect protruding through the palate into the oral cavity.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other nasal tumors—adenocarcinoma, squamous cell carcinoma, chondrosarcoma, osteosarcoma, lymphoma, transmissible venereal tumor (dogs), nasopharyngeal polyp (cats).
- Fungal rhinitis—aspergillosis and penicilliosis (dogs), cryptococcosis (cats), sporotrichosis (both).
- Rhinosporidiosis (dogs).
- Viral rhinitis—herpesvirus and calicivirus (cats).
- Foreign body.
- Thrombocytopenia or other coagulopathy.
- Tooth root abscess and oronasal fistula.

CBC/BIOCHEMISTRY/URINALYSIS

- Usually normal

OTHER LABORATORY TESTS

- Nasal flush for cytology and culture—rarely helpful
- Coagulation profile
- Buccal mucosal bleeding time
- Regional lymph node aspiration and cytology

IMAGING

- Skull radiographs—soft tissue opacity in the nasal cavity and/or frontal sinuses, as well as destruction of the turbinates, nasal septum, vomer, or surrounding palatine, maxillary, and/or frontal bones.
- Thoracic radiographs to screen for pulmonary metastasis.
- CT is superior to radiographs for detecting soft tissue opacity within the nasal cavity and surrounding sinuses, bony destruction, and extension through the cribriform plate into the brain.

DIAGNOSTIC PROCEDURES

- Blood pressure measurement and fundic examination.
- Mandibular lymph node cytology to screen for possible metastasis.
- Rhinoscopy can sometimes be helpful for visualizing a mass or fungal plaque and guiding a subsequent biopsy.
- Tissue biopsy and histopathology is needed for definitive diagnosis. The biopsy instrument should not pass the level of the medial canthus of the eye to avoid penetrating the cribriform plate.

TREATMENT

- Radiation therapy is the treatment of choice.
- Conventional linear accelerator is used most commonly. However, if available, stereotactic radiation therapy can reduce the number of radiation treatments and reduce adverse effects while maintaining treatment efficacy.
- Palliative radiation protocols (fewer treatments and lower total radiation dose) might be preferable for dogs with very advanced disease.
- Surgery alone is ineffective.

MEDICATIONS

DRUG(S)

- Prednisone (0.5–1 mg/kg PO q24h) to help relieve nasal congestion.

- Phenylephrine nasal spray can be used intermittently to help with epistaxis.
- Empiric antibiotic therapy can be considered for secondary bacterial infections.
- Consult a medical oncologist for current recommendations.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

PATIENT MONITORING

- Physical examinations every 2–3 months and thoracic radiographs every 3–4 months.
- CT of the nasal cavity can be considered to monitor disease regression or if clinical signs recur or worsen.

EXPECTED COURSE AND PROGNOSIS

- Overall metastatic rate is < 20% (usually involve regional lymph nodes and/or lungs).
- Median survival with palliative care alone is 3 months.
- With definitive radiation therapy, 1-year relapse-free survival rate is around 50% and 2-year relapse-free survival rate is around 30%.
- For patients with nasal tumors in general, extension into the frontal sinuses and/or erosion through the bones of the nasal passage is associated with a three-fold increase in risk of local recurrence.
- Brain involvement is a poor prognostic factor.
- Unilateral versus bilateral involvement is not a significant prognostic factor.

MISCELLANEOUS

SEE ALSO

Consulting Editor Timothy M. Fan

FIPRONIL TOXICOSIS

BASICS

OVERVIEW

- Phenylpyrazole compound with selective toxicity against insects.
- Discovered in 1987, registered as a pesticide in the United States in 1996; used worldwide today.
- Uses:
 - Topical flea and tick spot-on products ("plus" versions include S-methoprene)
 - Roach and ant-bait stations
 - Flea and tick sprays for pets
 - Granular turf products
 - Soil treatment
 - Crop pest control

F

SIGNALMENT

- Dogs:
 - Accidental ingestion and/or licking of topical spot-on products.
 - Chewing ant and roach-bait stations or licking gel products.
 - Ingesting liquid from bottles or granules from bags containing product.
- Cats:
 - Accidental ingestion of topical spot-on product from grooming.

SIGNS

- Dermal—skin irritation, alopecia, or dermal hypersensitivity reaction
- Oral—hypersalivation, nausea, vomiting, diarrhea
- Ingestion of large doses: CNS—hyperexcitability, tremors, convulsions, seizures, death

CAUSES & RISK FACTORS

- Ingestion by dogs, especially young dogs occurs more frequently due to behavioral factors. With chronic studies in dogs, severe neurotoxic signs were observed at a dose of 20 mg/kg.
- Wide availability and frequent access to products.
- Biggest concern is exposure to concentrated products frequently found on farms and ranches or used by pesticide control applicators.

DIAGNOSIS

- History of exposure.
- Detected in blood, tissue, hair with GC/MS.

- Differential diagnosis: dogs and cats—exposure to agents that can cause dermal hypersensitivity or CNS signs.

TREATMENT

- Baseline CBC, chemistry profile, and UA should be performed to rule out pre-existing organ dysfunction which could increase the risk for toxicosis.
- For dermal reaction, bathe with liquid dishwashing detergent and rinse thoroughly.
- Antihistamine or steroids for dermal hypersensitivity reaction.
- With ingestion of a large dose, one dose of activated charcoal with sorbitol may be beneficial.
- Methocarbamol for tremors.
- Anticonvulsants for seizures.
- IV fluids (balanced crystalloid) at twice maintenance if CNS signs occur.

MEDICATIONS

- Activated charcoal (0.5–1 mg/kg PO) and an osmotic cathartic (sorbitol or sodium sulfate, 125 mg/kg PO) × 1 dose for large ingestions.
- Methocarbamol for tremors—50–150 mg/kg IV. Max daily dose 330 mg/kg/day (cats and dogs).
- Anticonvulsants for seizures—diazepam 0.5–2 mg/kg IV (dogs and cats); phenobarbital 2–6 mg/kg IV (dogs and cats).
- Diphenhydramine 2–4 mg/kg q8–12h PO; 1 mg/kg q8–12h IM, SC, IV.
- Dexamebasone 0.5–1 mg/kg IV or IM (dogs); 0.125–0.5 mg/kg IV or IM (cats).

FOLLOW-UP

Patients usually recover well with symptomatic and supportive care; no long term organ damage is expected to occur.

MISCELLANEOUS

- Puppies/young dogs are less discriminate and more likely to chew up product containers.
- Young and geriatric animals may have lower detoxification capabilities.

PREGNANCY/FERTILITY/BREEDING

Fipronil was administered to rats (route of exposure not included) to determine reproductive effects. No reproductive effects were noted at 30 ppm (2.54 mg/kg/day in males and 2.74 mg/kg/day in females). The lowest dosage at which reproductive effects were observed was 300 ppm (26.0 mg/kg/day in males and 28.4 mg/kg/day in females) based on unspecified clinical signs in the offspring, reduced litter size, decreased body weights, decreased mating, reduced fertility, reduced post-implantation and offspring survival, and delay in physical development.

ABBREVIATIONS

- CNS = central nervous system
- GC/MS = gas chromatography/mass spectrometry
- PPM = parts per million
- UA = urinalysis

BASICS

DEFINITION

Excessive formation of gases in the stomach or intestinal tract. Eructation is the passage of gas from the stomach through the mouth, while flatus refers to the gas released through the anus.

PATHOPHYSIOLOGY

- Often results from a diet change or indiscretion but may herald a more serious gastrointestinal disease.
- Swallowed air (aerophagia) and the bacterial fermentation of nutrients are the main sources of gastrointestinal gas; less significant sources include the interaction of gastric acid and pancreatic/salivary bicarbonate and diffusion of gases from the blood.
- Poorly digestible diets that escape intestinal assimilation, and are therefore available for colonic fermentation, and diets that liberate odiferous gases are associated with flatulence; these include slowly absorbed or non-absorbable oligosaccharides (whole grains, soybeans, beans, and peas), spoiled food, high-fat diets, milk products, and spices.
- Fiber-containing foods contribute to flatus indirectly through reduced dry-matter digestibility and directly by fermentation of the fiber in the colon.
- Dogs and cats are lactose intolerant; a dietary concentration of 1.5 g/kg/day (11 g lactose in 1 cup of milk) may produce flatus and diarrhea.
- A rapid change in diet or an increase in the concentration of a dietary component, especially carbohydrate or fiber, may cause flatus during a period of intestinal adaptation.
- As much as 99% of flatus is composed of nitrogen, oxygen, hydrogen, carbon dioxide, and methane, all of which are odorless.
- Malodorous gases, including ammonia, hydrogen sulfide, indole, skatole, volatile amines, and short-chain fatty acids, compose the residual 1%. Protein maldigestion is often responsible for production of malodorous gases.
- Disease states causing malassimilation of nutrients (such as protein-losing enteropathies in dogs or inflammatory bowel disease), making them available for colonic fermentation, can cause flatus.

SYSTEMS AFFECTED

Gastrointestinal

GENETICS

No known genetic basis, although brachycephalic breeds are overrepresented.

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Common complaint in dog; rare in cat

Breed Predilections

Excessive aerophagia is seen in brachycephalic breeds, sporting dogs, and those with gluttonous/competitive eating behavior.

Mean Age and Range

Any age

Predominant Sex

None

SIGNS

Historical Findings

Increased frequency and possibly volume of flatus detected by the pet owner.

Physical Examination Findings

- Mild abdominal discomfort caused by gastrointestinal distention possible—mild discomfort can be difficult to recognize but may be reported by owner as a pet that has repeated swallowing efforts, restlessness, or lethargy.
- When flatus is due to gastrointestinal disease, concurrent gastrointestinal signs such as diarrhea, vomiting, borborygmus, changes in appetite, and weight loss may be present.

CAUSES

Increased Aerophagia

- Gluttony or competitive eating
- Respiratory disease or any cause of increased respiratory rate
- Feeding shortly after exercise
- Brachycephalic breeds

Diet-Related

- Diets high in non-absorbable oligosaccharides—soybeans, peas, beans.
- Diets high in fermentable fiber—lactose, pectin, inulin, psyllium, oat bran.
- Diets high in complex starches (e.g., whole grains) that are slowly digested.
- Spoiled diets.
- Milk products.
- Abrupt changes in diet.
- Spices and food additives/supplements.

Disease Conditions

- Acute and chronic intestinal disease—including protein-losing enteropathies, inflammatory bowel disease; intestinal dysbiosis; neoplasia; irritable bowel syndrome; parasitism; bacterial, protozoal, or viral enteritis; and food allergy or intolerance.
- Exocrine pancreatic insufficiency.

RISK FACTORS

- Nervous, gluttonous, or competitive eating.
- Eating soon after exercise.
- Brachycephalic breeds.
- Abrupt dietary changes.
- Inappropriate (feeding table food that is likely to be fermented) or spoiled foods.
- Sedentary lifestyle—a 1998 study reported that 43% of randomly chosen dog owners detected flatulence, most commonly in

sedentary pets, with no association to a particular diet.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Distinguish dietary and behavioral causes of flatus from gastrointestinal disease by thorough evaluation of the patient history; this allows the clinician to ascertain the type of diet, amount fed, frequency of feeding, frequency of dietary changes or additions, and the environment in which the patient is fed.
- Investigate feeding method—frequency, amount, relationship to exercise, how offered, and incidence of competitive eating. Observation of the patient while eating may be required to identify gluttony.
- Perform a complete physical examination with a focus on gastrointestinal evaluation. Palpate the abdomen for gassy bowel loops, pain, and distention, and auscultate the abdomen for bowel sounds, absence of which indicates ileus. Rectal examination for evaluation of rectal and pelvic anatomy.
- Assess body condition score; if low, this may indicate concurrent gastrointestinal disease or inadequate food intake. Obesity may be associated with a sedentary lifestyle that may be a risk factor.

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal unless significant bowel disease is present (e.g., hypoalbuminemia in PLE).

OTHER LABORATORY TESTS

- Rectal cytology to evaluate presence of neoplasia, parasites, fungal organisms.
- Zinc sulfate flotation tests or fecal ELISA to evaluate giardiasis.
- Fecal PCR for *Tritrichomonas* in young cats or kittens.
- Fecal cultures to evaluate salmonellosis or campylobacteriosis.
- Serum trypsin-like immunoreactivity to evaluate exocrine pancreatic insufficiency.
- Serum cobalamin and folate concentrations to test for severe small intestinal mucosal disease.

IMAGING

- Abdominal ultrasonography to diagnose gastrointestinal masses or mural thickening.
- Contrast studies may be needed in some cases to detect an obstructive pattern.
- Assessment of gut motility is difficult at best, but scintigraphic markers can be used in some referral facilities. Upper GI series using barium can be used to detect delayed gastric or intestinal emptying; however, the study can be extremely variable secondary to stress.

DIAGNOSTIC PROCEDURES

Gastrointestinal biopsy specimens obtained at surgery or via endoscopy to detect infiltrative gastrointestinal disease.

FLATULENCE

(CONTINUED)

TREATMENT

APPROPRIATE HEALTH CARE

Outpatient—treat any underlying gastrointestinal disease.

NURSING CARE

None

ACTIVITY

Encourage an active lifestyle—exercise increases GI motility, which will help expel flatus and increase regularity of defecation.

DIET

- Feed smaller meals more frequently in an isolated, quiet environment.
- Change diet to one that is highly digestible, with low fiber and fat concentrations (e.g., intestinal or hypoallergenic diets formulated for prescription purposes are all reasonable choices), or feed homemade diets containing boiled chicken and white rice (dogs) or whole chicken with skin (fat) balanced with vitamins and minerals. (Note: cats should not be fed a carbohydrate source, to eliminate carbohydrate intolerance as part of this issue.)
- A change in the protein or carbohydrate source, or removing the additives, benefits some individuals.

CLIENT EDUCATION

Discourage dietary indiscretion (e.g., garbage ingestion or coprophagia).

SURGICAL CONSIDERATIONS

None

MEDICATIONS

DRUG(S) OF CHOICE

- Carminatives are medications that relieve flatulence—there are no studies to show safety or benefit of these drugs in dogs or cats.
- Zinc acetate binds sulfhydryl compounds.
- Yucca schidigera* binds ammonia and is added to pet foods as a flavoring agent.
- Dry activated charcoal absorbs virtually all odiferous gases when mixed directly with human feces and flatus; however, the number of flatus events, gas volume, or odor were not decreased in people.
- Inclusion of activated charcoal, *Y. schidigera*, and zinc acetate in a treat reduced the frequency of highly odiferous episodes in dogs.
- Bismuth subsalicylate (dogs, 1 mL/kg PO initially then 0.25 mL/kg q6h) adsorbs hydrogen sulfide and has antibacterial properties; however, long-term, multiple daily

dosing precludes its practicality. Not recommended for use in cats due to potential for salicylate toxicity.

- Simethicone is an antifoaming agent that reduces the surface tension of gas bubbles, allowing easier coalescence and release of intestinal gas; however, gas production is unaltered.
- Pancreatic enzyme supplements may reduce flatulence in some patients with reduced pancreatic enzyme production.

CONTRAINDICATIONS

Avoid bismuth subsalicylate in cats and in dogs with gastroduodenal ulceration and bleeding disorders.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

- More than 30 herbal and botanical preparations are available; however, the dosage, safety, and efficacy are unknown.
- Use of probiotics to normalize or stabilize the intestinal microenvironment has been advocated and would be safe to try; however, no studies of efficacy of this approach have been completed.

FOLLOW-UP

PATIENT MONITORING

Response to therapy

PREVENTION/AVOIDANCE

- Avoid diets high in non-absorbable oligosaccharides and high in fermentable or non-fermentable fibers.
- Avoid milk products, spoiled diets, and abrupt changes in diet.
- Do not feed shortly after exercise.
- Use of probiotics to improve the commensal bacterial flora may be beneficial if bacterial disruption is the primary cause of flatulence.

POSSIBLE COMPLICATIONS

None

FLEA BITE HYPERSENSITIVITY AND FLEA CONTROL

BASICS

DEFINITION

- Flea infestation—large number of fleas and flea dirt.
- Flea bite dermatitis—non-hypersensitivity reaction to flea bites.
- Flea bite hypersensitivity (FBH)—allergic reaction to antigens in flea saliva.
- Biomass—population of immature stages (eggs, larvae, and pupae) and adult fleas.

FLEA LIFE CYCLE

- *Ctenocephalides felis* (cat flea) main cause: not host specific—parasitizes cats, dogs; has many wildlife hosts.
- Adult fleas mate on host and within 24 hours females lay up to 50 eggs per day.
- Eggs fall off pets in the environment and hatch.
- Larvae have negative phototropism and infest carpets, upholstery and under furniture.
- Eggs from wildlife and feral cats survive in moist, protected areas like sheds and covered spaces.
- Larvae undergo molts until they pupate; the cocoon enhances survival.
- Adults emerge when environmental conditions and host availability are favorable.
- Less than 5% of the total flea burden is found as adults on the pet.
- The majority of the biomass is found as immature stages in the home and in peridomestic areas that are shaded and moist.

PATOPHYSIOLOGY

- Flea bite hypersensitivity—caused by a low molecular weight hapten and two high molecular weight allergens.
- Increased binding to dermal collagen; form a complete antigen necessary for eliciting FBH.
- Flea saliva—contains histamine-like compounds that irritate skin.
- Intermittent exposure favors FBH; continuous exposure is less likely to result in hypersensitivity.
- Both IgE and IgG anti flea antibodies reported.
- Immediate and delayed hypersensitivity reactions reported.
- Late-phase IgE-mediated response; occurs 3–6 hours after exposure.
- Cutaneous basophil hypersensitivity; an infiltration of basophils into the dermis; mediated by either IgE or IgG; subsequent exposures cause the basophils to degranulate; manifests as immediate and delayed hypersensitivity.

SYSTEMS AFFECTED

Skin/Exocrine

GENETICS

FBH—unknown inheritance pattern; common in atopic breeds

INCIDENCE/PREVALENCE

Varies with climatic conditions and flea population. Microclimate in the home may allow year-round infestations.

GEOGRAPHIC DISTRIBUTION

FBH—may occur anywhere; non-seasonal in climates that are warm and humid, and year-round in animals housed indoors when flea infestations are not controlled.

SIGNALMENT

Species

Dogs and cats

Breed Predilections

FBH—any breed; common in atopic breeds

Mean Age and Range

FBH—rare < 6 months of age; average age range, 3–6 years, but may be seen at any age

Predominant Sex

N/A

SIGNS

Historical Findings

- Pruritus
- Chewing
- Licking
- Exposure to other animals
- Lack of consistent or effective flea control

Physical Examination Findings

- Determined by the severity of the reaction.
- Finding fleas and flea dirt is beneficial, although not essential, for the diagnosis of FBH. When appropriate signs are present flea parasitism should be suspected and flea control instituted.
- Sensitive animals require a low exposure and tend to over-groom, removing evidence of infestation.
- Dogs—lesions concentrated in the caudal-dorsal-lumbosacral region; caudal aspect of the thighs, lower abdomen, and inguinal region; primary lesions are papules; secondary lesions (e.g., hyperpigmentation, lichenification, alopecia, and scaling) and pyotraumatic dermatitis (“hotspots”) common in uncontrolled FBH.
- Cats—alopecia and crusting dermatitis in a wedge-shaped pattern over the caudal dorsal lumbosacral region and often around the head and neck; other presentations include “barbering” of the inguinal region, miliary dermatitis, and lesions of the eosinophilic granuloma complex.

CAUSES

See “Pathophysiology”

RISK FACTORS

FBH—intermittent exposure to fleas; incidence commonly seen in conjunction with atopy.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Food allergy
- Atopy
- Ectoparasitism
- Dermatophytosis
- Pyoderma
- Any pruritic skin disease

CBC/BIOCHEMISTRY/URINALYSIS

- Usually normal
- Cats—occasional eosinophilia

OTHER LABORATORY TESTS

- Skin scrapings—negative.
- Flea combings—fleas or flea dirt.
- RAST and ELISA—variable accuracy; both false-positive and false-negative results reported.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Diagnosis based on historical information and distribution of lesions and/or response to adequate flea control.
- Fleas or flea dirt is supportive but may be difficult to find, especially in cats.
- Identification of *Dipylidium caninum* segments in stool is supportive.
- Intradermal allergy testing with flea antigen—reveals positive immediate reactions in large numbers of flea-allergic animals; delayed reactions (24–48 hours) may sometimes be observed in allergic animals that show no immediate reaction.
- The most accurate test is response to appropriate treatment.

F

PATHOLOGIC FINDINGS

- Superficial perivascular dermatitis.
- Eosinophilic intraepidermal microabscesses.
- Eosinophils as a major cellular component of the dermis.
- Histopathologic evaluation—may not definitively differentiate FBH from atopy, food allergy, or other hypersensitivities.

TREATMENT

APPROPRIATE HEALTH CARE

Outpatient therapy

NURSING CARE

N/A

ACTIVITY

N/A

DIET

N/A

CLIENT EDUCATION

- Inform owners that there is no cure for FBH; flea-allergic animals often become more sensitive to flea bites as they age.
- Hypo sensitization is not considered effective.
- Medications that stop itching are meant to be a respite while flea control is instituted.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

TREATMENT STRATEGIES

- Itch relief
- Flea control
 - Pet-targeted
 - Insect-targeted
 - Premises-targeted
 - Environment-targeted

DRUG(S) OF CHOICE

Itch Relief

Corticosteroids

- Anti-inflammatory dosages for symptomatic relief to break itch-scratch cycle while instituting adequate flea control. Use only as much as is needed and for the shortest

FLEA BITE HYPERSENSITIVITY AND FLEA CONTROL

(CONTINUED)

duration to achieve the desired effect. Rapid relief from itching and the distress it causes both pets and owners is important, but does not replace counseling on methods to prevent reoccurrence. • Injectable—one dose is most often sufficient to stop itching while flea control is achieved. ◦ Triamcinolone acetonide injectable—dogs, 0.11–0.22 mg/kg IM/SC. ◦ Dexamethasone sodium phosphate injectable—dogs, 0.07–0.16 mg/kg IM/SC. • Methylprednisolone acetate injectable—cats, 5.5 mg/kg (20 mg per average-sized cat) IM/SC. • Oral: ◦ Prednisolone—cats, 0.5–1 mg/kg PO q12h for 5–7 days then taper; dogs, 0.5–1 mg/kg PO q24h for 7 days then taper.

Antihistamines

Little to no effect.

Flea Control

Goals are the immediate reduction or elimination of adult fleas on the host and to break the cycle of flea development in the home and in the immediate environment.

Pet-Targeted Flea Control

- Topical/Spot-On: ◦ Dinotefuran/pyriproxyfen—rapid-acting spot-on product for dogs and cats; a second canine product contains high-dose permethrin and should not be used on cats. ◦ Fipronil plus IGR (GABA antagonist)—spot-on treatment for cats and dogs (spray treatment for dogs). ◦ Imidacloprid plus IGR—monthly spot-on treatment for cats and dogs; a second canine product contains permethrin and should not be used on cats; also available as a collar. ◦ Etofenprox plus IGR—monthly spot-on for dogs and cats, non-carbamate sodium channel blocker, classified by EPA as a reduced risk pesticide. ◦ Indoxycarb—monthly spot-on, dogs only, sodium channel blocker, activated by flea digestive enzymes, contains permethrin, should not be used on cats. ◦ Selamectin—for dogs and cats, monthly spot-on, chloride channel blocker; also has IDI action. • Sprays: usually contain pyrethrins, and pyrethroids with IGR. When compared to cost of spot-on products the per-pet, per-application expense is much lower.

Insect Growth Regulators (IGRs)

S-methoprine and pyriproxyfen are analogs of insect juvenile hormone that bind to immature stages and prevent maturation.

Insect Development Inhibitors (IDIs)

- Lufenuron and selamectin inhibit chitin synthesis in egg shell, immature stages and adults. • Oral: ◦ Nitenpyram—neonicotinoid flea adulticide; orally administered; rapid onset, but short acting; for dogs and cats. ◦ Spinosad—monthly oral treatment for dogs and cats. ◦ Afoxolaner and Fluralaner—isoxazoline chloride channel blocker; oral product for dogs only.

Premises-targeted flea control

- Indoor treatment—"foggers/bombs" and premises sprays; contain organophosphates,

pyrethrins, and/or insect growth regulators. Etofenprox plus IGR and permethrin/pyrethrin plus IGR, available in inverted aerosol sprays; apply according to manufacturer's directions; treat all areas of the house; can be applied by the owner. Foggers/Bombs do not effectively penetrate all areas commonly inhabited by fleas such as under furniture; hand-held sprays are highly effective against biomass, may be directed where flea populations reside, and have long residual activity. • Professional exterminator—discuss products with representative.

Environment-targeted flea control

• Outdoor treatment—concentrate in shaded areas; sprays usually contain pyrethroids or organophosphates and an insect growth regulator; easy-to-use products applied by attaching dispensing container to garden hose; also available in premixed applicator containers; owners should be educated on areas of application based on likelihood of reinfestation from feral cats and wildlife. Nematode (*Steinerma carpocapsae*)—very safe and chemical-free but expensive and may not survive shipping.

CONTRAINDICATIONS

N/A

PRECAUTIONS

- Label instructions—must be strictly followed. • Spinosad can potentiate neurologic side effects of high-dose ivermectin—but is safe when combined with heartworm preventive dose. • Pyrethrin/pyrethroid-type flea products—adverse reactions include depression, hypersalivation, muscle tremors, vomiting, ataxia, dyspnea, and anorexia; do not use in cats.
- Organophosphates—use inappropriate given the current alternatives. • The animal should be bathed thoroughly to remove remaining chemicals and treated appropriately.

ALTERNATIVE DRUG(S)

- Powders and dips—adverse reactions and toxicity make their use inappropriate given the current alternatives. • Over-the-counter products often contain the same combinations or one active ingredient as veterinarian dispensed products but the absence of proper education concerning OTC product use and off-pet flea control often leads to failures in flea control as well as resolution of FBH.

FOLLOW-UP

PATIENT MONITORING

- Pruritus—a decrease means the FBH is being controlled. • Fleas and flea dirt—absence is not always a reliable indicator of successful treatment in very sensitive animals.

PREVENTION/AVOIDANCE

- Warm climates and infested premises require year-round flea control. • Seasonally warm climates—begin flea control in when temperatures consistently remain above freezing.

POSSIBLE COMPLICATIONS

- Secondary bacterial folliculitis • Acute moist dermatitis • Acral lick dermatitis

EXPECTED COURSE AND PROGNOSIS

Prognosis is good if strict flea control is instituted.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Approximately 80% of atopic dogs are also allergic to flea bites.

AGE-RELATED FACTORS

Package should be consulted for the minimum approved age for application.

ZOONOTIC POTENTIAL

In areas of moderate to severe flea infestation, people can be bitten by fleas; usually papular lesions are located on the wrists and ankles. Humans may also be infected with *Dipylidium caninum*, and fleas play a role in transmission of cat scratch disease (*Bartonella henselae*) among cats and humans.

PREGNANCY/FERTILITY/BREEDING

- Corticosteroids and organophosphates—do not use in pregnant bitches and queens.

SYNOMYS

Flea bite allergy

ABBREVIATIONS

- ELISA = enzyme-linked immunosorbent assay • FBH = flea bite hypersensitivity
- GABA = gamma-aminobutyric acid
- IDI = insect development inhibitor
- IGR = insect growth regulator • RAST = radioallergosorbent test

FOOD REACTIONS, DERMATOLOGIC

BASICS

DEFINITION

- Adverse reactions to food affecting the skin
- Associated with ingestion of one or more substances

PATHOPHYSIOLOGY

- Pathogenesis not completely understood.
- Immediate and delayed reactions to specific ingredients documented; immediate reactions presumed to be type I hypersensitivity reactions; delayed presumed to be type III or IV.
- Failure or prevention of the development of oral tolerance to food allergens may encourage sensitization.
- Food intolerance—non-immunologic, idiosyncratic reaction; involves metabolic, toxic, or pharmacologic effects of offending ingredients.
- Adverse food reaction is the most common term used, and does not distinguish between immunologic and idiosyncratic reactions.
- Adverse food reactions patients associated with an increased predisposition to atopy.
- Cutaneous adverse food reactions can trigger flares of atopic dermatitis.

SYSTEMS AFFECTED

- Skin/Exocrine
- Gastrointestinal
- Nervous

GENETICS

N/A

INCIDENCE/PREVALENCE

- Approximately 5% of all dermatitis and 10–15% of allergic dermatitis in dogs and cats is caused by adverse reactions to food.
- 13–30% of food allergic dogs have concurrent atopy or flea bite hypersensitivity.
- Third most common pruritic skin disease in the dog; second most common in the cat.
- Percentages vary greatly with clinicians and geographic location.

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Dogs and cats

Breed Predilections

- Dogs—none reported; breeds associated with Atopic dermatitis overrepresented.
- Cats—Siamese.

Mean Age and Range

- Any age: dogs—possibly increased development (over other allergic dermatoses) in patients < 12 months or > 7 years of age; cats—patients < 2 years or > 5 years of age.
- Most adult patients have been fed the offending allergen for over two years prior to becoming symptomatic.

Predominant Sex

None reported

SIGNS

General Comments

- Symptoms similar to other hypersensitivity reactions
- Pruritus is the main dermatological sign

Historical Findings

- Pruritus of any body location.
- Usually non-seasonal.
- Poor response to anti-inflammatory doses of glucocorticosteroids.
- Recurrent bacterial folliculitis with or without pruritus.
- Persistent otitis externa.
- Concurrent gastrointestinal symptoms in a minority of cases: vomiting and/or diarrhea, excessive borborygmus, flatulence, and frequent bowel movements.
- Very rare association of neurologic signs (seizures) with food hypersensitivity.
- Respiratory signs have been reported in dogs.

Physical Examination Findings

- Dogs—rump, perineum, axillae, groin, face, and interdigital areas frequently affected
- Cats—face, neck, and ears frequently affected
- Cats—lesions of the eosinophilic granuloma complex
- Otitis externa
- *Malassezia* dermatitis
- Secondary bacterial folliculitis
- Plaques
- Pustules
- Erythema
- Crusts
- Scale
- Self-induced alopecia
- “Psychogenic alopecia”
- Excoriation
- Lichenification
- Hyperpigmentation
- Urticaria
- Angioedema
- Pyotraumatic dermatitis
- Acral lick dermatitis

CAUSES

- Immune-mediated reactions (food hypersensitivity)—result from the ingestion and subsequent presentation to the immune system of one or more glycoproteins (allergens) either before or after digestion; sensitization may occur at the gastrointestinal mucosa, after the substance is absorbed, or both; cross-reactivity between various food allergens, and between food and pollen allergens, has been demonstrated.
- Non-immune-mediated reactions (food intolerance)—result of ingestion of foods with high levels of histamine or substances that induce histamine either directly or through histamine-releasing factors.

RISK FACTORS

- Unknown.
- Intestinal parasites or intestinal infections may damage the intestinal mucosa, resulting in the abnormal absorption of allergens and subsequent sensitization.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Flea bite hypersensitivity—usually confined to the caudal half of the body; often seasonal.
- Atopy—associated with pruritus of the face, feet, axilla, groin, and perineum; often seasonal; if pruritus first occurs at < 12 months or > 7 years of age in dogs, then food hypersensitivity should be investigated prior to work up for atopic dermatitis; 20–30% of dogs with adverse reactions to food also have atopic dermatitis.
- Drug reactions—history of drug administration before the development of signs and improvement after withdrawal of the suspected drug.
- Scabies mites—pruritus usually specific to the ears, elbows, and hocks (dogs) and head, ears, and neck (cats); mites in skin scrapings and/or response to specific therapy.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

In vitro (serum) allergy tests; poor correlation between test results and food exposure; poor correlation between diet trial and test results; not completely sensitive or specific; significant discrepancy between labs; currently no standard to enable comparisons between techniques; not recommended as a diagnostic test for food allergy or for choosing appropriate ingredients for food trials.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- There is no single laboratory test available to help the clinician to confirm or refute the presence of food sensitivity.
- Diagnosis is based on dietary exclusion in the form of restricted-ingredient food trials followed by challenge and redevelopment of symptoms.

Food Elimination Diet

- Definitive test for adverse food reactions.
- Tailored to the individual patient.
- Diet must be restricted to one novel protein and one novel carbohydrate.
- Most patients will improve within 6–8 weeks.
- Food trials should be continued up to 10 weeks unless improvement occurs earlier.
- Home-cooked food trials remove possible sources of antigen due to processing, storage,

FOOD REACTIONS, DERMATOLOGIC

(CONTINUED)

and cross-contamination from other ingredients.

Challenge and Provocation Diet Trials

- Used if the patient improves on the elimination diet.
- Challenge—feed the patient the original diet; a return of the signs confirms that the original diet contains an inciting ingredient; the challenge period should last until the signs return but no longer than 10 days.
- Provoke (provocation diet trial)—if the challenge confirmed the presence of an adverse food reaction, add single ingredients to the elimination diet; test ingredients include a full range of meats (beef, chicken, fish, pork, lamb), a full range of carbohydrates (corn, wheat, soybean, rice), eggs, and dairy products; the provocation period for each ingredient should last up to 10 days or less if signs develop sooner; results guide the selection of commercial foods that do not contain the offending substance(s).

PATHOLOGIC FINDINGS

- Skin biopsy—not diagnostic; help confirm or eliminate other differential diagnoses.
- Histopathologic findings—variable; common findings suggest hypersensitivity; secondary bacterial folliculitis or *Malassezia* dermatitis may be present.

TREATMENT

Avoidance of the offending food substance(s)

APPROPRIATE HEALTH CARE

Outpatient management

NURSING CARE

N/A

ACTIVITY

No change

DIET

Avoid any food substances that caused the clinical signs to return during the provocation phase of the diagnosis.

CLIENT EDUCATION

- Explain the principles involved in each phase of the diagnostic test diets.
- Instruct client to eliminate treats, chewable toys, vitamins, medication wraps, and flavored medications (e.g., heartworm preventive) as these may contain ingredients from the patient's previous diet.
- If a home-cooked diet is needed, the website www.balanceit.com is useful to create a diet with adequate supplementation.
- Outdoor pets must be confined to prevent foraging and hunting.
- Advise all family members to adhere to the restricted-ingredient diet trial protocol.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUG(S) OF CHOICE

- Systemic antipruritic drugs—may be useful during the first 2–3 weeks of diet trial to control self-mutilation.
- Antibiotics or antifungal medications—useful for secondary bacterial folliculitis or *Malassezia* dermatitis.

CONTRAINDICATIONS

- Antibiotics that are known to have anti-inflammatory effects (e.g., tetracycline, doxycycline, erythromycin, and trimethoprim-sulfamethoxazole) may confuse response to dietary trials.
- Glucocorticosteroids and antihistamines should be discontinued for at least 10–14 days while on the diet trial to allow correct assessment of the animal's response.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

None

ALTERNATIVE DRUG(S)

None

FOLLOW-UP

PATIENT MONITORING

Examine patient and evaluate and document the pruritus and clinical signs every 3–4 weeks.

PREVENTION/AVOIDANCE

- Avoid intake of any of the ingredients included in the previous diet including treats and chewable vitamins and toys.

POSSIBLE COMPLICATIONS

Other causes of pruritus must be eliminated or controlled to permit accurate assessment of the effect of dietary antigens on clinical signs.

EXPECTED COURSE AND PROGNOSIS

- Prognosis is good if food ingredients are the only cause of pruritus and offending ingredients are avoided.
- Rarely a dog or cat may develop hypersensitivity to new substances, requiring a new elimination diet trial.
- A partial response to a food elimination diet trial suggests a combined food reaction with atopy or with another cause of pruritus.

FOOD REACTIONS (GASTROINTESTINAL), ADVERSE

BASICS

DEFINITION

- Adverse food reactions encompass disorders with an immunologic basis (food allergy), non-immunologic reaction (food intolerance), and toxic reactions (food intoxication, uncommon).
- Adverse food reactions may be associated with gastrointestinal (GI) signs (vomiting and/or diarrhea) in dogs and cats. In a practical sense, food allergy and food intolerance may have similar signs, diagnostics, and treatments and may not be easily distinguishable.
- Food allergy is a common cause for cutaneous signs, such as pruritus, and may occasionally be associated with gastrointestinal signs. Food-allergic pets may uncommonly have both GI signs and cutaneous lesions.

PATOPHYSIOLOGY

- The pathogenesis of food allergy involves complex immunologic events: a leaky intestinal mucosal barrier, dysregulated immune responses, and loss of oral tolerance. Most food allergies are due to type 1 hypersensitivity reactions. Major food allergens include milk, eggs, beef, chicken, and plant proteins from corn, wheat, and soybeans.
- Food intolerance may be due to idiosyncratic reactions to dietary ingredients or additives, pharmacologic reactions to compounds in the diet, defects or deficiencies in the metabolic pathways needed to use the food, or a toxicity reaction to food ingredients or spoiled foodstuffs.
- Toxic reactions to food may occur when a foodstuff is ingested in large amounts (e.g., onion poisoning).
- Food that is spoiled or that contains microorganisms or their toxins can produce a wide range of clinical signs and severity.

SYSTEMS AFFECTED

- Dermatologic
- Endocrine/Metabolic
- Gastrointestinal

GENETICS

- Heritable food allergy is observed in soft-coated Wheaten terriers (suspect autosomal recessive trait).
- German shepherd dogs are at risk for immunologic-mediated intestinal inflammation (i.e., idiopathic IBD) associated with heritable defects in innate immunity. Dietary antigens may provoke adverse host responses in susceptible dogs which contribute to gut inflammation.
- Gluten-sensitive enteropathy has been seen primarily in Irish setters.
- Siamese and Siamese cross cats may be at increased risk.

- The specifics of a genetic basis are not well defined.

INCIDENCE/PREVALENCE

More common in cat than dog

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

- Cats and dogs of any age or breed and either sex can be affected.
- Irish setters are predisposed to gluten-sensitive enteropathy; they tend to display clinical signs by 4–7 months of age.
- Dogs with chronic enteropathies that are diet-responsive tend to be younger adult animals.

SIGNS

General Comments

- Food intolerance commonly produces diarrhea (small or large bowel), vomiting, flatulence, anorexia, and abdominal discomfort.
- Food allergy may cause cutaneous signs, such as pruritus and hair loss, which may be associated with GI signs.

Historical Findings

- Acute food intolerance may accompany feeding a novel foodstuff, a new food source, or dietary change.
- Clients may report cessation of clinical signs in the fasted state or within days of an elimination dietary trial.

Physical Examination Findings

The physical examination is generally nonspecific but may show abdominal discomfort, flatulence, bloating, or patchy areas of alopecia along the pinnae of the ears and periorbital regions, especially in cats.

CAUSES

- Idiosyncratic reactions to food additives—colorings, preservatives (BHA, monosodium glutamate, sodium nitrate, sulfur dioxide, etc.), spices, propylene glycol, etc.
- Pharmacologic reactions—vasoactive substances (i.e., histamine), psychoactive agents, stimulants (i.e., theobromine, caffeine), etc.
- Metabolic defects or deficiencies—brush border enzyme defects (i.e., lactase deficiency), inborn errors of metabolism, aminopeptidase N (in gluten-sensitive enteropathy).
- Toxic reactions to foods or spoiled foods—spices, oxalate toxicity, lectin toxicity, *N*-propyl disulfide aflatoxicosis, ergotism, botulism, dietary indiscretion, etc.
- Genetic mutations in innate immunity genes regulating host responses to dietary constituents.

RISK FACTORS

- Young Irish setters susceptible to gluten-sensitive enteropathy may be at greater

risk to develop the disease if exposed to gluten at an early age.

- Host genetic susceptibility is suspected in Wheaten terriers and German shepherd dogs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Inflammatory bowel disease, parasitism, exocrine pancreatic insufficiency, and antibiotic responsive diarrhea can produce signs similar to those of adverse food reactions.
- A presumptive diagnosis of adverse food reaction is made upon resolution of GI signs while feeding an elimination diet containing protein hydrolysates or a novel intact protein source.
- Dietary trials using a home-made diet are sometimes used but are generally not intended for long-term administration.
- Gastrointestinal signs often improve within days, especially in cats.

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal; animals with food allergy may occasionally have eosinophilia.

OTHER LABORATORY TESTS

- Few diagnostic tests are specific.
- Diagnostics are performed to rule out other differentials and to treat complicating factors.
- Fasting serum folate and cobalamin levels are useful in evaluating hypocabalaminemia and the distribution of small intestinal mucosal disease.
- Rule out exocrine pancreatic insufficiency by evaluating serum trypsin-like immunoreactivity.
- The detection of antigen-specific serum immunoglobulins is generally not recommended because they are considered unreliable in animals.

IMAGING

- Abdominal radiographs or ultrasound may be useful in eliminating differential diagnoses.
- Doppler evaluation (ultrasound) may detect alterations in blood flow through the celiac and cranial mesenteric arteries of dogs.

DIAGNOSTIC PROCEDURES

- Perform an elimination dietary trial of 2 weeks in cats and 3 weeks in dogs with GI signs.
- Following improvement on an exclusion diet, use challenge exposure to sequential single ingredients to specifically identify the incriminating dietary ingredient. While technically the gold standard this is generally impractical in a clinical setting.
- Exclusive feeding with a novel protein source indefinitely is generally required to prevent clinical relapse.
- Perform urinalysis and urine protein:creatinine ratio (if indicated) in diet-responsive Wheaten terriers to screen for

FOOD REACTIONS (GASTROINTESTINAL), ADVERSE

(CONTINUED)

concurrent glomerular injury with urinary protein loss.

PATHOLOGIC FINDINGS

- Villous atrophy and mild lymphoplasmacytic enteritis may be seen with food allergy.
- Endoscopic mucosal biopsy may confirm intestinal inflammation in food-allergic animals.

**TREATMENT****APPROPRIATE HEALTH CARE**

Generally treat on an outpatient basis

NURSING CARE

N/A

ACTIVITY

No restrictions

DIET

- Feed a hydrolysate or novel intact protein diet as previously described.
- Cats are generally sensitive to more than one dietary ingredient.
- Multiple high-quality commercial diets are available for use in dogs and cats with food-responsive enteropathy.
- If this approach is used, examination of the ingredients of the various diets is recommended to determine if any patterns exist that might help identify the offending ingredient(s).

CLIENT EDUCATION

Caution against feeding any scraps or varying from a set diet.

SURGICAL CONSIDERATIONS

N/A

**MEDICATIONS****DRUG(S) OF CHOICE**

- Generally no medications are used.
- Associated problems (e.g., ARD or IBD) may require medical therapy as suggested in the sections specific to these problems.

CONTRAINDICATIONS

N/A

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

N/A

**FOLLOW-UP****PATIENT MONITORING**

- Assess efficacy of elimination dietary trial by observing improvement in clinical (GI) signs.
- Consider repeating evaluation for primary mucosal disease (IBD) if animals are unresponsive to dietary therapy.

PREVENTION/AVOIDANCE

- Avoiding the offending food ingredient(s) is recommended.
- If no specific ingredient has been identified, adherence to a set exclusion diet is recommended.

POSSIBLE COMPLICATIONS

ARD and inflammatory bowel disease

EXPECTED COURSE AND PROGNOSIS

- Prognosis for a full recovery is excellent in most cases if dietary recommendations are strictly adhered to.
- Wheaten terriers with food allergy warrant a guarded prognosis for full recovery.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

ARD and inflammatory bowel disease may be associated with adverse food reactions.

AGE-RELATED FACTORS

The severity of gluten-sensitive enteropathy in susceptible Irish setter puppies may be reduced by avoiding gluten-containing cereals.

GALLBLADDER MUCOCELE

G

BASICS

OVERVIEW

- Accumulation of tenacious, thick, mucoid bile conglomerate in the gallbladder (GB), obstructing storage capacity and function.
- Inspissated biliary sludge expands the GB, leading to necrotizing cholecystitis. • A canine syndrome, rare in cats.

SIGNALMENT

- Dog • Shetland sheepdogs, miniature schnauzers, Cocker spaniels—overrepresented. • Middle-aged to older adults. • No sex predilection. • Associated with endocrinopathies.

SIGNS

General Comments

- Symptomatic or asymptomatic
- Asymptomatic discovered on abdominal ultrasonography for other health concerns

Historical Findings: symptomatic

- Episodic abdominal discomfort • Anorexia
- Vomiting • Polyuria/polydipsia • Lethargy
- Collapse: vasovagal or bile peritonitis

Physical Examination Findings

- May show no physical signs early in syndrome • Lethargy • Cranial abdominal discomfort • Jaundice late in syndrome
- Dehydration • Fever

CAUSES & RISK FACTORS

- Inborn errors of lipid metabolism may increase risk: miniature schnauzer, Shetland sheepdogs. • Medical conditions associated with hypercholesterolemia or promoting dyslipidemias: hypothyroidism, typical or atypical (sex hormone) adrenal hyperplasia, glucocorticoid therapy, diabetes mellitus, recurrent pancreatitis, feeding high fat diet to dog with a predisposing disorder. • GB dysmotility—may play a causal role. • Cystic hypertrophy of mucus-producing GB mucosa—common in older dogs; may play a causal or facilitatory role.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Conditions causing bile stasis—GB dysmotility; neoplasia; choleliths; pancreatitis

CBC/BIOCHEMISTRY/URINALYSIS

CBC

- Inflammatory leukogram—variable
- Non-regenerative anemia—if chronic inflammation or hypothyroidism

Biochemistry

- High liver enzymes—only sign of illness in some dogs or may be noted on acute presentation; ALP, GGT, ALT, ± AST. • High ALP: early in syndrome development may indicate an underlying glycogen-type vacuolar hepatopathy (VH) and endocrinopathy (adrenal related). • Variable hyperbilirubinemia. • Low albumin if ruptured biliary tree and bile peritonitis.
- Prerenal azotemia if ruptured GB, sepsis, or dehydration from postprandial vomiting.
- Electrolyte abnormalities with fluid and acid-base disturbances—reflecting bile peritonitis or extensive vomiting.

Urinalysis

No specific features

OTHER LABORATORY TESTS

- Triglyceride concentrations—high if inborn error of lipid metabolism: certain breeds, endocrinopathies, diabetes mellitus, hypothyroidism, or pancreatitis. • Coagulation tests—normal, unless chronic EHBDO, GB rupture, bile peritonitis, sepsis, or DIC.

IMAGING

- Abdominal radiography—normal or large liver; loss of detail in cranial abdomen if focal peritonitis (necrotizing cholecystitis, GB rupture); intrahepatic gas indicates septic inflammation with gas-producing bacteria (rare). • Abdominal ultrasonography—liver may be large, with rounded margins; diffuse to multifocal hyperechoic hepatic parenchyma common (associated with VH); typical US image is a GB lumen filled with amorphous echogenic debris appearing as a stellate or finely striated pattern, resembling a sliced kiwi fruit (“kiwi sign”); distended GB and sometimes distended common bile duct and cystic duct if EHBDO; fluid interface surrounding GB enhances wall image and suggests cholecystitis or GB rupture; diffusely thick GB wall with segmental hyperechogenicity and double-rimmed or laminated wall if necrotizing cholecystitis; edema may enhance GB wall imaging; may occur with hepatitis, cholangiohepatitis, or third-space fluid dispersals (hypoproteinemia, right heart failure, renal failure, pyelonephritis, abdominal effusion, iatrogenic fluid overload); GB rupture associated with discontinuous GB wall, or a difficult to image GB; GB mucocele (GBM) may be released into the abdominal cavity where a discrete free floating “mass” may be discovered; pericholecystic fluid or generalized effusion, and hyperechogenicity of surrounding tissues may indicate focal peritonitis and bile leakage; intrahepatic bile ducts may be difficult to

visualize or may appear prominent (ascending cholangitis) or distended (EHBDO). • GB motility study—indicated if impending GBM recognized serendipitously and GB volume ≥ 1.2 mL/kg body weight; sequential GB volume measurements after meal ingestion (100 g), may include 1 mg/kg erythromycin as motilin agonist provoking GB contraction. Normal GB contracts $\geq 25\%$ initial volume on one or more postprandial images: image GB at 0, 15, 30, 45, 60, 90, 120 minutes after feeding.

DIAGNOSTIC PROCEDURES

- Aspiration sampling—fluid adjacent to biliary structures or free in abdominal cavity; clarifies GB rupture and infection; **caution:** do not perform cholecystocentesis on a suspected GBM as this may cause bile peritonitis; GBM contents usually difficult to sample owing to their thick, tenacious character. • Laparotomy—for diagnosis, cholecystectomy and perhaps cholecystenterostomy. • Laparoscopy: only if technical excellence achieved for cholecystectomy by this method. • Liver biopsy—evaluates for coexistent or antecedent hepatobiliary disorders. Collect biopsy distant to the GB to avoid sampling perihepatic glands. • Bacterial culture /sensitivity—effusion, GB wall and contents, and liver; aerobic and anaerobic bacteria.
- Cytology—impression smears of GB, liver, and bile for immediate determination of suppurative septic inflammation and neoplasia. Make smears of bile particulates where bacteria are “tangled.”

PATHOLOGIC FINDINGS

- Gross—GB distended, wall may be erythematous or hemorrhagic with focal areas of necrosis; focal peritonitis may be evident; liver and extrahepatic biliary structures usually appear normal; GB contents: dark green-black, tenacious, firm, or organized solid yellow-green on cut surface with a rubbery texture. Proliferative lesions on GB mucosa usually represent cystic mucosal hyperplasia or papillary proliferations.
- Microscopic—variable mixed inflammatory infiltrate and fibrosis (chronic) in lamina propria of GB wall, focal areas of necrosis if necrotizing cholecystitis; GB mucosal hyperplasia—common; ascending cholangitis and cholangiohepatitis may develop as secondary complications; hepatocytes may demonstrate VH (glycogen and/or lipid inclusions) if underlying endocrinopathy (see associated conditions). Asymptomatic GB removed preemptively may only demonstrate cystic mucosal hyperplasia.

GALLBLADDER MUCOCELE

(CONTINUED)

TREATMENT

- Outpatient management with ursodeoxycholic acid and S-adenosylmethionine (SAMe) to induce cholerisis and provide hepatoprotection—medical therapy is not advised to resolve a GBM. Has resolved syndrome in some dogs but patients subject to GBM recurrence. Naïve treatment with choleretics may result in GB rupture.
- Inpatient—treatment depends on whether patient presents with severe acute necrotizing cholecystitis or syndrome determined incidentally on ultrasound examination.
- If patient is hyperlipidemic, investigate cause and restrict dietary fat (food, medications).
- Symptomatic patients require exploratory surgery for cholecystectomy and evaluation/treatment for potential bile peritonitis.
- Cholecystotomy and mucocele removal with GB retention may lead to GBM recurrence and bile peritonitis.
- Fluid therapy—balanced polyionic solutions to correct hydration and electrolytes.
- Be prepared for blood component therapy.
- Abdominal lavage—at surgery if bile peritonitis confirmed.

G

MEDICATIONS

DRUG(S)

Antimicrobials

Initiate broad-spectrum antimicrobials *before* surgery: enteric Gram-negative and anaerobic organisms most likely opportunists; continue treatment 4–8 weeks if septic complications; adjust drugs based on culture and sensitivity test reports.

Vitamin K₁

0.5–1.5 mg/kg IM or SC q12h for three doses—if jaundiced; oral route maybe ineffective if EHBDO: fat-soluble vitamin malabsorption.

Antiemetics/Antacids/Gastroprotectants

- Metoclopramide 0.2–0.5 mg/kg PO, IV, or SC q6–8h or 1–2 mg/kg/day by CRI.

- Ondasetron 0.5–1.0 mg/kg PO 30 min before feeding, maximum q8h or 0.1–0.2 mg/kg slow IV push q6–12h—if vomiting.
- H₂-receptor antagonists: famotidine 0.5 mg/kg PO, IV, SC q12–24h; may need to increase dose for efficacy.
- Omeprazole or pantoprazole may induce p450 cytochrome associated drug interactions; 24–48 h delay onset of action.
- Sucralfate 0.25–1.0 g PO q8–12h—for upper gastrointestinal bleeding.

Cholerisis

- Maintain hydration status.
- Ursodeoxycholic acid: choleretic, hepatoprotectant, anti-inflammatory, anti-endotoxic effects: (10–15 mg/kg PO divided BID daily with food), tablets provide best bioavailability; treat indefinitely
- S-adenosyl-methionine (SAMe) provides GSH-dependent choleretic effect, dose may be higher than used as an antioxidant (see below); choleresis with 40 mg/kg PO per day.

Antioxidants

- Vitamin E: α -tocopherol 10 IU/kg PO daily with food; antioxidant, anti-inflammatory, antifibrotic effects.
- S-adenosylmethionine (SAMe): 20 mg/kg PO daily 2h before feeding, use SAMe with proven bioavailability; give until liver enzymes normalize or indefinitely if chronic hepatitis.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

PATIENT MONITORING

- Repeat sequential hematology, biochemistry, and imaging to monitor response.
- Persistent clinicopathologic features may implicate underlying endocrinopathy requiring documentation and treatment, or an intrahepatic cholangiopathy.

POSSIBLE COMPLICATIONS

- Cholangitis or cholangiohepatitis • Bile peritonitis • EHBDO

EXPECTED COURSE AND PROGNOSIS

- Good with successful surgery, chronic choleretic therapy, correction or management of comorbid conditions, diet modification.
- Anticipate a protracted clinical course with ruptured biliary tract or peritonitis.
- Recrudescence may occur even if mucocele removed and GB retained, with or without chronic medical therapy.

MISCELLANEOUS

SEE ALSO

- Bile Peritonitis • Cholecystitis
- Cholelithiasis • Hepatitis, Chronic

GASTRIC DILATION AND VOLVULUS SYNDROME

BASICS

DEFINITION

- A disease in dogs in which the stomach dilates and subsequently rotates around its short axis. • Also known by the acronym GDV.

PATHOPHYSIOLOGY

- The exact mechanism involved in the development of GDV is poorly understood.
- The volvulus can occur in any direction, but the vast majority occurs in a clockwise rotation when the animal is in dorsal recumbency and the surgeon is viewing the patient from the caudal aspect.
- Factors thought to contribute include ingestion of a large amount of food or water, delayed gastric emptying, and excessive post-prandial activity. However, these factors do not occur with all cases of GDV.
- Subsequent to the gastric rotation, gas and fluid continue to become entrapped within the gastric lumen. Progressive distention of the stomach occurs.
- As the stomach becomes progressively distended, intra-abdominal pressure increases. This leads to compression of the compliant blood vessels of the abdomen including the caudal vena cava and portal vein. The reduction in blood flow through these major vessels leads to decreased cardiac return and hypovolemic shock.
- Decreased perfusion can lead to systemic effects including organ death, local and systemic inflammatory cascades, and disseminated intravascular coagulation.

SYSTEMS AFFECTED

- Gastrointestinal—decreased perfusion can lead to ischemic necrosis of the stomach. Due to the higher metabolic demand, the mucosa is predisposed to the effects of ischemia.
- Cardiovascular—significant decrease in the venous return to the heart results in a hypovolemic state. This leads to decreased cardiac output, which can lead to organ hypoxia and tissue damage/tissue death.
- Decreased myocardial perfusion, as well as the generation of inflammatory mediators, can lead to cardiac arrhythmias, particularly premature ventricular contractions.
- Hemic/Lymphatic/Immune—splenic insult is common, via avulsion of the short gastric vessels, splenic torsion, or splenic infarction.

GENETICS

No direct genetic predisposition confirmed; however, dogs with a first-order relative with a history of GDV are at an increased risk for development of GDV.

INCIDENCE/PREVALENCE

An incidence rate for large- and giant-breed dogs has been reported to be around 6%.

SIGNALMENT

Species

Dog

Breed Predilections

- Any large, deep-chested breed.
- Great Dane.
- German shepherd dog.
- Rarely reported in smaller, deep-chested breeds such as dachshund and Pekingese.

Mean Age and Range

Any age; risk increases with increasing age.

SIGNS

Historical Findings

- Vomiting, which often progresses to non-productive retching or “dry heaves”
- Anxious behavior
- Abdominal pain
- Abdominal distention
- Collapse
- Ptyalism
- Lethargy

Physical Examination Findings

- Possibly distended abdomen; however, distended stomach may be contained under ribs, in which case abdominal distention will not be seen.
- Tachycardia.
- Tachypnea or dyspnea.
- Weak pulses, pale mucus membranes with a prolonged capillary refill time are suggestive of hypovolemia.

CAUSES

- Unknown.
- Likely a multifactorial origin that includes anatomic, genetic, and environmental factors.

RISK FACTORS

- Classically has been linked to activity following a meal.
- Anatomic predisposition in deep-chested dogs, particularly large and giant breeds.
- It was also thought that a lowered food bowl encouraged aerophagia, which could lead to GDV. Recently eating from a RAISED food bowl has been identified as a risk factor for development of GDV.
- Having a first-degree relative with GDV and faster speed of eating have also been identified as being risk factors associated with the development of GDV.
- Possibly having gastrointestinal neoplasia, as it can cause motility disturbances as well as gastric retention of food and/or air.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other diseases that cause acute abdominal distention and potentially circulatory attenuation include septic peritonitis, hemoabdomen, intestinal volvulus, or acute gastroenteritis.
- “Food bloat” is the common name for gastric dilation without concurrent volvulus. This commonly occurs in dogs that engorge themselves with food.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC—stress leukogram, hemoconcentration, thrombocytopenia possibly.
- Biochemistry—electrolyte abnormalities are commonly encountered.

May see azotemia due to hypovolemia (prerenal). • Urinalysis—may see increased specific gravity with dehydration.

OTHER LABORATORY TESTS

Plasma lactate concentration has been found to be useful in predicting underlying gastric necrosis as well as prognosis. Median plasma lactate levels in dogs with gastric necrosis were significantly higher (6.6 mmol/L) than in dogs without gastric necrosis (3.3 mmol/L). Survival of dogs with plasma lactate levels < 6.0 mmol/L was 99%, compared with the 58% survival experienced by dogs with lactate levels > 6.0 mmol/L.

G

IMAGING

- Adequate stabilization is often necessary before obtaining radiographs.
- Abdominal radiography—a right lateral abdominal radiograph is the imaging modality of choice. Classically reveals compartmentalization of the stomach, which is considered to be pathognomonic.
- Dorsoventral view—may be helpful in confirming the disease.

DIAGNOSTIC PROCEDURES

- Very rarely, uncertainty may persist subsequent to obtaining survey radiographs.
- A positive-contrast upper GI can be attempted with CAUTION, as these patients are at an increased risk for aspiration!

PATHOLOGIC FINDINGS

- Splenic torsion may also be a concurrent finding.
- The stomach itself becomes edematous and undergoes vascular congestion and infarction, which can lead to necrosis.

TREATMENT

APPROPRIATE HEALTH CARE

- **This disease syndrome represents an emergency!** • Patients should be hospitalized, thoroughly assessed, and aggressively treated for cardiovascular insufficiency.
- A myriad of fluid therapy approaches are employed predicated on patient situation and personal preference. Crystallloid therapy, colloid therapy, or a combination can be used. If crystallloid therapy is chosen a dose of 90 ml/kg of an isotonic solution is administered over 30–60 minutes. Administered through cephalic or jugular venous access sites.
- Subsequent to cardiovascular stabilization, gastric decompression should be performed.
- Orogastic intubation is the preferred method of obtaining gastric decompression. Cardiovascular-sparing medications may be administered to patients in an effort to facilitate orogastric intubation. Commonly, considerable resistance is encountered upon reaching the esophageal hiatus. The lubricated tube can be twisted or repositioned to facilitate passage. Differing patient positions (sitting, standing, etc.) can also be attempted to facilitate passage.
- In cases where

GASTRIC DILATION AND VOLVULUS SYNDROME

(CONTINUED)

orogastric intubation is unsuccessful, percutaneous gastrocentesis can be attempted. A point of maximal tympany is located that typically corresponds to an area of the stomach that is gas-filled. A large diameter needle or catheter is passed into the stomach at this area. Gas typically will elicit an audible noise when escaping. Considerable time is necessary to achieve gastric decompression using this technique. • Upon patient stabilization and gastric decompression, surgical intervention is indicated. In rare cases in which patient is unresponsive to stabilization attempts, immediate surgical intervention may be taken.

ACTIVITY

Restriction of activity for approximately 2 weeks postoperative is recommended.

DIET

- Oral intake of food is recommended as soon as adequate recovery has been achieved.
- The role of food bowl height in the occurrence and recurrence of this disease is unclear at this time.
- Consider fat-restricted diets to enhance gastric emptying.

CLIENT EDUCATION

Owners of large- and giant-breed dogs who are not aware of the clinical signs of gastric dilation and volvulus should be educated.

SURGICAL CONSIDERATIONS

- Surgical intervention should be performed as soon as possible in a stable patient or in a patient in which diligent stabilization efforts have proved ineffective.
- Surgical intervention has three main goals: (1) anatomical reposition of the stomach (and spleen if applicable); (2) assessment of organ viability; (3) prevention of recurrence.
- Once repositioned, the stomach and spleen should be assessed. If non-vital areas are present, removal should be performed via partial gastrectomy and/or splenectomy.
- Prevention of recurrence is achieved through a permanent gastropexy. Multiple techniques for performing gastropexy have been described and choice of technique is largely based on surgeon preference.

MEDICATIONS

DRUG(S) OF CHOICE

- Perioperative antibiotics are indicated. The surgery itself, depending on severity and progression of disease, may be a clean, clean-contaminated, contaminated, or dirty surgery. It is often next to impossible to ascertain this information before the surgery is performed.
- Antibiotic selection should be predicated upon potential pathogens that the patient may be exposed to. Moderate-to-severe disease may expose the host to enteric

pathogens due to visceral perforation or loss of normal mucosal barriers to hematogenous bacterial translocation from the gastrointestinal tract. For these patients cefoxitin sodium (30 mg/kg IV q6–8h) may be an appropriate choice. For patients in which no entry into the gastrointestinal tract has occurred, cefazolin sodium (22 mg/kg IV q2h intraoperatively) is sufficient.

- Gastric protectants may be implemented to minimize or prevent gastrointestinal ulcerations.

CONTRAINdications

- The use of some synthetic colloids (e.g., hydroxyethyl starch) has been linked to disruption in the formation of the primary clot and may not be appropriate to use in certain patients with GDV, such as those with an underlying coagulopathy like concurrent DIC.
- Drugs that significantly depress cardiovascular function should be avoided if possible (e.g., acetylpromazine).

PRECAUTIONS

Patients may acutely decompensate at any time, particularly under anesthetic intervention.

ALTERNATIVE DRUG(S)

Efficacy of the administration of corticosteroids in patients affected with GDV is currently lacking.

FOLLOW-UP

PATIENT MONITORING

- Nursing care—some patients may require recumbent care for several days before eventual recovery.
- Adequate pain control.
- Premature ventricular contractions commonly occur postoperatively. These result from myocardial hypoperfusion and resultant ischemic damage, or due to splenic insult or removal. The monitoring of heart rhythm is recommended.
- Monitor urine production and renal function postoperatively.

PREVENTION/AVOIDANCE

- Elevation of food bowl is argued.
- Avoid exercise after eating or drinking.
- Possibly slowing the rate of consumption of meals.
- Some soak dry food in water before feeding or feed multiple, smaller meals.

POSSIBLE COMPLICATIONS

- Gastric dilation may recur, even after a gastropexy is performed. Recurrence of volvulus with an appropriately performed gastropexy is exceedingly rare.
- Failure to remove necrotic gastric tissue may result in eventual stomach perforation and septic peritonitis.
- Cardiac arrhythmias (particularly premature ventricular complexes), DIC, and gastric ulceration may also occur.

EXPECTED COURSE AND PROGNOSIS

- A heightened awareness by dog owners combined with an increased understanding of the complex pathophysiologic events associated with GDV have significantly reduced the mortality rate associated with this disease over the past 30 years.
- Prognosis in dogs treated appropriately that do not have gastric necrosis is excellent, with a reported survival rate of 98%.
- Dogs with gastric necrosis have a more guarded prognosis, with a reported survival rate of 66%.
- One article reported an overall short-term survival rate of 83.8%. Negative prognostic indicators included hypotension, DIC, peritonitis, and the need to perform both a splenectomy as well as a partial gastrectomy.

MISCELLANEOUS

AGE-RELATED FACTORS

A higher rate of GDV is typically seen in middle-aged to older dogs.

SYNOMYS

- Bloat
- Gastric torsion

SEE ALSO

GASTRIC MOTILITY DISORDERS

BASICS

DEFINITION

Gastric motility disorders result from conditions that directly or indirectly disrupt normal gastric emptying, which in turn may cause abnormal gastric retention, gastric distention, and subsequent gastric signs associated with anorexia, nausea, and vomiting.

PATHOPHYSIOLOGY

The stomach has two distinct motor regions. The proximal stomach relaxes to accommodate food and regulates the expulsion of liquids. Intrinsic slow contractions of this region push liquids through the pylorus. The distal stomach mechanically breaks down and expels solids through strong peristaltic contractions. The gastric pacemaker, an area of intrinsic electrical activity, located in the greater curvature of the stomach regulates distal gastric motility and emptying. Gastric electrical activity, dietary composition, and extrinsic factors all influence emptying. During fasting, indigestible solids are expelled from the stomach by migrating myoelectric complexes (MMC). These complexes produce strong “digestive housekeeper” contractions that sweep through the stomach and small intestine to mid-jejunum every 2 hours in the fasted state preparing the GI tract for the next meal. MMC motility is under the regulation of the hormone motilin. Dysrhythmias in normal gastric electrical activity may be fundamental in the pathophysiology of disorders affecting gastric motility.

SYSTEMS AFFECTED

Gastrointestinal

INCIDENCE/PREVALENCE

Unknown. Many factors can alter gastric emptying although they may not result in clinical disease.

SIGNALMENT

Species

Dog and cat

Breed Predilections

Unknown

Mean Age and Range

Signs occur at any age though it is uncommon to observe primary motility disorders in young animals.

SIGNS

General Comments

Clinical signs are often secondary to the primary etiology causing the gastric motility disorder.

Historical Findings

- The major clinical sign is chronic post-prandial vomiting of food. The stomach should normally be empty after an

average-sized meal in approximately 6–8 hours in dogs and 4–6 hours in cats (note: normal emptying times vary greatly from animal to animal and are influenced by meal volume, caloric density, fiber content, and environmental factors). Vomiting of undigested food > 12 hours following the meal suggests abnormal gastric motility or possibly outflow obstruction. Vomiting can occur, however, any time following eating.

- Other signs include gastric distention, nausea, anorexia, belching, pica, and weight loss.
- The distal esophageal sphincter may also be incompetent with gastric hypomotility and signs associated with reflux esophagitis may be present.

Physical Examination Findings

- Normal or findings associated with the underlying cause of the disorder.
- Palpation of a large, distended stomach.
- Decreased gastric sounds on abdominal auscultation.

CAUSES

- Primary idiopathic gastric motility disorders may arise from defects in normal myoelectric activity. Most motility disorders occur secondary to other primary conditions.
- Metabolic disorders include hypokalemia, uremia, hepatic encephalopathy, and hypothyroidism.
- Nervous inhibition as the result of stress, fear, pain, or trauma.
- Drugs such as the anticholinergics, β -adrenergic agonists, narcotics, and chemotherapeutics.
- Primary gastric disease such as outflow obstructions, gastritis, gastric ulcers, parvovirus, and gastric surgery.
- Gastric dilatation volvulus (GDV) syndrome is suspected to be in part the result of abnormal gastric motility associated with changes in myoelectric and mechanical activity. Some dogs with GDV may also continue to have signs of gastric hypomotility following surgical gastropexy.
- Gastroesophageal reflux and enterogastric reflux (see Biliary Vomiting Syndrome) may result from primary gastric hypomotility.
- Dysautonomia is associated with abnormal esophageal, gastric and intestinal motility.

RISK FACTORS

Any potential gastric disease may result in secondary hypomotility.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

The differential diagnosis is extensive and should include any condition causing vomiting. Gastric outflow obstructions must always be ruled out.

CBC/BIOCHEMISTRY/URINALYSIS

Routine hemogram, serum chemistry profile, urinalysis, and fecal flotation must be performed to rule out the potential cause of gastric hypomotility. Continued vomiting

may result in dehydration, electrolyte abnormalities, or acid-base imbalance.

OTHER LABORATORY TESTS

Specialized testing may be required to determine a specific cause of gastric hypomotility, and is individualized for each patient.

IMAGING

Survey Radiographs

Abdominal radiographs may reveal a gas-, fluid-, or ingesta-distended stomach. (Note: it is important to determine when the patient was last fed in relationship to when radiographs were taken.)

G

Liquid Barium Contrast Study

May be evidence of delayed gastric emptying and decreased gastric contractions if evaluated using fluoroscopy. Some cases may have normal emptying of liquids but abnormal emptying of solids. (Note: the stress of radiographs may decrease gastric emptying even in the normal animal.)

Food Barium Contrast Study

Barium mixed with a standard meal may demonstrate delayed gastric emptying of solids. Normal dogs should empty their stomachs by approximately 6–8 hours. Abnormal gastric retention is associated with significantly longer gastric emptying times.

Food-Marker Contrast Study

Barium-impregnated small markers (BIPS) or other radiopaque markers mixed with a standard meal will have delayed passage similar to the food barium contrast study.

Radionuclide Emission IMAGING

Radionuclide markers mixed with a meal give the most clinically accurate measurement of emptying. Gastric emptying times (time for a standard meal to leave the stomach) range from 4 to 8 hours.

Ultrasonography

Ultrasound can be used to evaluate antral and pyloric motility.

Smartpill

This is a non-invasive wireless sensor capsule that is given orally and transmits data on pressures, transit time, luminal pH and temperature as it passes through the stomach and small and large bowel. It has been validated for use in the healthy dog but as yet there are limited reports evaluating clinical conditions.

DIAGNOSTIC PROCEDURES

Endoscopy

Endoscopic findings are frequently normal in idiopathic conditions. Food may be found in the stomach when it should be empty following a 12-hour pre-endoscopic fasting period. Endoscopy will detect obstructive or inflammatory diseases of the stomach.

Pathologic Findings

- Idiopathic conditions have normal gastric mucosa.
- Gastric histology may identify

GASTRIC MOTILITY DISORDERS

(CONTINUED)

inflammatory or neoplastic causes to explain the gastric hypomotility.

TREATMENT

APPROPRIATE HEALTH CARE

- Most patients are treated as outpatients.
- With severe vomiting or dehydration and electrolyte imbalance, hospitalization and specific therapy are required.

NURSING CARE

G Dehydration with fluid and electrolyte imbalance requires appropriate fluid replacement.

ACTIVITY

Restrictions are based on the underlying disease.

DIET

- Dietary manipulation is important in the management of primary gastric motility disorders.
- Diets should be formulated that are liquid or a semi-liquid consistency and low in fat and fiber content.
- Small-volume meals with frequent feeding should be given.
- Often dietary manipulation alone is successful in managing patients with delayed gastric emptying from a motility disorder.

CLIENT EDUCATION

Discuss possible underlying etiologies of altered gastric motility and that the response to therapy varies with individual cases.

SURGICAL CONSIDERATIONS

- Large-breed dogs with chronic GDV syndrome and gastric retention should have a prophylactic surgical gastropexy.
- Following any gastric surgery it generally takes several days but up to 14 days for motility to return to normal.
- Patients with mechanical gastric outflow obstructions require surgical correction.

MEDICATIONS

DRUG(S) OF CHOICE

Gastric Prokinetic Agents

- Metoclopramide increases the amplitude of antral contractions, inhibits fundic receptive relaxation, and coordinates duodenal and gastric motility. It is a dopamine receptor antagonist in the proximal GI tract resulting in increased release of acetylcholine from enteric neurons. At higher concentrations it has serotonin (5HT₄) agonist effects. It also has antiemetic effects, blocking the chemoreceptor trigger zone in the brainstem in dogs but not cats. Oral dosage is 0.2–0.5 mg/kg q8h given 30 minutes before meals (use lower dose in cats) or as a CRI at 1–2 mg/kg q24h. Metoclopramide is generally considered to be a weak prokinetic

agent in dogs and recent studies suggest it has little effect at increasing the lower esophageal sphincter pressure.

- Cisapride works directly by cholinergic neurotransmission (5HT₄ agonist) of gastrointestinal smooth muscle, stimulating motility. The proposed mechanism of action is that it enhances the release of acetylcholine at the myenteric plexus, but does not induce nicotinic or muscarinic receptor stimulation. Cisapride increases lower esophageal sphincter pressure, improves gastric emptying, and promotes increased motility of both the small and large intestine. A suggested dose is 0.2–0.5 mg/kg PO q8–12h given before meals. Cisapride is currently available through compounding pharmacies because the human product has been removed from the market because of associated cardiac arrhythmias not identified to occur in dogs or cats. Mosapride (0.5–2 mg/kg PO q12–24h) and Prucalopride (0.02–0.6 mg/kg PO q12–24h) are also serotonergic (5HT₄ agonist) prokinetic agents not yet available in the United States.

• Macrolide antibiotics, including erythromycin and clarithromycin, are motilin receptor agonists and increase gastrointestinal motility. Motilin is a GI hormone that promotes MMC associated motility. Erythromycin given at low (sub-microbiologic) doses binds on motilin receptors promoting acetylcholine release, which in turn promotes gastric emptying. The suggested dose of erythromycin for specific motility effects is 0.5–1 mg/kg PO q8–12h, given 30 minutes before meals.

- Other drugs: Domperidone is a peripheral dopamine receptor antagonist that has been marketed outside the United States. It regulates the motility of gastric and small-intestinal smooth muscle similar to that of metoclopramide. Mirtazapine is a noradrenergic and specific serotonergic antidepressant and has reported gastric prokinetic effects in dogs.
- The H₂ receptor antagonists ranitidine (1–2 mg/kg q8h) and nizatidine (2.5–5 mg/kg q24h) have reported prokinetic effects on gastric motility due to acetylcholinesterase inhibition. They are considered as poor prokinetic drugs and recent studies question ranitidine's prokinetic activity in dogs. Neither cimetidine nor famotidine affect gastric emptying.

CONTRAINDICATIONS

- Gastric prokinetic agents should not be administered in patients with a gastric outflow obstruction.
- Metoclopramide is contraindicated with concurrent phenothiazine and narcotic administration or in animals with epilepsy.

PRECAUTIONS

- Metoclopramide may cause nervousness, anxiety, or depression.
- Cisapride may cause depression, vomiting, diarrhea, or abdominal cramping.
- Erythromycin may cause vomiting.

FOLLOW-UP

PATIENT MONITORING

- Response to therapy varies according to the underlying cause.
- Failure to respond medically necessitates further investigation for mechanical obstruction.

EXPECTED COURSE AND PROGNOSIS

- The length of treatment depends on the ability to resolve the underlying disorder or on the response to therapy.
- It may take gastric surgery or parvovirus cases several days to up to 2 weeks to regain normal gastric function.
- Generalized dysautonomia has a grave prognosis.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Gastric hypomotility may be associated with both reflux esophagitis and reflux gastritis (see biliary vomiting syndrome).

PREGNANCY/FERTILITY/BREEDING

Avoid gastric prokinetic agents in pregnant animals.

GASTRITIS, ATROPHIC

BASICS

OVERVIEW

A type of chronic gastritis characterized histologically by a focal or diffuse reduction in size and depth of gastric glands with associated inflammatory cells.

SIGNALMENT

- Variable, uncommon in young patients. • A high prevalence in the Norwegian Lundehund (range 4–13 years old), males overrepresented.

SIGNS

- Chronic vomiting, most often intermittent, food or bile. • Anorexia, lethargy, weight loss, edema or ascites.

CAUSES & RISK FACTORS

- Idiopathic inflammatory gastroenteritis a potential risk factor. • May reflect chronic gastritis of any cause. • Suspect genetic predisposition in the Norwegian Lundehund.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other forms of chronic gastritis and chronic enteritis

CBC/BIOCHEMISTRY/URINALYSIS

- Anemia with thrombocytopenia or thrombocytosis may be present if gastric ulceration is present. • Panhypoproteinemia with no proteinuria can be present with primary disease and in animals with concurrent protein-losing enteropathy.

OTHER LABORATORY TESTS

- Achlorhydria has been reported in dogs; may lead to intestinal dysbiosis. • Consider diagnostic testing for hepatobiliary and pancreatic disease, as well as for subnormal cobalamin concentration, in cats.
- Endoscopic biopsies of the small intestines should be performed to evaluate for infiltrative disease.

IMAGING

- Survey radiographs of the thorax and abdomen are typically unremarkable. Stomach may contain ingesta despite adequate fasting, suggesting delayed gastric emptying. • Ultrasonography of the abdomen may reveal a thickened or normal gastric wall, gastric masses, the presence or absence of mesenteric lymphadenopathy, thickened or normal intestinal walls, presence or absence of abdominal effusion. • Lymphadenopathy and masses may be present with gastric neoplasia.

DIAGNOSTIC PROCEDURES

Definitive diagnosis: gastroscopy with biopsy and histopathologic evaluation.

PATHOLOGIC FINDINGS

- Histopathologic examination of gastric biopsy specimens reveals glandular atrophy and inflammatory infiltrates (neutrophils or mononuclear cells). Majority of lesions are located in the fundic region. In non-Lundehunds, lymphocytic plasmacytic gastritis found with atrophy. Fibrosis may be present. • Mucin staining in Lundehunds gives abnormal mucus neck cells and pseudo-pyloric metaplasia. Neoplastic transformation may be associated with linear hyperplasia of neuroendocrine cells (requires special staining, request in suspected cases: chromagrin A, synaptophysin, Sevier-Munger method). • The role of *Helicobacter* infection is controversial. Cats developing atrophic gastritis have been found to have *H. pylori* infections, but active *Helicobacter* infections have not been documented in canine cases. Urease activity in gastric biopsies is not diagnostic and poorly correlated with actual infection. Clinical infection is supported by histological documentation of spiral bacteria in gastric mucosa and pits with associated inflammation.

TREATMENT

- Optimal therapy is unknown. Trial therapy for food-responsive gastropathy with an elimination diet can be tried. Tylosin can be administered in the event that the disorder has an antibiotic-responsive component. Treat any underlying etiology identified. • Enteral feeding tube may be indicated in cachexic patients. • If gastric emptying is delayed, low residue fat-restricted diets may aid in emptying; elimination diets containing novel, single protein sources may be helpful in select cases.

MEDICATIONS

DRUG(S)

- Histamine type-2 receptor antagonists (e.g., famotidine 0.5–1 mg/kg PO q12h) or proton pump inhibitors (e.g., omeprazole 0.7–1.5 mg/kg PO q12–24h) to inhibit gastric acid secretion and prevent esophagitis. Long-term use of omeprazole should be avoided if possible in light of potential adverse effects (hypocalcemia, osteoporosis, intestinal dysbiosis, hypocobalaminemia, increased risk of diarrhea). • If vomiting persists, antiemetics such as maropitant (1–2 mg/kg PO or SC q24h, for 5 days in dogs, 15 days in cats) or ondansetron (0.5 mg/kg PO or SC q24h for 5–7 days) or prokinetics such as metoclopramide (0.2–0.5 mg/kg PO q8h) or

cisapride (0.3–0.5 mg/kg PO q8–12h) may be indicated. • If infection with *Helicobacter* spp. is confirmed based upon histopathologic lesions in the stomach consistent with *Helicobacter* infection, consider triple therapy: amoxicillin at 11–22 mg/kg PO q12h, metronidazole 10–15 mg/kg PO q12h and famotidine 0.5–1.0 mg/kg PO q12h or omeprazole 0.7–1.5 mg/kg PO q24h for 2 weeks. This infection may recur.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Be cautious with medications known to exacerbate gastritis, such as corticosteroids and nonsteroidal anti-inflammatory drugs.

FOLLOW-UP

- Long-term intermittent antacid therapy may be required—long-term administration of omeprazole is discouraged. • Correlation with progression to gastric cancer (adenocarcinoma or neuroendocrine carcinoma) is suspected but not proven. However, this has been documented in the Norwegian Lundehund breed. If signs persist or recur, monitor for developing gastric tumors (chest radiographs, abdominal ultrasound).

MISCELLANEOUS

Hypergastrinemia and hypoacidity is suspected but not proven in veterinary patients.

ASSOCIATED CONDITIONS

- Chronic enteritis of inflammatory, autoimmune, or infectious causes.
- Protein-losing enteropathy in the Lundehund.

SEE ALSO

- Gastritis, Chronic • Vomiting, Chronic

Author Jessica M. Clemans-Ring
Consulting Editor Stanley L. Marks

GASTRITIS, CHRONIC

BASICS

DEFINITION

- Intermittent vomiting of > 1–2 weeks in duration secondary to gastric inflammation.
- Presence of gastric erosions or ulcers dependent on the inciting cause and duration.

PATHOPHYSIOLOGY

- Chronic irritation of the gastric mucosa by chemical irritants, drugs, foreign bodies, infectious agents, or hyperacidity syndromes resulting in an inflammatory response in the mucosal surface that may extend to involve submucosal layers.
- Chronic allergen exposure or immune-mediated disease may also produce chronic inflammation.

SYSTEMS AFFECTED

- Gastrointestinal—esophagitis may result from chronic vomiting or gastroesophageal reflux.
- Respiratory—aspiration pneumonia is infrequently seen secondary to chronic vomiting; it is more likely if concurrent esophageal disease exists or if the patient is debilitated.

INCIDENCE/PREVALENCE

Relatively common

SIGNALMENT

Species

Dog and cat

Breed Predilections

- Old, small-breed dogs (i.e., Lhasa apso, Shih Tzu, miniature poodle) are more commonly affected with antral mucosal hyperplasia and hypertrophy.
- Norwegian Lundehunds are predisposed to chronic atrophic gastritis.
- Basenjis and the Drentse patrijshond (aka Dutch partridge dog or Drent) breed can develop chronic hypertrophic gastritis.

Mean Age and Range

Varies with underlying cause

Predominant Sex

Varies with underlying cause

SIGNS

Historical Findings

- Vomitus is frequently bile-stained and may contain undigested food, flecks of blood, or digested blood ("coffee grounds").
- Frequency varies from daily to every few weeks and increases as gastritis progresses.
- Vomiting may be stimulated by eating or drinking.
- Early morning vomiting before eating may indicate bilious vomiting syndrome.
- May see weight loss with chronic anorexia.
- May see melena with ulceration (not common).
- Increased water intake.
- Diarrhea, if concurrent intestinal disease

Physical Examination Findings

- Generally within normal limits.
- May be thin with persistent anorexia.
- May have pale mucous membranes with anemia from

chronic blood loss.

- May find cranial abdominal pain (rarely noted).

CAUSES

- Inflammatory—immune-mediated, dietary allergy or intolerance, idiopathic.
- Dietary indiscretion—plant material, foreign objects, chemical irritants.
- Toxins—fertilizers, herbicides, cleaning agents, heavy metals.
- Metabolic/endocrine disease—azotemia, chronic liver disease, hypoadrenocorticism, pancreatitis.
- Neoplastic—common: gastrointestinal lymphoma, gastric adenocarcinoma, small cell lymphoma (especially cats, recent increase in dogs); infrequent: gastric polyps, gastrinoma, leiomyosarcoma, plasma cell tumor, mast cell tumor.
- Parasitism—*Physaloptera* spp. (dogs, cats), *Ollulanus tricuspis* and *Gnathostoma* spp. (cats).
- Drugs—NSAIDs, glucocorticoids.
- Infectious—*Helicobacter* spp., *Pythiosis*, viral (distemper in dogs, feline leukemia virus in cats).
- Miscellaneous—duodenogastric reflux (bilious vomiting syndrome), stress, achlorhydria.

RISK FACTORS

- Medications—NSAIDs, glucocorticoids.
- Environmental—unsupervised/free-roaming pets are more likely to ingest inappropriate foods or materials.
- Ingestion of a dietary antigen to which an allergy or intolerance has been acquired.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Although the causes listed above are included in the differential diagnosis of chronic gastritis, an identifiable cause is often not found for the gastric inflammation.
- Must differentiate chronic vomiting from chronic regurgitation (active vs. passive vomiting).
- Small intestinal inflammation and gastric or small intestinal neoplasia often present with signs and physical exam findings similar to those of gastric inflammation.
- Idiopathic gastritis—diagnosis of exclusion; often characterized by a predominantly lymphoplasmacytic infiltrate (superficial or diffuse).
- Eosinophilic gastritis, hypertrophic gastritis, granulomatous/histiocytic gastritis, and atrophic gastritis are less common; often overlap of histologic changes exists in the types of inflammatory infiltrates.
- Atrophic gastritis differs on endoscopic examination—resulting in visualization of the submucosal vessels secondary to thinning of the gastric mucosa.
- Hypertrophic gastritis—prominent mucosal folds that do not flatten with gastric insufflation.

CBC/BIOCHEMISTRY/URINALYSIS

- Hemogram usually unremarkable unless systemic disease present.
- Hemoconcentration if severe dehydration.
- May see

- nonregenerative (anemia of chronic disease) or regenerative anemia (blood loss).
- With ulceration—microcytic, hypochromic anemia associated with iron deficiency if prolonged, severe blood loss.
- May see eosinophilia with eosinophilic gastroenteritis.
- Azotemia with low urine specific gravity in uremic gastritis.
- Increased serum hepatic enzyme activities, total bilirubin, or hypoalbuminemia with chronic hepatic disease.
- Hyperkalemia and hyponatremia suggest Addison's disease.
- Hyponatremia, hypokalemia, hypochloremia, and an elevated bicarbonate level with an acidotic urine suggest a gastric outflow obstruction (hypochloremic metabolic alkalosis).

OTHER LABORATORY TESTS

Elevated serum gastrin level without azotemia suggests a gastrinoma.

IMAGING

- Survey abdominal radiographs—usually normal, but may reveal radiodense foreign objects, a thickened gastric wall, or gastric outflow obstruction with persistent gastric distension.
- Contrast radiography—may detect foreign objects, gastric outflow obstruction, delayed gastric emptying, or gastric wall defects or thickening.
- Ultrasonography—may detect gastric wall thickening, ulceration, and gastric foreign objects.

DIAGNOSTIC PROCEDURES

- Gastroscopy—usually adequate for visualization of the gastric mucosa and for biopsy but in most cases one should also evaluate and biopsy the duodenum.
- Gastric biopsy and histopathology is required for diagnosis, even if gastric mucosa appears normal.
- Foreign objects can be identified and retrieved via endoscopy.
- Exploratory celiotomy is indicated if a perforated ulcer or submucosal lesion of the gastric wall is suspected and partial gastrectomy or full-thickness biopsy is required.
- Fecal flotation may reveal intestinal parasites.

PATHOLOGIC FINDINGS

- Idiopathic gastritis—inflammatory infiltrates vary; can be lymphocytes, plasma cells, neutrophils, eosinophils, and/or histiocytes.
- Mucosal changes can be degenerative, hyperplastic, or atrophic.
- May see varying degrees of edema and fibrous tissue; may see *Helicobacter* spp. Must be noted within gastric glands to be significant and should be accompanied by a lymphofollicular gastritis; special stains can be requested for fungal hyphae and *Helicobacter*.
- May see lymphoplasmacytic inflammation along with *Helicobacter* spp. Treatment for *Helicobacter* may result in resolution of clinical signs without immunosuppressive therapy.
- If hyperplastic changes are noted, a gastrin level should be obtained before institution or after discontinuation of antacids, H₂ blockers or proton pump blockers.

(CONTINUED)

TREATMENT

APPROPRIATE HEALTH CARE

- Most patients are stable at presentation unless vomiting is severe enough to cause dehydration.
- Can typically manage as outpatient, pending diagnostic testing or undergoing clinical trials of special diets or medications.
- If patient is dehydrated or if vomiting becomes severe, hospitalize and institute appropriate intravenous crystalloid fluid therapy (see Vomiting, Acute).

DIET

- Soft, low-fat food ideally from a single carbohydrate and protein source.
- Non-fat cottage cheese, boiled skinless white meat chicken, boiled hamburger or tofu as a protein source, and rice, pasta, or potato as a carbohydrate source, in a ratio of 1:3.
- Frequent, small meals (q4–6h or more frequently).
- Can use novel protein source or hydrolyzed protein diet if dietary allergy is suspected.
- Feed diets for a minimum of 2–3 weeks to assess adequacy of response.
- Feed a late-night meal to help prevent bilious vomiting syndrome in the early morning hours.

CLIENT EDUCATION

- Gastritis has numerous causes.
- Diagnostic workup—may be extensive; usually requires a biopsy for a definitive diagnosis.

SURGICAL CONSIDERATIONS

- Surgical management if a granulomatous mass or hypertrophy is causing a gastric outflow obstruction.
- Gastrotomy for removal of foreign objects if endoscopic retrieval is unsuccessful or is not available.

MEDICATIONS

DRUG(S) OF CHOICE

- Treat any gastric erosions and ulcers (see Gastroesophageal Reflux Disease).
- Give glucocorticoids (prednisone 2–4 mg/kg PO q24h [rarely requires high end of dose to start]; taper by 25% every 2–3 weeks over 2–3 months) for chronic gastritis secondary to suspected immune-mediated mechanisms if no clinical response to dietary management. Never exceed a total dose of 60 mg of prednisone no matter how heavy the dog is.
- Treatment for *Helicobacter* gastritis—amoxicillin (22 mg/kg PO q12h), peptobismol (15 mg/kg PO q6–8h) and metronidazole (10 mg/kg PO q12h) for 3 weeks (see *Helicobacter* Infection).
- Antiemetics (maropitant 1 mg/kg PO/SC q24h) for fluid and electrolyte disorders caused by frequent or profuse vomiting (see Vomiting, Acute).
- Metoclopramide (0.2–0.4 mg/kg PO q6–8h), cisapride

(0.5–1 mg/kg PO q8h to q12h), or low-dose erythromycin (0.5–1 mg/kg PO q8h) to increase gastric emptying and normalize intestinal motility if gastric emptying is delayed or gastroduodenal reflux is present. Metoclopramide is most effective as a CRI administered at 1–2 mg/kg q24h.

CONTRAINDICATIONS

- Do not use prokinetics, metoclopramide, or cisapride if gastric outflow obstruction is present.
- Antacids are not indicated with atrophic gastritis and achlorhydria.

PRECAUTIONS

- Steroids are immunosuppressive, making close monitoring for secondary infections important.
- Steroids may also inhibit the normal gastric mucosal barrier, leading to ulceration.

ALTERNATIVE DRUG(S)

- Synthetic prostaglandin E1 (misoprostol 1–3 µg/kg PO q6–8h) to prevent gastric mucosal ulcers with NSAID toxicity.
- For additional immunosuppression when in need of an immediate response, add chlorambucil (0.1–0.2 mg/kg q24h for 7 days then q48h). Often used in place of azathioprine but can be used in addition. A recent study suggests that this addition may be superior to adding azathioprine.
- Immunosuppressive drugs such as azathioprine (2.2 mg/kg PO q24h, tapering to q48h after 2–3 weeks in dogs) if an immune-mediated mechanism is suspected and response to dietary management and glucocorticoid administration is inadequate. Expect response to occur in 2–3 weeks. Avoid use of azathioprine in cats because the drug is markedly myelosuppressive.

FOLLOW-UP

PATIENT MONITORING

- Resolution of clinical signs indicates a positive response.
- Recheck electrolytes and acid-base status if initially abnormal.
- Complete blood counts should be obtained weekly and then reduced to q4–6 weeks for patients on myelosuppressive drugs (i.e., azathioprine, chlorambucil). Additional chemistry monitoring q2–3 months as well.
- Repeat diagnostic workup and consider possible rebiopsy if signs decrease but do not resolve.
- Repeat diagnostic workup and consider rebiopsy if signs resolve and then recur several months to years later, especially in cats. IBD can progress to small cell lymphoma in the cat.

PREVENTION/AVOIDANCE

- Avoid medications (e.g., corticosteroids, NSAIDs) and foods that cause gastric irritation or allergic response in the patient.
- Prevent free-roaming and potential for dietary indiscretion.

GASTRITIS, CHRONIC

POSSIBLE COMPLICATIONS

- Progression of gastritis from superficial to atrophic gastritis.
- Gastric erosions and ulcers with progressive mucosal damage.
- Aspiration pneumonia.
- Electrolyte or acid-base imbalances.

EXPECTED COURSE AND PROGNOSIS

Varies with underlying cause

MISCELLANEOUS

AGE-RELATED FACTORS

Young animals are more likely to ingest foreign objects.

G

PREGNANCY/FERTILITY/BREEDING

- Prednisone has been used safely in pregnant women; corticosteroids have been associated with increased incidence of congenital defects, abortion, and fetal death.
- Azathioprine has been used safely in pregnant women and may be a good substitute for corticosteroids in pregnant animals.
- Do not administer misoprostol to pregnant animals.

SEE ALSO

GASTRODUODENAL ULCERATION/EROSION (GUE)

BASICS

DEFINITION

Ulcers are defects that extend completely through the mucosa; erosions only extend part way through the mucosa.

PATHOPHYSIOLOGY

- Gastroduodenal ulcers/erosions (GUE) result from various factors which damage or overwhelm normal gastric mucosal defense and repair mechanisms.
- Factors protecting the stomach from GUE include the mucus-bicarbonate layer, gastric epithelial cell turnover, gastric mucosal blood flow, and locally produced prostaglandins.

SYSTEMS AFFECTED

- Gastrointestinal—ulcers and/or erosion are most common in the stomach and then the proximal duodenum; however, neoplasia and some drugs (e.g., flunixin meglumine) can cause ulceration anywhere in GI tract.
- Cardiovascular—hemorrhage may cause anemia, tachycardia, systolic heart murmur, and/or hypotension.
- Peritoneal cavity—perforation may cause peritonitis/sepsis/SIRS.

INCIDENCE/PREVALENCE

- 40–60% in exercising Alaskan sled dogs.
- Relatively common in dogs receiving NSAIDs or dexamethasone.

SIGNALMENT

Species

- Primarily dog; cat uncommonly affected.

Breed Predilections

Chow chows, rough-coated collies, Staffordshire bull terriers, and Belgian shepherd dogs have increased incidence of gastric carcinoma.

Mean Age and Range

All ages

Predominant Sex

Male dogs are predisposed to gastric carcinoma.

SIGNS

General Comments

Patients can be asymptomatic, hyporexic, vomiting, and/or have GI bleeding. Severity of clinical signs is not necessarily proportional to size/number of GUE.

Historical Findings

- Some animals with GUE are asymptomatic (e.g., patients taking NSAIDs or dexamethasone, dogs working in extreme environments).
- Hyporexia is the most common clinical sign.
- Vomiting, hematemesis, and/or melena may be seen (in decreasing order of frequency).
- Cranial abdominal pain ("praying position") is rarely seen.
- Weakness, pallor, lethargy, and/or collapse if severe anemia or SIRS develops.

Physical Examination Findings

- Physical examination often normal.
- Melena is rare.
- Pale mucous membranes and weakness if severely anemic (infrequent).
- Tachycardia, hypotension, and prolonged capillary refill time if hypovolemic shock or perforation/SIRS occur.

CAUSES

Drugs

- NSAIDs—COX-2 selective NSAIDs are usually safer than non-selective NSAIDs, however, GUE and perforation can occur with all COX-2 selective NSAIDs.
- Coadministration of glucocorticoids (either systemic or local) enhances ulcerogenic potential of NSAIDs. Some NSAIDs are renowned for being extremely ulcerogenic (flunixin meglumine, naproxen, indomethacin).
- Glucocorticoids: dexamethasone is probably the most ulcerogenic. Prednisolone is much less likely to cause GUE unless there are additional stress factors (e.g., hypoxemia, hypoperfusion) affecting the GI mucosa.

Gastrointestinal Diseases

- Gastrointestinal neoplasia: carcinomas are most common cause of neoplastic ulceration, but leiomyomas/leiomyosarcomas are renowned for causing severe hemorrhage.
- Pythiosis can cause severe GUE. It is a regionally important disease and is becoming increasingly widespread in North America.
- Foreign bodies can be associated with GUE, but they are usually not an important cause in the stomach. Intestinal foreign bodies (especially linear foreign bodies) commonly cause intestinal ulceration/perforation.
- Gastric hyperacidity.

Infectious Diseases

Pythiosis

Metabolic Diseases

- Hepatic disease
- Hypoaldrenocorticism
- Pancreatitis

Toxicity

Heavy metal poisoning (arsenic, zinc, thallium, iron, or lead are rare causes)

Neoplasia

- GI neoplasia (carcinoma, lymphoma, leiomyoma, GI stromal tumor [GIST])
- Paraneoplastic hyperacidity (mastocytosis, gastrinoma)

Stress/Major Medical Illness

- Shock/severe hypotension (e.g., secondary to trauma or surgery)
- SIRS (heat stroke, sepsis)
- Burns
- Sustained strenuous exercise (especially in extreme environments, either cold or hot)

RISK FACTORS

- Ulcerogenic drugs (NSAIDs, dexamethasone)
- Hypovolemic shock/SIRS
- Extreme exercise

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Esophageal disease (neoplasia, esophagitis, foreign body) diagnose with radiography and/or esophagoscopy.
- Coagulopathies (thrombocytopenia, anticoagulant poisoning): diagnose with platelet count, coagulation testing.
- Bronchopulmonary disease causing hemoptysis: diagnose with radiography and/or bronchoscopy.
- Regurgitation or vomiting of blood (hematemesis) swallowed from respiratory tract or swallowed with food.
- Pepto-Bismol, sucralfate, or activated charcoal cause stool to resemble melena.

CBC/BIOCHEMISTRY/URINALYSIS

- Acute blood loss (i.e., 3–5 days): non-regenerative anemia/hypoalbuminemia.
- Blood loss > 7 days: regenerative anemia/hypoalbuminemia.
- Chronic blood loss: iron deficiency anemia (i.e., microcytic, hypochromic, variable reticulocytosis) and hypoalbuminemia.
- BUN:creatinine ratio may be elevated with acute, severe GI hemorrhage, but this is hard to evaluate without recent pre-bleed laboratory values.

OTHER LABORATORY TESTS

- Fecal flotation (parasitism)
- Bile acids (hepatic insufficiency)
- Resting serum cortisol (screen for hypoadrenocorticism)
- Serum gastrin concentrations (gastrinoma is rare)

IMAGING

- Abdominal radiography (GI foreign body, abdominal mass, pancreatitis, pneumoperitoneum, effusion, hepatic disease).
- Barium contrast radiography is very insensitive for GUE.
- Ultrasonography has high specificity but questionable sensitivity for GI lesions (e.g., infiltrates, altered layering, ulcer); cannot detect erosions.

DIAGNOSTIC PROCEDURES

- Endoscopy is most sensitive test for GUE. It also allows biopsy of lesions. Can try to biopsy margin including normal and abnormal tissue; however, it is optimal to biopsy normal appearing tissue around GUE plus the periphery of the ulcer. Be careful about biopsying center of ulcers as this occasionally causes perforation.
- Fine-needle aspirates or biopsies of infiltrative lesions in GI tract.
- Abdominocentesis may reveal septic peritonitis if ulcer perforates.
- Exploratory surgery can be done to look for GUE, but it can be hard to see GUE or other mucosal lesions from serosal surface. It is easy to look into stomach through gastrostomy incision and miss lesions.

PATHOLOGIC FINDINGS

- GUE are grossly visible.
- Gastric body and antrum are most common sites of GUE (especially from NSAIDs and

(CONTINUED)

GASTRODUODENAL ULCERATION/EROSION (GUE)

dexamethasone), but GUE can occur anywhere in stomach. • Proximal duodenal ulceration is classic but not diagnostic for excessive gastric acid secretion (mast cell tumor, gastrinoma). • Microscopically can see inflammation, neoplasia, or fungal organisms.

**TREATMENT****APPROPRIATE HEALTH CARE**

VERY IMPORTANT: Remove underlying cause if possible, especially drugs, toxins, and/or poor perfusion. Some GUE resolve spontaneously if cause is removed.

SUPPORTIVE CARE

- IV fluids if needed to maintain hydration, gastric mucosal perfusion, and/or treat shock.
- Transfusions if patient has severe GI hemorrhage.

ACTIVITY

Based upon patient's condition

DIET

- Discontinue oral intake if vomiting.
- When feeding is resumed, feed small amounts of low-fat/low-fiber diet.

CLIENT EDUCATION

- Dogs are especially prone to NSAID-induced GUE because these drugs usually have a longer half-life in dogs than in humans. • Never administer an NSAID (especially if sold for human use) unless specifically told to use it by a veterinarian. For example, a low dose of aspirin at 0.5 mg/kg q24h is frequently used to prevent thromboembolic disease in dogs at increased risk. • Hyporexia is often the first sign of GUE and may be the only evidence in patients receiving NSAIDs. • Adverse effects of NSAIDs reduced by giving drug with food.
- Proton pump inhibitors help prevent NSAID-induced GUE, but misoprostol is probably the most effective prophylactic drug.
- No drug is effective in preventing dexamethasone-induced GUE.

SURGICAL CONSIDERATIONS

- If GI blood loss is potentially life threatening, perform gastroduodenoscopy to identify sites of hemorrhage and then either surgically resect lesions or cauterize sites endoscopically (either electrically or chemically). • Surgical excision of ulcers is indicated if medical treatment shows no evidence of helping after 5–7 days. • Rarely need to do intraoperative endoscopy to locate lesions which cannot be found at surgery.
- Rarely may need to have surgeon telescope intestines over the tip of the endoscope to allow thorough examination of entire jejunal mucosa.

**MEDICATIONS****DRUG(S) OF CHOICE**

• Proton pump inhibitors (PPIs) are currently the most potent inhibitors of gastric acid secretion. They irreversibly block the parietal cell proton pump. They require 3–5 days to achieve maximum efficacy, but immediate effects are still superior to that of H₂ receptor antagonists. They can be used as first-line therapy for any GUE, but they are especially indicated for gastrinomas. Omeprazole (1–2 mg/kg PO q12–24h, dog), esomeprazole or lansoprazole (1 mg/kg PO q24h, dog) can be administered orally whereas pantoprazole (1 mg/kg IV q24h, dog) can be administered parenterally. • Histamine (H₂) receptor antagonists competitively inhibit gastric acid secretion. Ranitidine (1–2 mg/kg SC, PO, IV q8–12h, dog and cat); famotidine (0.5–1 mg/kg PO, IV q12–24h, dog and cat); nizatidine (5 mg/kg PO q24h, dog). Famotidine is most potent. Cimetidine should be avoided in light of its short half-life and relative ineffectiveness. Lafutidine is a new H₂ receptor antagonist that is supposed to be as effective as a PPI, but there is currently no experience with its use in veterinary medicine.

• Sucralfate (0.5–1 g PO q6–8h) protects ulcerated tissue by binding to ulcer sites and stimulating prostaglandin synthesis.

• Antiemetics if vomiting is frequent or nausea is severe. Maropitant (1 mg/kg SC q24h for 5 days, dog; 2 mg/kg PO q24h for 5 days, dog); ondansetron (0.5 mg/kg IV q12h, dog; 0.2 mg/kg IV q12h, cat). • Oral antacids (e.g., calcium carbonate) are poorly effective and not recommended.

POSSIBLE INTERACTIONS

- Sucralfate may slow absorption of other drugs. • Antacids may slow absorption of other drugs.

ALTERNATIVE DRUG(S)

Misoprostol, synthetic prostaglandin E1 analogue, (2–5 µg/kg PO q8–12h) used prophylactically to prevent NSAID-induced ulcers. Can be used to treat any existing ulcer. Do not use in pregnant patients (causes abortion).

**FOLLOW-UP****PATIENT MONITORING**

If medications are going to be effective, the patient should show evidence of clinical improvement within 5–7 days.

PREVENTION/AVOIDANCE

- Administer NSAIDs with food.
- Concurrent use of PPI when chronically

administering NSAIDs helps prevent GUE. If PPIs are inadequate, misoprostol is usually more effective. • COX-2 selective or dual LOX/COX inhibitors are less likely to cause GUE than non-selective NSAIDs, but they can still cause GUE and perforation/peritonitis.

POSSIBLE COMPLICATIONS

- Hemorrhage, ulcer perforation, and/or septic peritonitis

EXPECTED COURSE AND PROGNOSIS

• Varies with underlying causes. • GUE not due to local malignancy can usually (not always) be treated successfully medically (especially if one can remove the cause). However, if perforation has occurred, surgery is necessary.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Anemia

AGE-RELATED FACTORS

Neoplasia more common in older animals

ZOONOTIC POTENTIAL

GASTROENTERITIS, EOSINOPHILIC

BASICS

DEFINITION

An inflammatory disease of the stomach and intestine, characterized by an infiltration of eosinophils, usually into the lamina propria, but occasionally involving the submucosa and muscularis.

PATOPHYSIOLOGY

- Antigens bind to IgE on the surface of mast cells, resulting in mast cell degranulation.
- Some of the products released are potent eosinophil chemotactants.
- Eosinophils contain granules with substances that directly damage the surrounding tissues.
- Eosinophils can also activate mast cells directly, setting up a vicious cycle of degranulation and tissue destruction.

SYSTEMS AFFECTED

- Gastrointestinal—generally stomach and small intestine; large intestine may be affected.
- In the cat, hypereosinophilic syndrome can involve the GI tract, liver, spleen, kidney, adrenal glands, and heart. There are also rare reports in the dog, particularly in rottweilers.

GENETICS

N/A

INCIDENCE/PREVALENCE

- Eosinophilic gastroenteritis is reportedly more common in dogs than in cats.
- Less common than lymphocytic-plasmacytic gastroenteritis.
- A mixed cellular infiltrate of eosinophils, lymphocytes, and plasma cells may be present occasionally.

SIGNALMENT

Species

Dog and cat

Breed Predilections

German shepherds, rottweilers, soft-coated Wheaten terrier, and Shar-Pei may be predisposed.

Mean Age and Range

- Dogs—most common in animals <5 years of age, although any age may be affected.
- Cats—median age, 8 years; range, 1.5–11 years reported.

Predominant Sex

None reported

SIGNS

Historical Findings

- Intermittent vomiting, small bowel diarrhea, anorexia/hyporexia, and/or weight loss are the most common findings, similar to other causes of gastroenteritis.
- One report states that 50% of cats with eosinophilic gastritis/enteritis had hematochezia or melena.

Physical Examination Findings

- Cats—thickened bowel loops may be palpated.
- Evidence of weight loss may be present.
- If hypereosinophilic syndrome is the cause of the GI disease, enlarged

peripheral lymph nodes, mesenteric lymphadenopathy, hepatomegaly, and splenomegaly may also be noted.

CAUSES

- Idiopathic eosinophilic gastroenteritis
- Parasitic • Immune-mediated—food allergy; adverse drug reaction; associated with other forms of inflammatory bowel disease
- Systemic mastocytosis • Hypereosinophilic syndrome • Eosinophilic leukemia
- Eosinophilic granuloma

RISK FACTORS

N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- All of the causes listed above are included in the differential diagnosis of eosinophilic infiltrates in the stomach and small intestine.
- Idiopathic eosinophilic gastroenteritis is a diagnosis of exclusion.
- Multiple fecal floatations and direct smears are imperative to rule in or rule out intestinal parasitism.
- Routine deworming with a broad-spectrum product is commonly indicated, even when all fecal examinations are negative.
- Intestinal biopsy differentiates the other causes of inflammatory bowel disease from eosinophilic gastroenteritis.
- Dietary trial should rule-in or rule-out food allergy or hypersensitivity.

CBC/BIOCHEMISTRY/URINALYSIS

- Hemogram may reveal a peripheral eosinophilia—more common in cats than dogs, especially common and pronounced in hypereosinophilic syndrome.
- Panhypoproteinemia or hypoalbuminemia may be present if a protein-losing enteropathy is also present.
- Liver enzyme elevations and/or azotemia may be seen with hypereosinophilic syndrome.
- Urinalysis is usually normal.

OTHER LABORATORY TESTS

- Buffy-coat smear to help rule out systemic mastocytosis, when suspected.
- Serum cobalamin levels may be low suggesting ileal disease, folate levels may be increased suggesting small intestinal bacterial overgrowth.

IMAGING

- Plain abdominal radiographs provide little information but are useful to rule out other diseases that may present with similar clinical signs.
- Barium contrast radiography may demonstrate thick intestinal walls and mucosal irregularities but does not provide any information about etiology or the nature of the thickening.
- Ultrasonography—used to measure stomach and intestinal wall thickness and to rule out other diseases; used to examine the liver, spleen, and mesenteric lymph nodes in animals with

hypereosinophilic syndrome. When seen, aspirates of these organs are often indicated.

DIAGNOSTIC PROCEDURES

- Definitive diagnosis often requires histopathology of biopsy samples obtained via endoscopy or laparotomy.
- Bone marrow aspirates are recommended if systemic mastocytosis or significant peripheral eosinophilia is apparent.
- Exploratory laparotomy may be indicated if distal small intestine is involved, or abdominal organomegaly is present.

PATHOLOGIC FINDINGS

- Thickened rugal folds, erosions, ulcers, and increased mucosal friability may be present in the stomach, although grossly it can appear normal.
- Ulcerations and erosions may be seen in the intestine.
- Eosinophilic infiltrates can be patchy in the intestine; multiple biopsies may be necessary to obtain a diagnosis.
- Histopathology reveals a diffuse infiltrate of eosinophils into the lamina propria; the submucosa and muscularis can also be involved (more common in cats).

TREATMENT

APPROPRIATE HEALTH CARE

- Most treated on an outpatient basis.
- Patients with systemic mastocytosis, protein-losing enteropathies, or other concurrent illnesses may require hospitalization until they are stabilized.

NURSING CARE

- If the patient is dehydrated or must be NPO because of vomiting, any balanced crystalloid solution such as lactated Ringer's solution is adequate; otherwise, select fluids on the basis of secondary diseases.
- If severe hypoalbuminemia from protein-losing enteropathy, consider colloids such as hetastarch. Small dogs under 15 pounds (7 kg) may benefit from a plasma transfusion resulting in transient increase in albumin. This may result in improved stability during anesthesia, allowing for further diagnostics and biopsies.

ACTIVITY

No need to restrict unless severely debilitated.

DIET

- Dietary manipulation is usually a critical component of therapy and may take several forms.
- Highly digestible diets with limited macronutrient sources (elimination or hydrolyzed diets)—extremely useful for eliciting remission; can be used as maintenance diets once the patient is stabilized. Most cases are managed successfully long term in this way.
- Dogs—examples include: Hill's Prescription Diet d/d and Hill's z/d; Purina HA; Royal Canin Hypoallergenic diets; Iams Response Formula FP or KO; balanced homemade diets.
- Cats—examples

(CONTINUED)

include: Hill's Prescription Diet z/d and d/d; Purina HA; Royal Canin Hypoallergenic diets; Iams Response LB. • Monomeric diets (e.g., elemental diet)—have non-allergenic components; can be used in patients that are not vomiting but have moderate-to-severe GI inflammation; useful if a food allergy is suspected. However, treatment with monomeric diets is rarely necessary. • In patients with severe intestinal involvement and significant protein-losing enteropathy, total parenteral nutrition may be indicated until remission is obtained. TPN is rarely necessary. • Once the patient is stabilized, an elimination diet trial may be instituted if food allergy or intolerance is the suspected cause to determine the offending nutrient. This is generally not done.

CLIENT EDUCATION

Explain the waxing and waning nature of the disease, the necessity for lifelong vigilance regarding inciting factors, and the potential for long-term therapy.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUG(S) OF CHOICE

- Glucocorticoids: prednisone 2–4 mg/kg PO q24h (rarely requires high end of dose to start). Never exceed a total dose of 50 mg/day in a dog, no matter how heavy. • Gradually taper corticosteroids approximately 25% every 2–3 weeks until at 25% of original dose, then extend to 4- to 8-week intervals before discontinuing; relapses are more common in patients that are taken off corticosteroids too quickly. • Occasionally other immunosuppressive drugs can be used to allow a reduction in corticosteroid dose and avoid some of the adverse effects of steroid therapy. These medications are also added in refractory cases. • When in need of rapid immunosuppression, add chlorambucil (0.1–0.2 mg/kg q24h for 7 days then q48h). Often used in place of azathioprine but can be used in addition. A recent study suggests that this addition may be superior to adding azathioprine. Avoid the simultaneous implementation of 3 different immunosuppressive drugs at the same time.
- Immunosuppressive drugs such as azathioprine (2.2 mg/kg PO q24h, tapering to q48h after 2–3 weeks) if an immune-mediated mechanism is suspected and response to dietary management and glucocorticoid administration is inadequate. Expect response to occur in 2–3 weeks.
- Budesonide, an orally administered glucocorticoid with a high first-pass effect, has been used successfully to treat cats and dogs with inflammatory bowel disease; it appears to have more of a topical effect on the

intestinal tract. Reports have shown that some absorption and secondary effects on the adrenal pituitary axis occur. Current dose recommendations are 2–3 mg/m² q24h with a gradual taper over the course of 8–10 weeks (not based on scientific research) and often requires compounding for smaller dogs. The dose for cats and dogs weighing < 10 kg is 1 mg q24h with a gradual taper over the course of 8–10 weeks.

CONTRAINDICATIONS

If secondary problems are present, avoid medications that might be contraindicated for those conditions.

PRECAUTIONS

- Prednisone and budesonide (less commonly) can cause GI ulceration. Once evidence has been seen, the addition of gastric protectants is indicated. Use of gastric protectants has not been shown to prevent damage but is effective as a treatment.
- Azathioprine and chlorambucil can rarely cause bone marrow suppression in dogs; avoid the use of azathioprine in cats due to its myelosuppressive effects. All patients receiving azathioprine or chlorambucil should have a complete blood count 10–14 days after the start of treatment, with rechecks monthly and then bimonthly thereafter for the entire treatment period; bone marrow suppression can be seen at any time during treatment but is usually cumulative. It is generally reversible with drug discontinuation if caught early. A chemistry panel should also be regularly evaluated. • Pancreatitis, hepatic damage, and anorexia are other potential side effects of these drugs.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

N/A

FOLLOW-UP

PATIENT MONITORING

- Initially frequent for severely affected patients; monitoring peripheral eosinophil counts may be helpful; the corticosteroid dosage is usually adjusted during these visits.
- Patients with less severe disease may be checked 2–5 weeks after the initial evaluation; monthly to bimonthly thereafter until corticosteroid therapy is completed. • Patients receiving azathioprine—monitor as mentioned above. • Patients usually do not require long-term follow-up unless the problem recurs.

PREVENTION/AVOIDANCE

If a food intolerance or allergy is suspected or documented, avoid that particular nutrient and adhere strictly to dietary restrictions.

GASTROENTERITIS, EOSINOPHILIC

POSSIBLE COMPLICATIONS

- Weight loss, debilitation in refractory cases.
- Adverse effects of corticosteroid therapy.
- Bone marrow suppression, pancreatitis, hepatitis, or anorexia caused by azathioprine and/or chlorambucil.

EXPECTED COURSE AND PROGNOSIS

- The vast majority of dogs with eosinophilic gastroenteritis respond to a combination of dietary manipulation and steroid therapy.
- Cats often have a more severe form of the disease, with a poorer prognosis than dogs.
- Cats often require higher doses of corticosteroids for longer periods of time to elicit remission.

MISCELLANEOUS

ZOONOTIC POTENTIAL

A consideration only when eosinophilic infiltrates are secondary to parasites (e.g., *Ancylostoma*, *Giardia*, and ascarids).

PREGNANCY/FERTILITY/BREEDING

- Prednisone has been used safely in pregnant women; corticosteroids have been associated with increased incidence of congenital defects, abortion, and fetal death. • Azathioprine has been used safely in pregnant women and may be a good substitute for corticosteroids in pregnant animals.

GASTROENTERITIS, HEMORRHAGIC

BASICS

DEFINITION

A peracute hemorrhagic enteritis of dogs characterized by a sudden onset of severe bloody diarrhea that is often explosive, with vomiting, hypovolemia, and marked hemoconcentration due to a dramatic loss of water and electrolytes into the intestinal lumen.

PATHOPHYSIOLOGY

- Many conditions result in hemorrhagic diarrhea, but the acute hemorrhagic gastroenteritis (HGE) syndrome of dogs appears to have unique clinical features that distinguish it as a clinical entity separate from other conditions.
- HGE is characterized as a peracute loss of intestinal mucosal integrity with the rapid movement of blood, fluid, and electrolytes into the gut lumen. Dehydration and hypovolemic shock occur quickly. Translocation of bacteria or toxins through the damaged intestinal mucosa may result in septic or endotoxic shock.
- Histological examination of the intestinal tract shows superficial mucosal hemorrhagic necrosis without inflammation. Gastric mucosa is spared.

SYSTEMS AFFECTED

- Gastrointestinal
- Cardiovascular

GENETICS

Unknown; however, there appear to be specific small or toy breeds that may be overrepresented.

INCIDENCE/PREVALENCE

A common clinical condition

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Dog

Breed Predilections

- All breeds can be affected but the incidence is greater in small-breed and toy-breed dogs.
- Breeds most represented include miniature schnauzer, dachshund, Yorkshire terrier, and miniature poodle.

Mean Age and Range

Usually in adult dogs with a mean age of 5 years.

Predominant Sex

N/A

SIGNS

General Comments

- Clinical findings are variable in both the course and severity of the disease. The disease is usually peracute and associated with concurrent hypovolemic shock.

- Most animals affected were previously healthy with no historical environmental changes or concurrent gastrointestinal disease.

Historical Findings

- The signs usually begin with acute vomiting, anorexia, and lethargy that is followed by watery diarrhea quickly changing to bloody diarrhea.
- Signs progress rapidly and become severe within a period of hours (usually 8–12 hours) and are the result of hypovolemic shock and hemoconcentration.

Physical Examination Findings

- The patient is generally lethargic and weak and has prolonged capillary refill time and weak pulse pressure.
- Skin turgor as a reflection of dehydration may appear normal owing to the peracute nature of the disease and the lag time in compartmental fluid shifts.
- Abdominal palpation may be painful and fluid-filled bowel can be detected.
- Rectal examination identifies bloody diarrhea, and later in the course of disease a "raspberry jam" characteristic stool develops.
- Occasionally fever, but often the temperature is normal or even subnormal.

CAUSES

- The etiology is unknown; allergic, autoimmune and infectious causes have all been implicated.
- There is increasing evidence to suggest that *Clostridium perfringens* (CP) type A enterotoxin is involved in the disease and has been identified in necrotic mucosal surfaces.

RISK FACTORS

- Unknown.
- Most dogs are previously healthy with no major concurrent illness.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Parvovirus
- Circovirus
- Acute gastrointestinal ulceration
- Bacterial enteritis such as salmonellosis or *Campylobacter*
- Conditions resulting in endotoxic or hypovolemic shock
- Intestinal obstruction or intussusception
- Hypoadrenocorticism
- Heat stroke
- Pancreatitis
- Coagulopathy

CBC/BIOCHEMISTRY/URINALYSIS

- Hemoconcentration with the PCV generally > 60% and sometimes as high as 75% with discordant plasma proteins that are normal to decreased due to protein loss into the GI tract. Usually a stress leukogram.

- Biochemistry profile may reveal secondary hepatic enzyme elevations and high BUN due to prerenal causes.

OTHER LABORATORY TESTS

Fecal Tests

- The stool is negative for parasites.
- ELISA for parvovirus is negative.
- Fecal cytology shows many RBCs and occasional WBCs.
- Clostridium* may be cultured in high concentrations from healthy dogs and should not be used as a diagnostic test for dogs with HE. Fecal ELISA test for detection of *C. perfringens* enterotoxin is often positive. Culture for other enteric pathogens is negative. Fecal PCR for detection of *C. perfringens* alpha toxin gene alone is not sufficient to diagnose this disorder.

Coagulogram

Usually normal but rarely secondary DIC is a complication.

IMAGING

Abdominal radiographs or ultrasound show fluid- and gas-filled small and large intestine.

DIAGNOSTIC PROCEDURES

Electrocardiogram

Cardiac arrhythmias such as ventricular premature contractions and ventricular tachycardia may be noted.

Endoscopy

- Endoscopy is rarely indicated.
- Stomach may appear normal but small and large intestine will show diffuse mucosal hemorrhage, ulceration, and hyperemia.

PATHOLOGIC FINDINGS

Changes in the intestine include gross congestion and microscopic evidence of autolysis that is devoid of marked inflammation.

TREATMENT

APPROPRIATE HEALTH CARE

Patients suspected of having acute HGE should be hospitalized and treated aggressively because clinical deterioration is often rapid and can be fatal.

NURSING CARE

- Rapid volume replacement through a large-bore IV catheter is required in all cases.
- Balanced electrolyte solutions are given up to the rate of 40–60 mL/kg/hour IV until the PCV is < 50%.
- A moderate rate of maintenance fluids is given to maintain circulatory function and correct any potassium or other electrolyte deficits during the recovery period.
- Continued GI fluid losses should be estimated and that volume added to the fluid requirements.
- Hypoproteinemic animals may require colloids or plasma.

(CONTINUED)

GASTROENTERITIS, HEMORRHAGIC**ACTIVITY**

Restricted

DIET

- NPO during acute disease.
- During recovery period a bland, low-fat, low-fiber gastrointestinal diet should be fed for several days before returning to the normal diet.
- Consider increased dietary fiber to alter the intestinal microbiota to reduce the likelihood of recurrence of *C. perfringens*-associated diarrhea.

CLIENT EDUCATION

- Discuss the need for immediate and aggressive medical management. With appropriate therapy, mortality is usually low.
- Recurrence is reported in about 10% of the cases.

SURGICAL CONSIDERATIONS

N/A

**MEDICATIONS****DRUG(S) OF CHOICE**

- Parenteral antibiotics are generally recommended; however, their use in aseptic cases has been questioned. Antibiotics are used for potential septicemia. Amoxicillin/sulbactam (50 mg/kg q8h IV) is suggested prophylactically.
- An antiemetic such as maropitant (1 mg/kg q24h) is suggested to control nausea and vomiting.
- Antacids such as famotidine (0.5–1 mg/kg q12h) or pantoprazole (1 mg/kg q24h) given IV may be indicated.
- Excessive blood loss may require a blood transfusion (rare).

CONTRAINDICATIONS

N/A

PRECAUTIONS

Septic and or hypovolemic shock can occur quickly and consequently the animal should be monitored closely.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

- Oral antibiotics and intestinal protectants are of little benefit and generally not administered.

- Rectal administration of mucosal protectants such as sucralfate is of questionable value.
- Antidiarrheal drugs are contraindicated.
- Consider probiotics to alter the intestinal microbiota to reduce the likelihood of recurrence of *C. perfringens*-associated diarrhea.

**FOLLOW-UP****PATIENT MONITORING**

- Monitor the PCV and total solids frequently (at least every 4–6 hours).
- Modify the fluid replacement-based PCV, continued GI fluid losses, and circulatory function.
- If there is a failure of clinical improvement in 24–48 hours, re-evaluate the patient, as other causes of hemorrhagic diarrhea are probable.

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

- Occasionally DIC may develop. Neurologic signs or even seizures secondary to the hemoconcentration may occur.
- Cardiac arrhythmias occur from suspected myocardial reperfusion injury.
- A hemolytic-uremic syndrome may occur (rare).
- Most dogs recover. Mortality rate can be high in untreated dogs. Fewer than 10% of treated dogs die, and 10–15% have repeated occurrences.

EXPECTED COURSE AND PROGNOSIS

- The course of the disease is generally short, lasting from 24 to 72 hours.
- The prognosis is good, and most patients recover with no complications.
- Sudden death is uncommon if adequately treated.

G

GASTROENTERITIS, LYMPHOCYTIC-PLASMACYTIC

BASICS

DEFINITION

- The most common form of inflammatory bowel disease characterized by lymphocyte and plasma cell infiltration into the lamina propria of the stomach and intestine; usually accompanied by other criteria of mucosal inflammation.
- Less commonly the infiltrates may extend into the submucosa and muscularis.

G

PATHOPHYSIOLOGY

- An aberrant immune response to environmental stimuli likely resulting in loss of mucosal homeostasis; alterations in intestinal microbiota (i.e., dysbiosis) maybe a trigger.
- Continued antigen exposure, coupled with dysregulated inflammation, results in disease, although the exact mechanisms and patient factors remain unknown.

SYSTEMS AFFECTED

- Gastrointestinal—typically small intestine and occasionally stomach; the colon can be independently or simultaneously affected.
- Extra-intestinal manifestations of inflammation are occasional seen (e.g., mild thrombocytopenia) although they are not well characterized.

GENETICS

Basenjis, Lundehunds, and soft-coated Wheaten terriers have familial forms of inflammatory bowel disease.

INCIDENCE/PREVALENCE

The most common form of IBD affecting dogs and cats.

SIGNALMENT

Breed Predilections

- Lundehunds and basenjis have unique forms of IBD; gluten-sensitive enteropathy affects Irish setters; protein-losing enteropathy and nephropathy affects soft-coated Wheaten terriers.
- German shepherds and Chinese Shar-Peis are predisposed to lymphocytic-plasmacytic gastroenteritis.
- Pure-breed cats (Asian breeds) may have a higher incidence.

Mean Age and Range

- Most common in middle-aged and older animals.
- Dogs as young as 8 months and cats as young as 5 months of age have been reported.

Predominant Sex

None reported

SIGNS

Historical Findings

- Signs associated with lymphocytic-plasmacytic gastritis with or without enteritis can vary in type, severity, and frequency.
- Generally have an intermittent or cyclical, chronic course over time. Flares are

characterized by spontaneous exacerbations and remissions.

- Cats—intermittent, chronic vomiting is the most common; chronic small bowel diarrhea is second.
- Dogs—chronic small bowel diarrhea is the most common; if only the stomach is involved, vomiting is the most common.
- Dogs and cats—anorexia and chronic weight loss are common; hematochezia, hematemesis, and melena are occasionally noted.

Physical Examination Findings

Varies from normal examination to a dehydrated, cachectic, and depressed patient depending on the disease severity and organ affected.

CAUSES

Pathogenesis is likely multifactorial and involves complex interactions between genetic, immunologic, and environmental (i.e., microbiota) factors.

Infectious Agents

- Giardia*, *Salmonella*, *Campylobacter*, and normal gastrointestinal microbiota have been implicated. Increased mucosally associated bacteria have been observed in dogs and cats with IBD compared to healthy animals.

Dietary Agents

- Meat proteins, food additives, artificial coloring, preservatives, milk proteins, and gluten (wheat) may contribute to the pathogenesis of chronic mucosal inflammation.

Genetic Factors

- Certain forms of IBD are more common in some breeds of dogs (see above).
- Certain major histocompatibility genes may render an individual susceptible to development of IBD.

RISK FACTORS

See "Causes"

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other infiltrative inflammatory bowel conditions (e.g., eosinophilic gastroenteritis, granulomatous IBD).
- Food hypersensitivity.
- Metabolic disorders.
- Neoplasia.
- Infectious diseases (e.g., histoplasmosis, toxoplasmosis, giardiasis, salmonellosis, *Campylobacter* enteritis, and bacterial overgrowth).
- Miscellaneous diseases (e.g., lymphangiectasia, gastrointestinal motility disorders, and exocrine pancreatic insufficiency).
- In the cat, consider hyperthyroidism, systemic viral infection (e.g., FeLV, FIV, FIP), and chronic pancreatitis.

CBC/BIOCHEMISTRY/URINALYSIS

- Often normal.
- Mild nonregenerative anemia and mild leukocytosis with or without a mild left shift.
- Hypoproteinemia is more common in dogs than cats with IBD.

OTHER LABORATORY TESTS

- Alterations in serum cobalamin and folate may serve to localize enteric regions of small intestinal inflammation.
- Serum pancreatic specific lipase to screen for pancreatic inflammation.
- Fecal alpha1-proteinase inhibitor to evaluate for protein-losing enteropathy.
- Trypsin-like immunoreactivity to evaluate for exocrine pancreatic insufficiency.
- Cats—T₄ and FeLV/FIV/toxoplasmosis serology are recommended to screen for infectious causes for gastrointestinal signs.

IMAGING

- Survey abdominal radiographs are usually normal.
- Barium contrast studies occasionally reveal mucosal abnormalities and thickened bowel loops but are typically not helpful in establishing a definitive diagnosis.

DIAGNOSTIC PROCEDURES

- Initiate a hypoallergenic dietary trial to rule out adverse food reactions; if signs resolve then additional diagnostics are not necessary.
- Always perform direct and indirect fecal examinations for parasites.
- Definitive diagnosis requires mucosal biopsy and histopathology, usually obtained via endoscopy.
- Exploratory laparotomy or laparoscopy may be indicated when portions of the GI tract, unapproachable by endoscopy, are involved or if abdominal organomegaly, lymphadenomegaly, or masses are present.
- Clinical assessment of disease severity using the canine IBD activity index (CIBDAI) is a useful tool.

PATHOLOGIC FINDINGS

- Grossly, stomach and intestinal appearance can range from normal to edematous, thickened, and ulcerated.
- The hallmark histopathologic finding is an infiltrate of lymphocytes and plasma cells in the lamina propria; architectural changes including villus atrophy, fusion, fibrosis, crypt abscessation and lymphangiectasia may be present to varying degrees.
- The distribution may be patchy, so numerous biopsy specimens are necessary to make the diagnosis.

TREATMENT

APPROPRIATE HEALTH CARE

- Outpatient, unless the patient is debilitated from dehydration, hypoproteinemia, or cachexia.
- Monitor therapeutic responses using CIBDAI scores.

NURSING CARE

- If the patient is dehydrated or must be NPO because of severe vomiting, a balanced crystalloid such as lactated Ringer's solution is adequate; additional electrolyte supplementation may be necessary if alterations are present (e.g., potassium chloride).
- Colloids (dextrans or hetastarch)

(CONTINUED)

GASTROENTERITIS, LYMPHOCYTIC-PLASMACYTIC

should be given if severe hypoalbuminemia from protein losing enteropathy is present.

ACTIVITY

No restrictions

DIET

- Dietary therapy with an elimination or hydrolyzed diet is an essential component of patient management.
- Patients with severe intestinal involvement and protein-losing enteropathy may require total parenteral nutrition until stable.
- Highly digestible diets decrease the intestinal antigenic load, thus helping to reduce mucosal inflammation; appropriate diet therapy can contribute to clinical remission and can be used as a maintenance diet.
- Modification of the n3:n6 fatty acid ratio may also help to modulate the inflammatory response.
- Parenteral cobalamin supplementation is essential if serum levels are subnormal. Deficiencies in cobalamin can contribute to clinical signs and limit the effectiveness of dietary and medical therapy.
- Numerous commercial elimination diets that meet the above criteria are available for dogs and cats; home-cooked diets are also an excellent option but are more time-consuming for owners.
- Use fiber supplementation in dogs and cats with colitis.

CLIENT EDUCATION

- IBD is more likely to be controlled rather than cured, as relapses are common.
- Patience is required during the various food and medication trials that are often necessary.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Corticosteroids—the mainstay of treatment for idiopathic lymphocytic-plasmacytic enteritis; prednisone or prednisolone is used most frequently (1 mg/kg PO q12h) in dogs and cats; cats may require a higher dose to control their disease. Gradually taper the corticosteroid dose after 2–4 weeks of induction therapy when clinical signs are resolved; relapses are common if patients are tapered too quickly. Maintenance dosages q48–72h may be necessary in some patients. Cats may respond better to prednisolone than prednisone. Budesonide, a locally active steroid, may be used in patients that cannot tolerate the systemic side effects of prednisone. Parenteral steroids may be needed in severe cases in which oral absorption may be limited.
- Azathioprine (2 mg/kg q24–48h PO in dogs; not recommended in cats)—an immunosuppressive drug that can be used to allow a reduction in corticosteroid dose; delayed onset of activity (up to 3 weeks) limits effectiveness in acute cases.
- Chlorambucil (2 mg q48–72h PO in cats) is an effective alternative to azathioprine.

- Metronidazole—has antibacterial and antiprotozoal properties; some evidence that it also has immune-modulating effects in rodents; the dosage for IBD in dogs and cats is 10 mg/kg PO q12h.

ALTERNATIVE DRUG(S)

- Cyclosporine—may be useful in the therapy of refractory cases of lymphocytic-plasmacytic gastroenteritis; using Atopica, 2–5 mg/kg PO q12h for dogs, 1–4 mg/kg q12–24h for cats; dosage is very individualized so monitoring trough levels is recommended.
- Sulfasalazine—a sulfa analog that is broken down by luminal bacteria into sulfapyridine and mesalamine, the latter of which provides anti-inflammatory effects in the colon; dosage for dogs with colonic IBD is 10–30 mg/kg PO q8–12h. Use cautiously in cats and at reduced dosage due to the potential for salicylate toxicity.

PRECAUTIONS

- Azathioprine—causes bone marrow suppression, especially in cats; routine CBCs are recommended at 2 weeks, 1 month, and then bimonthly; bone marrow suppression is typically reversible if the drug is discontinued as soon as suppression is noted.
- Metronidazole—can cause reversible neurotoxicity at high dosages; discontinuation of the drug usually reverses the neurologic signs.
- Cyclosporine—can cause vomiting, gingival hyperplasia, and papillomatosis; associated with the development of lymphoma in humans.

POSSIBLE INTERACTIONS

- Cyclosporine can interfere with the metabolism of phenobarbital and phenytoin.
- Ketoconazole, erythromycin, and cimetidine can decrease hepatic metabolism of cyclosporine.
- Any drugs that are potentially nephrotoxic should be used with caution in conjunction with cyclosporine.

**FOLLOW-UP****PATIENT MONITORING**

- Severely affected patients on bone marrow suppressive medications require frequent monitoring (see above); adjust medications during these visits based on bloodwork and clinical signs.
- Check patients with less severe disease 2–3 weeks after their initial evaluation and then monthly to bimonthly until medications are tapered and clinical signs are resolved.

PREVENTION/AVOIDANCE

When a food intolerance or allergy is suspected or documented, avoid that particular item and adhere strictly to dietary restriction.

POSSIBLE COMPLICATIONS

- Weight loss and debilitation in refractory cases.
- Iatrogenic hyperadrenocorticism and steroid side effects.
- Bone marrow suppression, pancreatitis, hepatopathy, or anorexia can be caused by azathioprine.
- Vomiting, diarrhea, and anorexia with cyclosporine; decreasing the dosage temporarily typically will result in resolution of gastrointestinal signs.
- Keratoconjunctivitis sicca with sulfasalazine.

EXPECTED COURSE AND PROGNOSIS

- Dogs and cats with mild-to-moderate inflammation have a good-to-excellent prognosis for full recovery.
- Patients with severe infiltrates, particularly if other portions of the GI tract are involved, have a more guarded prognosis.
- Other prognostic indices associated with negative long-term outcome include severe mucosal lesions on endoscopy, hypocabalaminemia, and hypoalbuminemia.
- Often the initial response to therapy sets the tone for a given individual's ability to recover.

G

**MISCELLANEOUS****PREGNANCY/FERTILITY/BREEDING**

- Corticosteroids have been associated with increased incidence of congenital defects, abortion, and fetal death.
- Azathioprine has been used safely in pregnant women, and may be a good substitute for corticosteroids in pregnant animals.
- Sulfasalazine should be used with extreme caution during pregnancy.

GASTROESOPHAGEAL REFLUX

BASICS

OVERVIEW

- Reflux of gastric or intestinal fluid into the esophageal lumen.
- Incidence unknown; probably more common than clinically recognized.
- Transient relaxation of the gastroesophageal sphincter or chronic vomiting may permit reflux of gastrointestinal juices into the esophageal lumen. Reflux is common in dogs with sliding hiatal hernias. A small amount of gastroesophageal reflux is a normal phenomenon in dogs and cats.
- Gastric acid, pepsin, trypsin, bicarbonate, and bile salts are all injurious to the esophageal mucosa with prolonged or repetitive contact.
- Esophagitis resulting from reflux may vary from mild inflammation of the superficial mucosa to severe ulceration involving the submucosa and muscularis.

SIGNALMENT

- Dog and cats; male or female.
- No breed predilections reported.
- May be associated with congenital hiatal hernia seen in Chinese Shar-Pei dogs and other brachycephalic breeds.
- Occurs at any age; younger animals may be at increased risk because of developmental immaturity of the gastroesophageal sphincter.
- Young animals with congenital hiatal hernia may also be at increased risk.

SIGNS

Historical Findings

- Regurgitation
- Hypersalivation
- Painful swallowing (odynophagia)
- Anorexia

Physical Examination Findings

- Often unremarkable.
- Changes consistent with brachycephalic syndrome that can increase the likelihood of reflux and hiatal herniation. Hypersalivation—with severe ulcerative esophagitis; possible pain on palpation of cervical esophagus.

CAUSES & RISK FACTORS

- Anesthesia with relaxation of lower esophageal sphincter tone.
- Retained gastric contents.
- Foreign body ingestion with esophagitis.
- Pill ingestion in cats especially associated with tetracyclines.
- Acquired or congenital hiatal hernia.
- Chronic vomiting with secondary esophagitis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Oral or pharyngeal disease
- Ingestion of caustic agent
- Esophageal foreign body

- Esophageal tumor
- Megaeosophagus—idiopathic; myasthenia gravis; vascular ring anomaly
- Hiatal hernia
- Gastroesophageal intussusception

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal

OTHER LABORATORY TESTS

N/A

IMAGING

- Survey thoracic radiography—usually unremarkable; may be air in the distal esophagus (nonspecific finding).
- Barium contrast radiography—reveals gastroesophageal reflux in some, but not all, animals; videofluoroscopy is superior to esophagram; aspiration pneumonia may be evident in the dependent portions of the lung.

DIAGNOSTIC PROCEDURES

- Esophagoscopy—the best means of confirming reflux esophagitis—irregular mucosal surface with hyperemia or active bleeding in the distal esophagus. Refluxed gastroduodenal secretions may be seen pooling in the distal esophagus near the LES which may or may not be open.
- Radiography is of little value in confirming mucosal lesions of GER.

TREATMENT

- Generally, managed as outpatient.
- Not necessary to restrict activity.
- Moderate-to-severe cases—may withhold food for 24 hours to promote esophageal rest and to minimize further reflux; thereafter, feed low-fat, low-protein meals in small, frequent feedings; dietary fat decreases gastroesophageal sphincter pressure and delays gastric emptying; protein stimulates gastric acid secretion and may precipitate GER.

MEDICATIONS

DRUG(S)

- Oral sucralfate suspension (0.5–1 g PO q8h).
- Gastric acid antisecretory agents—H2 blockers: ranitidine (1–2 mg/kg PO q12h); famotidine (0.5–1 mg/kg PO, SC, IV q12–24h); proton pump inhibitors: omeprazole (0.7–1.5 mg/kg PO q24h); pantoprazole (1 mg/kg IV q24h).
- Prokinetic agents—cisapride (0.3–0.5 mg/kg PO q8–12h); ranitidine (1–2 mg/kg PO, IV, SC q8–12h); metoclopramide (0.5 mg/kg, PO, q6–8h or 1–2 mg/kg q24h as CRI).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Sucralfate suspension may interfere with the absorption of other drugs (e.g., cimetidine, ranitidine, omeprazole, cisapride).

FOLLOW-UP

- Patients rarely require follow-up endoscopy.
- It may be appropriate in many patients to simply monitor clinical signs.
- Consider endoscopy for patients that do not respond to empirical medical therapies. Severe mucosal damage (esophagitis) may progress to stricture.
- Clients should avoid feeding high-fat foods; they promote gastric retention and might exacerbate reflux.
- Administer water (“wet” swallow) via syringe following pill administration in cats and dogs.
- The most important complications are esophagitis and stricture formation.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Hiatal hernia
- Administration of oral medications (pills) in cats and dogs

AGE-RELATED FACTORS

May be worse in younger animals because of developmental immaturity of the gastroesophageal sphincter mechanism.

ZOONOTIC POTENTIAL

GASTROINTESTINAL OBSTRUCTION

BASICS

DEFINITION

The partial or complete physical impedance to the flow of ingesta and/or secretions aborally through the pylorus into the duodenum (gastric outlet obstruction) or through the small intestine. Obstructions in the pharynx, esophagus, large intestine, and rectum, and motility disorders are addressed in separate chapters (refer to "See Also").

PATHOPHYSIOLOGY

Gastric Outflow Obstruction

- Ingesta and fluids accumulate in the stomach.
- Vomiting results in loss of fluids rich in hydrochloric acid (from gastric secretions) with subsequent hypochloremic metabolic alkalosis.
- Varying degrees of dehydration, tissue compromise, malaise, and weight loss occur, depending on underlying etiology, severity, and chronicity.

Small Intestinal Obstruction

- Ingesta and fluids accumulate proximal to the obstruction.
- Vomiting may result in significant dehydration and electrolyte imbalances (particularly hypokalemia), depending on location (proximal vs. distal), partial or complete obstruction, and chronicity.
- Mucosal damage and bowel ischemia can result in endotoxemia and sepsis.

SYSTEMS AFFECTED

- Behavioral—associated with abdominal discomfort or pain (praying position, change in temperament).
- Cardiovascular—hypovolemic shock; tachycardia.
- Gastrointestinal—anorexia; vomiting; diarrhea; and malaise.
- Respiratory—aspiration pneumonia.

GENETICS

Unknown (see "Breed Predilections")

INCIDENCE/PREVALENCE

Common

SIGNALMENT

Species

- Dog and cat.
- Foreign bodies more common in dogs due to indiscriminate ingestion.

Breed Predilections

- Congenital pyloric stenosis—more common in brachycephalic breeds (e.g., boxers, Boston terriers) and Siamese cats.
- Acquired chronic hypertrophic gastropathy—more common in Lhasa apsos, Shih tzus, Pekingese, and poodles.
- Gastric dilation and volvulus—more common in large-breed dogs (e.g., German shepherds, Great Danes).

Mean Age and Range

- Foreign bodies—more common in young animals, but can occur at any age.
- Pyloric stenosis—occurs most often in young animals.
- CHG—more common in

middle-aged and older animals.

- Intussusceptions—most common in young animals.

SIGNS

Historical Findings

- Vomiting—hallmark sign; important to differentiate vomiting (forceful abdominal contractions) from regurgitation (passive); may occur soon after eating, especially with gastric outlet obstruction; vomiting food ingested > 8 hours after ingestion is consistent with delayed gastric emptying; usually more severe clinical signs with gastric and proximal small intestinal obstructions; may be characterized as projectile.
- Other variable clinical signs—anorexia; lethargy; malaise; ptalism; diarrhea; melena; and weight loss.
- Animals may continue to have bowel movements even with intestinal obstruction.
- Clients should be questioned about possible foreign body ingestion.

Physical Examination Findings

- The physical examination is often the most useful diagnostic procedure for intestinal obstruction.
- Findings can vary from normal to animal in life-threatening crisis—include dehydration, shock, palpable foreign body, abdominal discomfort or pain, and abdominal mass (intussusception or tumor).
- Linear foreign bodies—careful sublingual examination essential for detection; although more common in cats, linear foreign bodies also occur in dogs; sedation or anesthesia for oral examination and abdominal palpation is often very helpful in diagnosis.

CAUSES

Gastric Outflow Obstruction

- Foreign bodies
- Pyloric stenosis
- CHG
- Neoplasia
- GDV
- Granulomatous gastritis or gastroenteritis (e.g., pythiosis)

Small Intestinal Obstruction

- Foreign bodies
- Intussusception
- Hernias (with incarceration)
- Mesenteric torsion or volvulus
- Neoplasia
- Granulomatous enteritis
- Stricture

RISK FACTORS

- Exposure to and tendency to ingest foreign bodies.
- Intussusception—associated with intestinal parasitism and viral enteritis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Metabolic disease (e.g., renal failure, hepatic disease, diabetic ketoacidosis, hypoadrenocorticism).
- Infectious gastroenteritis (e.g., viral, bacterial, parasitic).
- Pancreatitis.
- Peritonitis.
- Toxicity.
- Gastroduodenal ulcer disease.
- Nonspecific gastroenteritis.
- CNS disease.

CBC/BIOCHEMISTRY/URINALYSIS

- These diagnostic tests are useful to rule out other causes for clinical signs (e.g., renal

failure, pancreatitis, liver disease, hypoadrenocorticism, diabetic ketoacidosis)

and to evaluate overall health status of the patient.

- Hemogram—may reveal anemia from gastrointestinal blood loss, stress leukocytosis, or a degenerative left-shifted leukocytosis or leukopenia due to severe mucosal injury or intestinal perforation with subsequent septic peritonitis.
- Chemistry profile and blood gas analysis—often reveal hypochloremic metabolic alkalosis with gastric outlet obstruction; hypokalemia and prerenal azotemia are variable findings.
- Hyperlactemia may be present due to hypoperfusion.

G

IMAGING

Survey Abdominal Radiography

- May reveal a radio opaque foreign body in the stomach or intestine, severe gastric distention, or obstructed loops of intestine with dilation due to fluid and/or gas.
- It is important to differentiate adynamic or functional ileus (usually diffuse) from obstruction (usually segmental).
- Radiographic interpretation must be done within the context of the history, physical examination, and other laboratory data to avoid misdiagnosis and unnecessary surgery.

Contrast Radiography

- Positive-contrast studies—may reveal delayed gastric emptying (> 4 hours with liquid contrast and > 8–10 hours with liquid contrast mixed with food), foreign bodies, complete obstruction, and masses.
- Pneumocolon—may be useful when ileocolic intussusception is suspected.

Abdominal Ultrasonography

May be useful in detecting foreign bodies, obstruction (especially intestinal intussusception), and marked disturbances in GI motility. Abdominal ultrasound can miss gastric foreign bodies and any animal suspected of having a GI foreign body should have abdominal radiographs performed if ultrasound is unremarkable.

Abdominal CT

Utilized when other imaging modalities have failed and as possible alternative to exploratory laparotomy.

DIAGNOSTIC PROCEDURES

- Gastrointestinal endoscopy—may be useful for confirming gastric and proximal intestinal obstruction and for obtaining biopsies of masses; particularly useful with some types of foreign bodies as retrieval may be possible. This may be performed in conjunction with exploratory laparotomy.
- Abdominal paracentesis or diagnostic peritoneal lavage and cytologic analysis—more sensitive than physical examination and radiography (i.e., can detect small amounts of abdominal effusion); may reveal non-septic inflammation associated with intestinal vascular compromise (prior to perforation) or septic

GASTROINTESTINAL OBSTRUCTION

(CONTINUED)

peritonitis; can indicate the need for exploratory laparotomy.

PATHOLOGIC FINDINGS

Histopathology of gastrointestinal masses causing obstruction—can reveal granulomatous inflammation, fungal infection (e.g., pythiosis), and neoplasia.

TREATMENT

APPROPRIATE HEALTH CARE

- Inpatient—for diagnosis, initial supportive medical care, and relief of the obstruction (usually with surgery).
- Surgery—acute intestinal obstructions are emergencies, and surgery should be performed as soon as possible after immediate supportive medical care; intestines do not tolerate vascular compromise well; intestinal resection and anastomosis frequently required (with associated increased morbidity and potential complications), but enterotomy may be successful if earlier diagnosis is made.
- Delay in diagnosis may result in intestinal necrosis, perforation, septic peritonitis, and increased likelihood of death.

NURSING CARE

- Intravenous crystalloid fluids—necessary for rehydration, circulatory support, and to correct acid-base and electrolyte abnormalities; for severe circulatory compromise (shock), administer isotonic crystalloid fluids at 90 mL/kg (dogs) or 45–60 mL/kg (cats) over 1 hour.
- Colloids (voluven or hetastarch)—may also be beneficial; frequent evaluation of hydration and electrolytes (with appropriate treatment adjustments) is necessary; for gastric outlet obstruction causing hypochloremic metabolic alkalosis, fluid of choice is 0.9% saline; otherwise, lactated Ringer's solution or other balanced electrolyte solution is adequate.
- Appropriate potassium supplementation—important.

ACTIVITY

Restricted

DIET

- Nothing by mouth until relief of obstruction and resolution of vomiting; then feed bland fat-restricted diet for 1–2 days, with gradual return to normal diet.
- Enteral tube feeding or parenteral feeding may be required postoperatively.

CLIENT EDUCATION

Warn that animals with the tendency to ingest foreign bodies are often repeat offenders; all reasonable efforts to prevent access to foreign bodies should be made.

SURGICAL CONSIDERATIONS

Gastric Outflow Obstruction

- Pyloroplasty or pyloromyotomy—for pyloric stenosis or CHG.
- Gastrotomy—for

foreign bodies not able to be removed with endoscopy.

- Resection (e.g., Billroth I gastroduodenostomy, Billroth II gastrojejunostomy)—for granulomatous or neoplastic masses.
- Gastropexy—for GDV.

Intestinal Obstruction

- Enterotomy
- Resection and anastomosis—with bowel ischemia and necrosis
- Open peritoneal lavage—with perforation and septic peritonitis
- Closed suction drainage—may be easier and as effective
- Prophylactic enteropexy—with intussusception

MEDICATIONS

DRUG(S)

- Broad-spectrum parenteral antibiotics—with significant mucosal injury or sepsis; ampicillin (20 mg/kg IV q8h) or ampicillin/clavulanate (50 mg/kg IV q8h) and an aminoglycoside (gentamicin 6.6 mg/kg IV q24h, amikacin 15 mg/kg IV q24h) or a fluoroquinolone (enrofloxacin 5–10 mg/kg IV q24h; for cats, ciprofloxacin 10 mg/kg IV q8h). Aminoglycoside antimicrobials should not be used until patient is well hydrated and adverse effects on kidney must be closely monitored via urinalysis (glycosuria, proteinuria, renal casts, decreased urine SG) and assessment of BUN, creatinine, and serum phosphorus values.
- Antiemetics—metoclopramide (0.2–0.5 mg/kg SC or IV q6–8h or 1–2 mg/kg q24h as a CRI); may be given *after* the obstruction has been relieved; cisapride is more potent than metoclopramide but is only available in an oral form (0.3–0.5 mg/kg q8–12h); maropitant may be used in dogs > 8 weeks and cats > 16 weeks at 1 mg/kg SC q24h.
- GI protectants-H₂-receptor antagonists (e.g., famotidine 0.5–1.0 mg/kg, SC, IM, IV q12h) and/or the gastric mucosal protectant sucralfate (250 mg/cat PO q8–12h or 250–1,000 mg/dog PO q8–12h)—may be used in patients with mucosal ulceration.
- Pantoprazole 0.7–1 mg/kg q12–24h.

CONTRAINDICATIONS

Prokinetic agents (e.g., metoclopramide and cisapride) must be avoided until obstruction is resolved.

PRECAUTIONS

Aminoglycoside antibiotics should be not used with shock, dehydration, or renal compromise because of their potential nephrotoxicity.

FOLLOW-UP

PATIENT MONITORING

- Monitor hydration, packed cell volume/total solids, and electrolyte status closely;

adjust fluid therapy accordingly.

- Monitor postoperatively for signs of peritonitis.

PREVENTION/AVOIDANCE

- Clients should be cautioned that some pets with tendencies to ingest foreign bodies may do so repeatedly.
- Efforts to prevent ingestion of foreign bodies are important.

POSSIBLE COMPLICATIONS

- Aspiration pneumonia
- Septic peritonitis (intestinal necrosis and perforation, dehiscence)
- Adynamic ileus and/or gastroparesis

EXPECTED COURSE AND PROGNOSIS

- Uncomplicated cases—prognosis good to excellent.
- Intestinal perforation and septic peritonitis—prognosis guarded initially.
- Obstructive granulomatous gastroenteritis—prognosis guarded to poor, especially with pythiosis.
- Mesenteric torsion or volvulus—prognosis poor to grave (most patients die despite surgery).

GIARDIASIS

BASICS

OVERVIEW

- Enteric infection of dogs and cats with lumen-dwelling protozoan parasite, *Giardia*.
- Direct transmission by ingestion of cysts that are immediately infective when shed in feces.
- Trophozoites, motile (flagellated) organisms released from ingested cysts, attach to surface of enterocytes in small intestine with ventral sucking disc; move from site to site.
- Can cause small bowel diarrhea, but infection often asymptomatic.

SIGNALMENT

- Dogs—up to 50% for pups, up to 100% in kennels.
- Cats—up to 11%.

SIGNS

- Clinical signs more common in young hosts; older dogs, cats usually asymptomatic.
- Signs can be acute, transient, intermittent, or chronic.
- Malabsorption syndrome with soft, frothy, greasy, voluminous feces (diarrhea), usually with rancid odor.

CAUSES & RISK FACTORS

- Transmitted by ingestion of cysts from feces in/on food, water, environment, or fur.
- Indirect water-borne transmission most common; cool, moist conditions favor cyst survival.
- Higher risk of infection in puppies and kittens, in high-density populations (kennels, catteries, animal shelters), and in dogs/cats with compromised immunity.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other infectious and non-infectious causes of small bowel diarrhea, maldigestion, and malabsorption syndromes, especially pancreatic exocrine insufficiency, inflammatory bowel disease.
- In cats, differentiate from infection with *Tritrichomonas blagburni*, a cause of large bowel diarrhea.

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Detection of *Giardia* trophozoites, cysts, or antigen in feces.
- Trophozoites ($15 \times 8 \mu\text{m}$) detectable in fresh feces, especially diarrhea, and in duodenal aspirates obtained by endoscopy; identify in smear stained with Diff-Quik or Lugol's iodine by teardrop shape, with two prominent nuclei and in wet mount of aspirate or small amount of feces in saline by "falling leaf" motility; flotation media lyse trophozoites.
- Cysts, $\sim 12 \mu\text{m}$ long, oval with 2–4 nuclei, shed intermittently; centrifugal flotation of fresh feces in zinc sulfate (s.g. 1.18) preferred method; examination of three samples collected at 2- to 3-day intervals detects > 70% of infections; cysts distorted (crescent-shaped) in sugar or other flotation solution with s.g. > 1.25; formalin-ethyl acetate sedimentation useful in cases of steatorrhea.
- Commercial ELISA-based test kits available for in-house detection of *Giardia* antigen in feces; have variable sensitivity compared to zinc sulfate centrifugal flotation; can detect asymptomatic infection. False-negative or -positive results can occur with all methods. It is recommended that the ELISA kits are used to confirm suspicious cases rather than as a screening tool in healthy animals.

TREATMENT

- Treat as outpatients unless debilitated or dehydrated.
- Drug therapy should be combined with environmental cleaning and disinfection plus bathing of patient to prevent infection.
- Giardia* vaccines commercially available. Efficacy is poor and the vaccine is not widely used.

MEDICATIONS

DRUG(S)

- All drug use is extra-label.
- Fenbendazole 50 mg/kg PO q24h for 3 days (dogs) or 5 days (cats); second course of treatment may be necessary.
- Metronidazole 20–22 mg/kg q12h for 5 days in dogs.
- Metronidazole benzoate 22–25 mg/kg PO q12h for 5–7 days in cats.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Metronidazole only 67% effective in dogs; bitter taste; can cause anorexia; vomiting, CNS signs.
- Albendazole (25 mg/kg PO q12h for 2 days in dogs or 5 days in cats) is effective but is not recommended because it can be teratogenic and/or cause anorexia, depression, vomiting, ataxia, diarrhea, abortion, or myelosuppression.

FOLLOW-UP

- Repeat fecal examinations to confirm efficacy of treatment and to detect reinfection.
- Chronic infection can lead to debilitation.

MISCELLANEOUS

ZOONOTIC POTENTIAL

- In North America, *Giardia* is the most common intestinal parasite in humans.
- Molecular data indicates that dog and cat isolates are host-specific and there is little data to demonstrate transmission from dogs or cats to humans.
- Most *Giardia* infections in humans are zoonotic or originate from livestock.
- Risk of zoonotic transmission from pets to immunocompetent humans appears to be low but is likely increased for humans with compromised immunity.

PREGNANCY/FERTILITY/BREEDING

Do not use albendazole in pregnant dogs or cats; it can be teratogenic.

ABBREVIATIONS

- CNS = central nervous system
- ELISA = enzyme-linked immunosorbent assay

GINGIVAL HYPERPLASIA/ENLARGEMENT

BASICS

OVERVIEW

- Enlargement of gingival tissue due to proliferation of its elements (abnormal multiplication or increase in the normal number of cells in normal arrangement).
- Probable familial tendency—boxers.

SIGNALMENT

- Dogs and rarely cats. • Breed predilections—boxers, Great Danes, collies, Doberman pinschers, Dalmatians.

G

SIGNS

- Thickening and increase in height of attached gingiva and gingival margin—sometimes completely covers tooth surface.
- Resultant formation of “pseudopockets”—increase in pocket depth due to increased gingival height; not due to loss of attachment, unless untreated and progresses to concurrent periodontal disease. • Gingival margin may be symmetrically enlarged, especially at incisors.
- Locally affected areas possible (shelves), but typically more generalized pattern found.
- Focally affected areas, other than the marginal gingiva, may develop hyperplastic areas due to chronic irritation, such as the “gum chewer’s lesion.” These areas should be evaluated for therapeutic need (excision).
- May form as protuberant masses (grape cluster) at gingival margins—biopsy necessary to rule out neoplasia.

CAUSES

Chronic inflammatory response to presence of bacteria in plaque associated with periodontal disease.

RISK FACTORS

- Breed predilection (see “Signalment”).
- Chronic drug administration—diphenylhydantoin, cyclosporine, nitrendipine, nifedipine.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Presumptive diagnosis based on clinical appearance, especially if generalized and found in breed with high predilection. • Oral neoplasia—e.g., peripheral odontogenic fibromas; usually not generalized; sometimes osseous changes present. • Oral papillomatosis—papilloma usually on mucosal surfaces. • Operculum—seen in young animals during eruption phase of teeth; incomplete loss and/or persistence of gingival tissue covering erupting tooth.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

Intraoral radiography—to rule out any underlying osseous changes (more common with epulides or tumors).

DIAGNOSTIC PROCEDURES

- Biopsy—focal area or areas that do not respond to standard therapy.
- Histopathology—to rule out neoplasia and other causes; histologic evaluation is only way to confirm.

TREATMENT

APPROPRIATE HEALTH CARE

Regular dental cleanings and homecare—to minimize effects of plaque and bacterial accumulation.

CLIENT EDUCATION

- Chronic, recurring problem that often needs repeated therapy. • Encourage the highest level of homecare and regular professional cleaning.

SURGICAL CONSIDERATIONS

Gingivectomy (Excising Excess Tissue) and Gingivoplasty (Recontouring)

- To remove excess gingival tissue and return pocket depths to normal. • Provide appropriate patient monitoring and support during anesthetic procedures. • Regional and local anesthetic injections or topical gels.
- Periodontal probe—to determine depth of pseudopocket; can mark pocket depth on outside of pocket with end of probe (“dots”).
- Excise excess tissue and reshape gingival margin. • Cold steel—sharp, stout scissors or scalpel blade. • Connect the dots made by probe with blade to approximate normal gingival margin or use scissors, following pocket depth to remove bulk tissue.
- Twelve-fluted bur on high-speed handpiece—contour margin to feather angle; assists in hemostasis. • Electrocautery or radiosurgery—use fully or partially rectified current; avoid damage to underlying bone or tissue. • Laser—use appropriately and avoid damage to tooth and bone. • Excessive thickness (incisor and canine region)—modified Widman technique; envelop flap to lift gingiva off tooth surfaces; excise tissue wedge to remove gingiva at the inside of the pocket to provide a more narrow width of attached gingiva; suture interdentally to secure gingiva; use digital pressure to reposition.
- Tincture of myrrh and benzoin—use dropper; coat cut margins and dry; 4–5 layers.
- Hemostatic solutions—to aid in hemorrhage control as needed.

MEDICATIONS

DRUG(S)

- Oral antimicrobials—chlorhexidine; zinc ascorbate gel.
- Postoperative pain management.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Patients on chronic administration of diphenylhydantoin or cyclosporine may be predisposed to hyperplastic changes.

FOLLOW-UP

PATIENT MONITORING

- Post-operative comfort—give pain medication as needed. • Regular examinations and professional cleaning and treatment—to avoid recurrence, which is common.

PREVENTION/AVOIDANCE

Regular professional cleaning, meticulous homecare.

POSSIBLE COMPLICATIONS

- Possible exacerbation of periodontal disease in pseudopockets if left untreated; deeper pockets are more susceptible to anaerobic bacterial infections. • Excessive heat with electrosurgical treatment may result in damaged teeth (pulpitis, pulpal death) and alveolar bone.

EXPECTED COURSE AND PROGNOSIS

- Good prognosis with regular care.
- Recurrence common.

Wiggs RB, Lobprise HB. Veterinary Dentistry: Principles and Practice. Philadelphia: Lippincott-Raven, 1997.

Author Heidi B. Lobprise

Consulting Editor Heidi B. Lobprise

BASICS

DEFINITION

• High IOP that causes characteristic degenerative changes in the globe, optic nerve, and retina with subsequent loss of vision. • Diagnosis—IOP > 25–30 mmHg (dogs) or > 31 mmHg (cats) as determined via applanation, rebound, or Schiotz tonometry (using the 1955 Friedenwald human conversion chart that accompanies the Schiotz instrument) with changes in vision or the appearance of the globe, optic nerve, and/or retina.

PATOPHYSIOLOGY

• Develops when the normal outflow of aqueous humor is impaired. • May be result of primary eye disease (narrow or closed filtration angles and goniodysgenesis, which have a genetic predisposition). • May be secondary to other eye diseases (primary lens luxation, anterior uveitis, intraocular tumor, or hyphema).

SYSTEMS AFFECTED

Ophthalmic system (uncontrolled, glaucoma is a painful, blinding disorder).

GENETICS

Dogs—predisposing anomalous configuration of the filtration angles is thought to be inherited; mode of inheritance uncertain.

INCIDENCE/PREVALENCE

Dogs—more common in some breeds; overall incidence of primary glaucoma is more than 0.8% of all hospital admissions listed with the North American Veterinary Medical Data Base. The prevalence of secondary glaucoma in any breed is approximately 0.8% as listed in the NAVMDB.

SIGNALMENT

Species

• Dog—primary and secondary. • Cat—primary rare; secondary seen in patients with signs of long-standing uveitis or with lens luxation.

Breed Predilections

• Goniodysgenesis—Arctic circle breeds (e.g., Norwegian elkhound, Siberian huskie, malamute, Akita, Samoyed); Bouvier des Flandres; Basset hound; chow chow; Shar-Pei; spaniels (e.g., American and English cocker, English and Welsh springer). • Narrow filtration angles—spaniel; chow chow; Shar-Pei; toy breeds (e.g., poodle, Maltese, and Shih Tzu). • Secondary to lens luxations—terriers (e.g., Boston, cairn, Manchester, Dandie Dinmont, Norfolk, Norwich, Yorkshire, Scottish, Sealyham, West Highland white, Parson Jack Russell, and fox) and Shar-Pei.

Mean Age and Range

• Primary (dogs)—any age; predominantly affects middle-aged (4–9 years of age).

- Secondary to primary lens luxations (dogs)—usually affects young (2–6 years of age).
- Secondary to chronic uveitis (cats)—usually affects older cats (> 6 years).

SIGNS

General Comments

• Cannot be accurately diagnosed without instrument tonometry. • All well-equipped small animal hospitals should have a tonometer.

Historical Findings

• Acute angle closure—apparent pain (blepharospasm, tenderness about the head, serous to seromucoid discharge); may note a cloudy or red eye; unless bilateral, vision loss usually not noticed. • Secondary—depends on primary disease. • Uveitis—may note pain (for many days), scleral injection, and corneal edema. • Anterior lens luxation—may note acute pain, scleral injection, and corneal edema; may see lens in the anterior chamber (if corneal edema is not severe). • Chronic uveitis (cats)—may note no signs of pain; enlarged, seemingly painless eye or a dilated pupil common. • Globe enlargement—may be noticed first by owners.

Physical Examination Findings

Acute Primary

• High IOP (often > 30 mmHg). • Blepharospasm. • Enophthalmos. • Episcleral injection. • Diffuse corneal cloudiness. • Dilated pupil. • Vision loss—may be detected by lack of a menace or dazzle response and/or lack of a direct or consensual pupillary light reflex. • Optic nerve may be normal in appearance or may be depressed or cupped.

Chronic (End Stage)

• Globe enlargement (buphthalmos). • Descemet's streaks ("Haab's striae"). • Subluxated lens with an aphakic crescent. • Optic nerve head atrophy. • Retinal necrosis—detected by peripapillary or generalized tapetal hyper-reflectivity.

Uveitis Induced

• Elevated IOP. • Episcleral injection. • Corneal edema. • Inflammatory debris in the anterior chamber. • Miotic pupil (±). • Posterior synechia (±). • Iris bombe (±).

CAUSES

- Primary—filtration angle anomalies.
- Secondary—impediment to aqueous humor outflow (e.g., uveitis: inflammatory cells or debris; lens luxation: lens or attached vitreous; hyphema: RBCs; ocular tumors: neoplastic cells).

RISK FACTORS

- Anterior uveitis. • Lens luxation.
- Hyphema. • Intraocular neoplasia.
- Topically applied mydriatics—may precipitate acute glaucoma in predisposed animals.
- Primary glaucoma (dogs)—consider all cases to be bilateral, even if one eye is normotensive; evaluation of the

unaffected eye by a veterinary ophthalmologist for filtration angle anomalies is indicated to determine the risk for future glaucoma in unaffected eye.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- See Red Eye. • Conjunctivitis—IOP not high; pupil not dilated; conjunctival hyperemia a more diffuse, red discolored instead of episcleral vessel engorgement.
- Uveitis—initially IOP is subnormal or hypotensive; usually results in a miotic pupil.
- Tonometry—usually differentiates glaucoma from other causes of a red eye.

CBC/BIOCHEMISTRY/URINALYSIS

- Primary—typically normal. • Secondary—abnormalities consistent with the primary systemic disease (e.g., thrombocytopenia with hyphema).

OTHER LABORATORY TESTS

Serologic testing for infectious diseases—may help diagnose cause of uveitis.

IMAGING

• Thoracic radiography or abdominal ultrasonography (secondary disease)—may demonstrate systemic lesions consistent with fungal or neoplastic dissemination to the eye as a cause of uveitis or hyphema. • Ocular ultrasound (secondary disease)—may facilitate evaluation of the eye if the ocular media is opaque.

DIAGNOSTIC PROCEDURES

- Instrument tonometry—essential. • Acute disease—refer to a veterinary ophthalmologist for a detailed ocular examination of both eyes, including evaluation of the filtration angles (gonioscopy). • ERG—may help determine if affected eye is capable of vision restoration with medical and/or surgical treatment; normal tracing does not necessarily indicate that the eye will be visual; decreased amplitude or flat tracing guarantees that vision will not return despite treatment.

PATHOLOGIC FINDINGS

- Histopathologic evaluation may reveal collapse of the filtration angle. • Loss of retinal ganglion cells. • Photoreceptor disruption. • Gliosis and "cupping" of the optic nerve head.

TREATMENT

APPROPRIATE HEALTH CARE

- Acute (dogs)—inpatient medical care.
- After discharge—reevaluate every 1–2 days for 1 week to monitor for return of increased IOP.

GLAUCOMA

(CONTINUED)

CLIENT EDUCATION

- Warn client that primary glaucoma is a bilateral disease; more than 50% of dogs develop glaucoma in the other eye within 8 months without prophylactic therapy.
- Warn client that up to 40% of dogs will be blind in the affected eye within the first year regardless of therapy.

SURGICAL CONSIDERATIONS

- Primary and lens luxation—induced cases are best treated surgically. • Primary (dogs)—many patients undergoing medical treatment alone will be non-visual at the end of the first year. • Procedures—enhance aqueous humor outflow (filtration devices); decrease production of aqueous humor (e.g., Nd:YAG or diode laser transcleral cyclophotocoagulation; endoscopic diode cyclophotocoagulation; or transcleral cyclocryosurgery to cause ciliary body ablation); possibly endoscopic diode laser cyclophotocoagulation more effective in maintaining normal IOP and vision. Removal of anteriorly luxated lens may result in visual eye as well as help lower IOP. • Blind, painful eyes—enucleate; evisceration and intraocular prosthesis implantation (if no intraocular infection or neoplasia); intravitreal gentamicin or cidofovir injection; all to minimize long-term medical therapy.

MEDICATIONS

DRUG(S) OF CHOICE

Use multiple agents to lower IOP into the normal range as quickly as possible in an attempt to salvage vision.

Acute Primary (Dogs)

- Emergency medical treatment may include one or more of the following: • If available, first try the prostaglandin/miotic agents latanoprost 0.005% (Xalatan; q12h), travoprost 0.004% (Travatan; q12h), or bimatoprost 0.03% (Lumigan; q12h).
- Apply one drop to affected eye, followed by another drop in 30 minutes. If IOP not normal 2 hours following first application (or prostaglandin/miotic agents not available), use: • Hyperosmotic agents—mannitol (1–2 g/kg IV over 20 minutes) or glycerin (1–2 mL/kg PO q8–12h); will dehydrate the vitreous humor to lower IOP. • Miotic agents—2% pilocarpine solution (q6–12h); 0.25% demecarium bromide (available only from compounding pharmacies such as Wedgewood Pharmacy, 800–331–8272; q12h); enhance aqueous outflow. • Oral carbonic anhydrase inhibitor—methazolamide (2–4 mg/kg q8–12h); reduce production of aqueous humor. • ± topical carbonic anhydrase inhibitors—dorzolamide 2% (Trusopt; q8h), brinzolamide 1% (Azopt; q8h); reduce aqueous humor production. • ± Topical beta-adrenergic

antagonists—timolol maleate 0.5% (q12h), levobunolol 0.5% (q12h), betaxolol 0.5% (q12h); reduce aqueous humor production.

Anterior Lens Luxation or Uveitis Induced (Dogs)

- Treated like primary disease. • Miotic agents—do not use. • Topical corticosteroids—used to reduce inflammation if no ulcerative keratitis.

Chronic Smoldering Uveitis (Cats)

- Topical corticosteroids. • Topical beta-blockers. • Topical carbonic anhydride inhibitors.

CONTRAINdications

- Topical atropine—do not use. • Miotic agents—do not use with primary anterior lens luxation or uveitis. • Use only one miotic agent. • Use only one beta-antagonist. • Use only one carbonic anhydride inhibitor (topical or systemic).

PRECAUTIONS

- Topical pilocarpine—irritating; may cause conjunctivitis and painful brow ache; may worsen uveitis. • Systemic absorption of topical beta-antagonists—may cause bronchoconstriction and bradycardia in small dogs and cats. • Systemic carbonic anhydride inhibitors—cause metabolic acidosis and electrolyte imbalances seen as panting, weakness, disorientation, and/or behavioral change. • Osmotic diuretics—may initiate acute pulmonary edema in patients with compromised cardiovascular-pulmonary disease. • Glycerin—do not use with diabetes mellitus; causes hyperglycemia.

POSSIBLE INTERACTIONS

Demecarium bromide—cholinesterase inhibitor; may lead to organophosphate poisoning if used in conjunction with organophosphate parasiticide products.

ALTERNATIVE DRUG(S)

Other diuretics (furosemide, thiazides, etc.) will *not* reduce IOP.

FOLLOW-UP

PATIENT MONITORING

- IOP—monitored often (initially daily followed by weekly) and regularly after starting initial therapy; if a hypotensive level is maintained for many weeks, slowly taper drug therapy. • Monitor for drug reactions.

PREVENTION/AVOIDANCE

- Primary—bilateral disease; recommend that a veterinary ophthalmologist examine the unaffected eye to determine its risk of developing glaucoma. • Prophylactic therapy for the predisposed, unaffected eye—0.25% demecarium bromide (q24h, at bedtime or q12h) or 0.005% latanoprost (q24h, at bedtime) or 0.5% timolol maleate (q12h) or

2% dorzolamide (q8–12h); delays onset of glaucoma in second predisposed eye.

POSSIBLE COMPLICATIONS

- Blindness • Chronic ocular pain

EXPECTED COURSE AND PROGNOSIS

- Chronic disease that requires constant medical treatment (even with surgical intervention). • With medical treatment only—most patients ultimately go blind.
- Surgical treatment—better chance of retaining vision longer; most patients do not remain visual for more than 2 years after initial diagnosis. • Secondary to lens luxation—may carry a fair prognosis with successful removal of the luxated lens and postoperative medical therapy. • Secondary to anterior uveitis—may carry a fair prognosis with control of uveitis.

MISCELLANEOUS

PREGNANCY/FERTILITY/BREEDING

- All listed drugs may affect pregnancy.
- Primary and lens luxation cases—herited; do not breed affected animals.

SEE ALSO

- Anterior Uveitis—Cats • Anterior Uveitis—Dogs • Red Eye

GLOMERULONEPHRITIS

BASICS

DEFINITION

- Inflammation and progressive dysfunction of glomeruli. Commonly a consequence of intraglomerular immune complex deposition; with or without inflammatory cell infiltration.
- “Glomerulonephritis” (GN) should not be used as an umbrella term for all glomerular diseases, as glomerular injury may be initiated and progress without inflammation.
- Circulating antigen-antibody complexes may be deposited or trapped within glomeruli. Alternatively, immune complexes may form within the glomerular capillary wall when circulating antibodies react with “planted” antigens. Immune complexes activate complement and induce leukocyte infiltration, platelet aggregation, and fibrin deposition, all of which may contribute to glomerular damage; urinary loss of serum proteins and macromolecules also contribute to progressive tubular damage.
- Progressive cellular proliferation and glomerular basement thickening may progress to glomerular hyalinization and sclerosis, nephron loss, and azotemic CKD.

SYSTEMS AFFECTED

- Renal/Urologic—initial proteinuria with few or no white or red blood cells. With progressive disease, azotemia and uremic CKD occur.
- Cardiovascular—edema and ascites secondary to hypoalbuminemia and sodium retention may develop. Hypertension is common. Hypercholesterolemia and hypercoagulability may result in thromboembolic disease.

GENETICS

- Familial GN has been reported in Bernese mountain dogs, Brittany spaniels, bull terriers, bullmastiffs, French mastiffs, Dalmatians, Samoyeds, Doberman pinschers, cocker spaniels, Newfoundlands, rottweilers, Pembroke Welsh corgis, beagles, and soft-coated Wheaten terriers.

INCIDENCE/PREVALENCE

Subclinical glomerular disease is common in dogs. Up to 90% of random-source dogs have glomerular lesions noted on necropsy.

SIGNALMENT

Species

Dog; less commonly, cat

Breed Predilections

- See “Genetics.” • Labrador and golden retrievers may be predisposed to *Borrelia burgdorferi*-associated GN and rapidly progressive renal failure.

Mean Age and Range

- Dogs—mean age at diagnosis, 6.5–8.5 years. Hereditary nephritis may result in proteinuria prior to 6 months of age.
- Cats—mean age at diagnosis, 4 years.

Predominant Sex

- Dogs—no gender predilection
- Cats—75% are males

SIGNS

General Comments

- Proteinuria is often first noted on routine health screenings or during evaluation of urine for other medical problems.
- Clients may seek veterinary care for animals due to underlying infectious, inflammatory, or neoplastic diseases responsible for initiating immune complex formation.

Historical and Physical Examination Findings

- Mild-to-moderate protein loss—proteinuria does not itself result in clinical signs. Nonspecific signs noted by clients may include lethargy or weight loss.
- Severe protein loss (i.e., serum albumin concentration < 1–1.5 g/dL)—may result in transudative edema and/or ascites.
- Once nephron loss progresses to azotemic renal failure, polyuria/polydipsia, anorexia, nausea, and vomiting may occur.
- Dogs with pulmonary thromboembolism (uncommon) may be presented for acute dyspnea or unexplained panting.
- Acute blindness in dogs secondary to retinal hemorrhage or detachment may occur with severe systemic hypertension (uncommonly recognized).

CAUSES

- True auto-immune GN, in which antibodies target a native renal antigen, is rarely found in dogs and cats.
- Numerous infectious and inflammatory diseases associated with glomerular immune complex deposition or formation (see below). In many dogs and cats, however, no antigen source can be identified, and glomerular disease is considered idiopathic. Diseases associated with glomerulonephritis include:
 - Dogs—*infectious diseases* (anaplasmosis, babesiosis, brucellosis, dirofilariasis, ehrlichiosis, hepatozoonosis, infectious canine hepatitis, leishmaniasis, pyometra, borreliosis, chronic bacterial infections such as endocarditis and discospondylitis, trypanosomiasis); *neoplasia*; *inflammatory diseases* (e.g., systemic lupus erythematosus); *endocrinopathies* (hyperadrenocorticism, diabetes mellitus, long-term administration of corticosteroids); *hereditary nephritides*; *miscellaneous causes* (sulfonamides).
 - Cats—*infectious diseases* (e.g., FeLV, FIP, FIV, *Mycoplasma polyarthritis*); *neoplasia*.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Proteinuria—commonly due to inflammation of the post-glomerular urinary tract (e.g., bacterial cystitis/pyelonephritis, urolithiasis, tubular renal failure, neoplasia). Lower urinary tract inflammation is usually (but not always) associated with active urine sediment. Hyperglobulinemia may result in proteinuria, particularly when the sulfosalicylic acid turbidimetric test is used for protein detection. Like glomerulonephritis, renal amyloidosis often causes severe proteinuria with inactive urine sediment. Renal biopsy is the only accurate method for differentiating the various glomerular disease subtypes.
- Hypoalbuminemia—may result from decreased albumin production (liver disease) or gastrointestinal loss (protein-losing enteropathies).

G

CBC/BIOCHEMISTRY/URINALYSIS

- CBC usually unremarkable.
- Hypoalbuminemia and hypercholesterolemia occur in severe cases.
- Persistent proteinuria with inactive urine sediment (although hyaline casts may be noted).
- Microalbuminuria oftentimes precedes overt proteinuria, and may allow early detection of glomerular damage.
- With progressive glomerular disease, biochemical changes consistent with renal failure develop. Azotemia may precede complete loss of urine concentrating ability.

OTHER LABORATORY TESTS

Urine Protein:Creatinine Ratio

- Confirms increased loss of urine protein, and quantifies magnitude of proteinuria.
- The urine protein:creatinine ratio (UPC) can be used to assess therapeutic response and progression or remission of glomerular disease.
- The UPC ratio may also decrease once progressive glomerular sclerosis results in renal failure, the UPC ratio may decrease.

Protein Electrophoresis

- Urine and serum protein electrophoresis may identify monoclonal gammopathies or urinary immunoglobulin light chains (Bence-Jones proteins) in patients with lymphoid malignancy.

IMAGING

May be helpful when screening for initiating inflammatory, neoplastic, or infectious diseases. Mild renomegaly may be observed.

DIAGNOSTIC PROCEDURES

- Permits differentiation of the various histologic subtypes of glomerular disease.

GLOMERULONEPHRITIS

(CONTINUED)

Biopsy results may influence treatment recommendations, and provide prognostic information. Renal biopsies should be considered only once less invasive tests (e.g., CBC, serum biochemistry profile, urinalysis, and quantitation of proteinuria (UPC)) have been completed, and if coagulation testing is normal. • Relative contraindications: a solitary kidney, thrombocytopenia or other coagulopathies, renal lesions associated with fluid accumulation (e.g., hydronephrosis and renal cysts and abscesses). • Biopsy-related complications are more likely in dogs or cats weighing < 5 kg, or with severe azotemia.

G

PATHOLOGIC FINDINGS

- Varying severity of GBM thickening (membranous) and increased mesangial cellularity (proliferative); glomerular scarring may be noted (glomerulosclerosis).
- Biopsy tissue should be placed in special fixatives and preservatives at the time of collection rather than in formalin. Immunofluorescent and/or immunohistochemical staining and electron microscopy maximize the information gained from evaluation of renal biopsies.

TREATMENT

DIET

Sodium-reduced, high-quality, low-quantity protein diets are usually recommended. Most prescription "renal" diets meet these criteria.

CLIENT EDUCATION

Once azotemia and uremia occur, prognosis is guarded to poor due to rapidly progressive disease.

MEDICATIONS

DRUG(S) OF CHOICE

- The most specific and effective therapy is elimination of any source of antigenic stimulation. In most dogs the initiating disease or antigen source cannot be definitively identified, or may be impossible to eliminate (e.g., neoplasia).
- ACE inhibitors reduce proteinuria by altering glomerular filtration pressure. Enalapril (0.5 mg/kg q12–24h) has antihypertensive and antiproteinuric effects and slows renal disease progression in dogs with naturally-occurring idiopathic GN. Because proteinuria is directly toxic to renal tubules, ACE-inhibitor therapy should be initiated at the time of initial disease diagnosis unless severe azotemia is present.
- No controlled

veterinary clinical trials have demonstrated a beneficial effect from immunosuppressive therapy, despite inflammation being a consequence of an inappropriately activated immune system. Glucocorticoids and cyclosporine have independently been shown to worsen proteinuria and prognosis in some patients.

- Aspirin decreases pro-inflammatory thromboxane production. Low-dose aspirin (0.5 mg/kg PO q12–24h) may decrease platelet aggregation and prevent reductions in beneficial prostaglandins. Aspirin therapy should be initiated once serum albumin is < 2.2–2.5 g/dL, or when serum antithrombin is known to be decreased (regardless of albumin concentration).

CONTRAINdicATIONS

Some glomerular disease subtypes, particularly membranous glomerulopathy prior to onset of azotemia, may favorably respond to immunosuppressive drugs. Biopsy is recommended prior to attempting immunosuppressive therapy. If a biopsy cannot be obtained, then immunosuppression can be considered in dogs with serum creatinine > 3.0 mg/dL, progressive azotemia, or severe (< 2.0 g/dL) hypoalbuminemia and inadequate responses to standard therapy alone.

PRECAUTIONS

- Dosages of highly protein-bound drugs and/or drugs eliminated by the kidneys (e.g., aspirin) may require adjustment.
- ACE inhibitors should be used cautiously in azotemic patients. Once serum creatinine is approx. > 3.5 g/dL, reduced ACE inhibitor doses should be considered. Serum creatinine should be monitored 4–7 days after dosage increase to evaluate the status of azotemia.

FOLLOW-UP

PATIENT MONITORING

- UPC—is the least invasive method to assess progression or remission of GN.
- Magnitude of proteinuria will also decrease as nephrons are lost to progressive disease, interpret changes in the UPC ratio in light of serum creatinine changes.
- Monitor serum urea nitrogen, creatinine, albumin, and electrolyte concentrations, blood pressure, and body weight at each evaluation.
- Ideal reexamination schedule in stable patients is 1, 3, 6, 9, and 12 months after initiation of treatment.

PREVENTION/AVOIDANCE

Do not breed animals with suspected familial disease.

POSSIBLE COMPLICATIONS

- Nephrotic syndrome
- Hypertension
- Chronic renal insufficiency or failure
- Thromboembolic disorders

EXPECTED COURSE AND PROGNOSIS

- Guarded to poor
- Often progress despite treatment

MISCELLANEOUS

SYNOMYMS

- Glomerulonephropathy
- Protein-losing nephropathy

GLUCAGONOMA

BASICS

OVERVIEW

- Glucagonoma is an uncommon pancreatic islet cell tumor originating from the alpha cells, which secrete glucagon. Glucagonomas may secrete other hormones as well, such as gastrin, pancreatic polypeptide and in rare cases insulin.
- Excess circulating glucagon results in increased protein catabolism, lipolysis, gluconeogenesis, and glycogenolysis. The culmination of these biochemical changes results in hyperglycemia, hypoaminoacidemia, anemia, and weight loss. Glucagon can also exert a secretory effect on the small intestine, leading to diarrhea.
- Glucagonomas can affect numerous organ systems, including musculoskeletal, integumentary, endocrine, gastrointestinal, nervous/behavioral, and hepatobiliary.

SIGNALMENT

- Dog—rare; older animals
- Cat—no reports to date

SIGNS

- The hallmark sign is a characteristic dermatopathy most commonly called NME or necrolytic migratory erythema. This has also been reported in the veterinary literature as metabolic epidermal necrosis, superficial necrolytic dermatitis, hepatocutaneous syndrome, and diabetic dermatopathy.
- Skin lesions include erythema, erosions, and crusting generally located around mucocutaneous junctions (perineum, face, and genitalia), distal extremities, and footpads. Lesions are often pruritic with hyperkeratotic and painful footpads. In many cases, footpads are the only affected area.
- Other systemic signs may include lethargy, polyuria/polydipsia, diarrhea, secondary pyoderma and/or yeast infections, and weight loss.

CAUSES & RISK FACTORS

The etiology of glucagonoma is unknown; however, glucagonomas are commonly represented in multiple endocrine neoplasia syndrome.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Glucagonoma should always be added to the differential list when the presence of skin lesions consistent with NME is found; however, additional and more common differentials should include nonspecific liver disease and hypoaminoacidemia.
- Metabolic epidermal necrosis has been associated with diabetes, pancreatic tumors, and hepatic disease. Other dermatopathy

differentials include pemphigus foliaceus, systemic lupus erythematosus, vasculitis, food dermatoses, vitamin A responsive dermatosis, and zinc deficiency dermatopathy.

- It is important to note that mild-moderate hyperglucagonemia can be seen secondary to non-glucagonoma diseases such as liver disease, pancreatic disease, chronic renal failure, starvation, bacteremia, diabetic ketoacidosis, and hyperadrenocorticism.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC—may be normal; however, normocytic, normochromic anemia and/or mature neutrophilia is common.
- Biochemistry—may be normal; however, mild liver enzyme and/or total bilirubin elevations with mild hyperglycemia and/or hypoalbuminemia may be noted.
- Bile acid and liver function tests are generally within normal limits.
- Urinalysis—decreased urine specific gravity is common. If secondary diabetes mellitus is present, glucosuria may be present.

OTHER LABORATORY TESTS

- Plasma glucagon levels are generally extremely elevated (i.e., > 1,000 pg/mL); however, normal to mildly elevated glucagon levels do not rule out glucagonoma.
- Plasma amino acid levels are generally severely reduced and are thought to be pathophysiologically associated with the development of NME.
- Zinc levels are generally reduced and are also thought to be pathophysiologically associated with the development of NME.
- Fructosamine may be elevated in patients with secondary diabetes mellitus.

IMAGING

- Ultrasonography—useful to detect pancreatic glucagonomas, peripancreatic metastases, and hepatic metastases.
- CT, MRI, PET scans, selective visceral angiography, and somatostatin receptor scintigraphy (octreoscan and radioiodinated MIBG) are used to increase glucagonoma detection sensitivity in humans

DIAGNOSTIC PROCEDURES

Increased blood serum glucagon and clinical signs consistent with NME are indicative of glucagonoma, but the definitive diagnosis can only be made by biopsy, histopathological examination, and documentation of immunohistochemical glucagon expression. Immunohistochemical assays for other pancreatic and gastrointestinal hormones are commonly performed.

DIAGNOSTIC PROCEDURES

- Skin biopsies taken from affected glucagon-associated NME lesions typically histopathologically exhibit severe superficial to mid-epidermal edema, diffuse parakeratotic hyperkeratosis, and irregular epidermal hyperplasia. This triad of histopathologic

findings is commonly referred to as a “red, white, and blue” pattern.

- Biopsies taken from the primary glucagonoma (and/or metastases) typically histopathologically exhibit pleomorphic islet cells with fine cytoplasmic granules and occasional mitoses with immunohistochemical glucagon expression (and often other secretory hormones).

TREATMENT

- Surgical excision of non-metastatic primary pancreatic glucagonoma represents the best chance for cure. Unfortunately, there is a high rate of post-operative morbidity and mortality reported in dogs. Furthermore, glucagonoma syndrome reported in people is associated with thromboembolic disease, which can further exacerbate morbidity and mortality.
- Combined debulking (primary tumor and/or metastases) and octreotide medical therapy can temporarily resolve skin lesions and provide relief.
- If surgery and/or octreotide therapy are not possible, symptomatic palliative therapies may be beneficial and include high-protein diet with egg whites (approximately two to four egg whites/day for a 25-kg dog), zinc supplementation (may be beneficial in the face of normal serum zinc levels) as outlined below, and fatty acid supplementation.
- Secondary bacterial and/or yeast skin infections are common and should be appropriately treated.

MEDICATIONS

DRUG(S)

- Octreotide, a somatostatin analog that inhibits the conversion of preproglucagon to glucagon, may be beneficial in patients with unresectable and/or metastatic glucagonoma. Side effects reported in human use include injection site pain, vomiting, diarrhea, and cholestasis. The safe and effective dosage of octreotide (or long-acting lanreotide) has not been reported in dogs; however, 10–20 µg/dog SC q8–12h has been reported, whereas a one-time safe dose of 50 µg/dog SC has been reported in healthy dogs.

- Chemotherapeutics have been utilized in human glucagonoma syndrome. Doxorubicin and streptozotocin appear to have the best, albeit, limited activity. The use of streptozotocin as an islet-cell lytic agent has been reported previously in a small number of dogs with insulinoma, but has not been reported in dogs with glucagonoma.

- Glucocorticoids may improve the secondary pruritis of the skin lesions in NME but are not recommended for use in glucagonomas as they are likely to exacerbate hyperglycemia,

GLUCAGONOMA

since many glucagonoma patients have secondary diabetes mellitus.

- Intravenous amino acids (500 mL of essential amino acids added to saline or lactated Ringer's solution given over 12 hours or 10% amino acid solution at 24 mL/kg given over 8–12 hours in a large central vein) have shown variable improvement in skin lesions in dogs. Treatments may be repeated every 1–2 weeks if effective until clinical signs abate or resolve.
- Sulfur/salicylic acid-based shampoos or very mild shampoos may help remove crusts, soften skin, and improve the pain and/or pruritus associated with footpad and/or skin lesions.
- Oral zinc sulfate 10 mg/kg/day or zinc methionine 2 mg/kg/day or zinc gluconate 3 mg/kg/day may be considered.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Glucocorticoids may exacerbate hyperglycemia if secondary diabetes mellitus is present.

FOLLOW-UP

- Serial blood work should be performed post-operatively to ensure the prior hyperglucagonemia (and any other abnormalities) is resolving and continues to be within normal limits.
- Strong considerations should be made for serial follow-up ultrasounds and three-view chest radiographs to monitor for metastasis.

GLUCOSURIA

BASICS

DEFINITION

Positive, semiquantitative urine glucose concentration detected via routine laboratory tests (e.g., reagent test strips). Low concentrations normally present (2–10 mg/dL in humans) are undetectable using routine screening tests. Persistent glucosuria (via screening tests) is abnormal (pathologic).

PATHOPHYSIOLOGY

- Glucose is freely filtered through the glomerular capillaries; therefore, blood and glomerular filtrate have equivalent glucose concentrations.
- Glucose is actively reabsorbed from the proximal renal tubular lumen by sodium-glucose linked transporters in the epithelial cell brush border. Physiologic levels of filtered glucose are mostly removed during health with excreted levels too low to detect using screening tests).

Hyperglycemic Glucosuria

- Glucosuria will be present when plasma glucose concentration exceeds the renal tubular epithelial transport maximum (T_m) (approximately 170–180 mg/dL for dogs, 260–310 mg/dL for cats). If hyperglycemia is present, determine whether glucosuria is transient or persistent.

Transient

- Physiologic—usually transient and associated with release of endogenous “stress” hormones (catecholamines, glucagon, glucocorticoids); especially common in cats. Serum may be normoglycemic or hyperglycemic at urine collection because different concentrations of glucose excreted in urine over time equilibrate in the bladder.
- Pharmacologic—may occur following administration of glucose-containing solutions (e.g., dextrose, total parenteral nutrition). Some hormones (adrenocorticotrophic hormone, glucocorticoids, glucagon, adrenaline, progesterone) and drugs (epinephrine, morphine, phenothiazine, xylazine in cats, diazoxide, l-asparaginase) may cause glucosuria.
- Toxic—ethylene glycol.
- Pathologic—possible with acute pancreatitis.

Persistent

Pathologic—diabetes mellitus, hyperadrenocorticism (\pm), pheochromocytoma, glucagonoma, acromegaly, progesterone (endogenous or exogenous), extreme stress, chronic liver disease, \pm CNS lesions.

Normoglycemic Glucosuria

- Impaired renal proximal tubular epithelial cell reabsorptive capacity.

Congenital

Primary glucosuria, following an overnight fast (Scottish terriers).

Fanconi syndrome (basenji dogs; also sporadic in Norwegian elkhounds, Shetland sheepdogs, miniature schnauzers, Labrador retrievers, border terriers, whippets, Yorkshire terriers, and mixed-breed dogs); decreased reabsorption of glucose, amino acids, and phosphorus plus decreased secretion of hydrogen ions.

Acquired

- Fanconi syndrome due to toxicity such as heavy metal poisoning (lead, mercury, cadmium, uranium or copper associated hepatitis) or dried chicken treats made in China, drugs (gentamicin, cephalosporins, outdated tetracycline, cisplatin, streptozotocin, amoxicillin), chemicals (Lysol, maleic acid).
- Acute renal failure with significant tubular lesions (\pm).

SYSTEMS AFFECTED

- Renal/Urologic—normoglycemic patients have abnormal renal tubular epithelial cell function. Dogs with Fanconi syndrome may develop metabolic acidosis and CKD with secondary multisystem involvement. Glucosuria predisposes to bacterial urinary tract infection.
- Endocrine—hyperglycemic patients may have diabetes mellitus and/or hyperadrenocorticism.
- Liver—copper associated hepatitis; centrilobular hepatitis with copper accumulation, increased serum ALT and ALP; \pm total bilirubin; decreased albumin, urea nitrogen, fasting ammonia concentrations, prolonged hemostasis testing.

SIGNALMENT

- Frequently adult dogs and cats develop persistent hyperglycemic glucosuria due to adult onset diabetes mellitus.
- Dogs with congenital Fanconi syndrome typically develop clinical disease due to defective reabsorption of glucose and amino acids at 4–5 years of age; males and females are equally affected.
- Familial renal tubular disorders have been reported (see “Pathophysiology”).
- Primary renal glucosuria (Scottish terriers) may be recognized at an early age as an incidental finding.
- Copper associated hepatitis with acquired Fanconi syndrome (Labrador retrievers).
- Dogs (any breed or age) fed dried chicken treats made in China.

SIGNS

Clinical signs are variable depending upon the primary cause.

Historical Findings

- Persistent glucosuria results in polyuria (osmotic diuresis), leading to compensatory polydipsia.
- Glucosuria predisposes to urinary tract infections; resultant signs are associated with upper and/or lower urinary tract infection.
- Breed (see “Pathophysiology”) and therapeutic history (see “Pathophysiology”) are important.

Physical Examination Findings

- Patients with hyperglycemic glucosuria may exhibit systemic signs; see Diabetes Mellitus chapters.
- Patients with normoglycemic glucosuria may have normal body functions.

- Dogs with Fanconi syndrome may develop signs of metabolic acidosis, electrolyte abnormalities, and CKD.

CAUSES

Hyperglycemic Glucosuria

Transient

- Physiologic—stress; common in cats
- Pharmacologic—see “Pathophysiology”

Persistent

- Diabetes mellitus (100% of patients); insulin deficiency or resistance.
- Hyperadrenocorticism (5–10% of patients); insulin resistance.
- Acute pancreatitis (\pm); insulin deficiency.
- Other less common causes—CNS lesions, pheochromocytoma, increased growth hormone concentration due to increased progesterone (endogenous or exogenous) or acromegaly, glucagonoma, chronic liver failure (due to failure to metabolize glucagon).

Normoglycemic Glucosuria

Congenital

- Primary renal glucosuria (Scottish terrier).
- Fanconi syndrome (see “Pathophysiology”).
- Congenital diseases may be associated with renal dysfunction (Norwegian elkhound).

Acquired

- Acute renal failure associated with significant proximal tubular lesions
- Fanconi syndrome (see “Pathophysiology”)
- CKD (rare)

RISK FACTORS

Vary with underlying causes

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Persistent hyperglycemic glucosuria in fasted patients is frequently associated with endocrinopathies (diabetes mellitus, hyperadrenocorticism).
- Acute pancreatitis.
- Renal tubular reabsorptive dysfunctions cause normoglycemic glucosuria.
- Stressed patients frequently exhibit mild transient hyperglycemia and glucosuria.

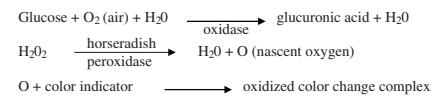

LABORATORY FINDINGS

Screening Tests

Normally negative (urine glucose concentration below detection).

Glucose Oxidase Tests

- Specific for glucose; more sensitive (~40–100 mg/dL) than copper reduction methods.

- Glucose oxidase, peroxidase, and a color indicator are impregnated into reagent test strips; react specifically with glucose at room

GLUTEN ENTEROPATHY IN IRISH SETTERS

BASICS

OVERVIEW

A rare inherited disease in which there is a predisposition to develop a sensitivity to dietary gluten present in wheat and other grains. In affected dogs, there is villous atrophy, reduced brush border enzyme expression, lymphocytic infiltration of the intestinal mucosa, and goblet cell hyperplasia.

SIGNALMENT

- Irish setter breed.
- Signs develop in young to middle-aged dogs.
- Genetic transmission of gluten sensitive enteropathy is likely under the control of a single major autosomal recessive locus.
- Gluten enteropathy has not been reported in other dog breeds or in cats.

SIGNS

- Poor weight gain (or weight loss)
- Poor body condition
- Mild small intestinal diarrhea that can be intermittent
- Variable vomiting

CAUSES & RISK FACTORS

The enteropathy and clinical signs are exacerbated by gluten-containing diet.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Inflammatory bowel disease
- Infectious diseases such as *Giardia*, hookworms, and roundworms
- Metabolic abnormalities
- Exocrine pancreatic insufficiency

CBC/BIOCHEMISTRY/URINALYSIS

- Biochemistry can be unremarkable or may show panhypoproteinemia
- CBC may show eosinophilia

OTHER LABORATORY TESTS

- Serum folate concentrations are subnormal in some patients, reflecting chronic malabsorption in the jejunum.
- Other tests are recommended to rule out other differentials, such as fecal flotation to rule out enteric parasites and serum trypsin-like immunoreactivity to rule out exocrine pancreatic insufficiency.
- Serum TLI and cobalamin concentrations are usually unremarkable.

IMAGING

Not useful

DIAGNOSTIC PROCEDURES

Intestinal biopsy specimens (jejunal) obtained via endoscopy or laparotomy.

PATHOLOGIC FINDINGS

- Histologic examination of jejunal biopsy specimens from affected dogs reared on a wheat-containing diet reveals partial villus atrophy and accumulation of intraepithelial lymphocytes.
- Jejunal abnormalities improve following gluten withdrawal but recur with gluten challenge.

TREATMENT

Treatment is on an outpatient basis. Avoid diets containing gluten (wheat, rye, barley, triticale, brewers yeast, and wheat starch for the life of the animal).

MEDICATIONS

DRUG(S)

Folate (0.5–2 mg PO q24h for 2–4 weeks) if serum folate concentration is markedly subnormal (< 4 µg/L).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

G

FOLLOW-UP

Consider periodic assay of serum folate (q6–12 months)

MISCELLANEOUS

ABBREVIATION

- TLI = trypsin-like immunoreactivity

GLYCOGEN STORAGE DISEASE

BASICS

OVERVIEW

- Also known as glycogenoses: rare inherited disorders of defective or deficient enzyme activity governing glycogen metabolism.
- Tissue glycogen accumulation—leads to organ enlargement and dysfunction; may affect liver, heart, skeletal muscle, kidney, and CNS.
- Impaired hepatic glycogenolysis—leads to symptomatic hypoglycemia (neuroglycopenia).
- Classification—based on enzymatic defect and primary organ(s) involvement: more than 12 types in humans, four types in dogs (Ia, II, III, and VII), 1 type in cats (IV).

SIGNALMENT

- Clinical signs manifest in juveniles—may be days to months after birth.
- Type Ia (von Gierke's disease)—Maltese puppies. Autosomal recessive mutation of glucose-6-phosphatase gene (gene symbol: *G6PC*).
- Type II (Pompe's disease)—Swedish Lapland, Finnish and Swedish Lapphund dogs; onset by 6 months of age. Autosomal recessive, single mutation in acid α -glucosidase (gene symbol: *GAA*).
- Type III (Cori's disease)—young female German shepherds, curly-coated retrievers. Autosomal recessive mutation in glycogen debranching enzyme (gene symbol: *AGL*).
- Type IV (Andersen disease)—Norwegian forest cats; may be stillborn or fade shortly after birth; may manifest signs at 5–7 months with progressive neurologic decline. Autosomal recessive mutation in glycogen branching enzyme (complex rearrangement mutation (gene symbol *GBE1*)).
- Type VII (Tarui disease)—English Springer, American Cocker, whippets, mixed breeds; PFK (M-PFK) muscle isoform single missense mutation; different missense mutation in Wachtelhunds. Adult dogs, no sex predilection.
- Autosomal recessive inheritance—Maltese, Lapland, Lapphund, English Springer spaniels, Norwegian forest cats, other M-PFK affected breeds; also suspected in German shepherds.

SIGNS

- Depend on enzymatic defect.
- Type Ia (Maltese puppies)—failure to thrive; mental depression; hypoglycemia; abdominal distention; hepatomegaly; death or euthanasia by 60 days of age.
- Type II (Lapland dogs)—vomiting and regurgitation related to megaesophagus; progressive muscle weakness; cardiac changes; death before 2 years of age.
- Type III (German shepherds, curly-coated retrievers)—depression; weakness; stunted; abdominal distention from hepatomegaly; mild hypoglycemia, high liver enzymes and CK.
- Type IV (Norwegian forest cats)—perinatal death common; intermittent fever; generalized muscle tremors; muscle atrophy;

weakness progressing to tetraparesis; sudden death from myocardial degeneration and terminal dysrhythmia. Glucose administration can enable cats to survive to adulthood.

- Type VII (English Springer spaniels)—compensated hemolytic anemia; episodic weakness, exercise-induced with intravascular hemolysis; hemoglobinuria; one patient with a progressive myopathy at 11 years of age—no liver effect.

CAUSES & RISK FACTORS

Deficiencies

- Type Ia—glucose-6-phosphatase
- Type II—acid- α -glucosidase
- Type III—amylo-1,6-glucosidase
- Type IV—glycogen branching enzyme (α -1,4-d-glucan)
- Type VII—phosphofructokinase

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- High index of suspicion for diagnosis.
- Breed affiliation—familial history.
- Differentiate other causes of juvenile hypoglycemia—malnutrition; endoparasitism; transient fasting hypoglycemia; portosystemic vascular anomaly.
- Other causes of muscular weakness—infectious diseases; endocrinopathy; immune-mediated causes; hypokalemia; other neuromyopathies.

CBC/BIOCHEMISTRY/URINALYSIS

- Types I and III—hypoglycemia
- Type I: lactic acidemia, increased cholesterol, triglycerides, uric acid
- Type VII—anemia; reticulocytosis; pigmenturia, no hepatic effects

OTHER LABORATORY TESTS

Genetic testing: type I—in Maltese dogs, type II: in Lapland and Lapphund dogs, type III in curly-coated retrievers, type IV in Norwegian forest cats, type VII in breeds listed previously and *in vitro* erythrocyte testing.

IMAGING

- Type II—thoracic radiography; cardiomegaly and megaesophagus.
- Types Ia and III—abdominal radiography; hepatomegaly.
- Abdominal ultrasonography—hepatomegaly, hyperechoic parenchyma consistent with hepatic glycogen accumulation.
- Types II and IV—echocardiography may reveal cardiac changes.

DIAGNOSTIC PROCEDURES

- Tissue enzyme analysis and glycogen determination
- Electromyography—depends on disorder
- Electrocardiography—depends on disorder
- Genetic testing

PATHOLOGIC FINDINGS

- Type Ia—emaciation; massive hepatomegaly due to hepatocyte glycogen and lipid vacuolation and similar change in renal tubular epithelium.
- Type II—glycogen

accumulation in skeletal, smooth, and cardiac muscle.

- Type III—hepatomegaly due to hepatic glycogen accumulation; also in skeletal muscle.
- Type IV—generalized muscle atrophy; glycogen accumulation: skeletal muscle, CNS, and peripheral nervous system.
- Type VII—polysaccharide deposits in skeletal muscle.

TREATMENT

NURSING CARE

- Supportive care.
- Types I and III—may require intravenous or SC dextrose for management of hypoglycemic crisis; long-term management usually futile.
- Gene therapy with adeno-associated virus vector experimentally survived type 1a dogs.

DIET

Control hypoglycemia (types I and III) with frequent feedings of a high-carbohydrate diet until diagnosis is confirmed; glucose solutions usually used.

CLIENT EDUCATION

- Advise that specimens be submitted for genetic/enzyme characterizations.
- Discuss known mechanisms of inheritance to modify breeding programs.

MEDICATIONS

DRUG(S)

N/A

FOLLOW-UP

- Monitor for hypoglycemia.
- Cull parents from breeding programs.
- Prognosis—poor; most patients with glycogen storage disorders causing hypoglycemia and hepatomegaly and stunted growth die or are euthanized owing to progressive deterioration.

MISCELLANEOUS

Consulting Editor Sharon A. Center

GLYCOGEN-TYPE VACUOLAR HEPATOPATHY

BASICS

DEFINITION

- Glycogen-type vacuolar hepatopathy (VH)—reversible hepatocellular cytosolic vacuolation.
- Reflects many primary disorders including: glucocorticoid treatment, hyperadrenocorticism, atypical adrenal hyperplasia (sex hormone hyperplasia), chronic systemic illnesses (inflammatory, neoplastic), and rarely, congenital glycogen storage disorders.
- Typified by high ALP activity—usually without hyperbilirubinemia or hepatic insufficiency.
- Similar but remarkably severe VH in hepato-cutaneous disease (See Diabetic Hepatopathy); may reflect chronic phenobarbital administration.
- Glycogen VH may coexist with cytosolic lipid vacuolation—comparatively rare in dogs but may associate with: idiopathic hyperlipidemia, diabetes mellitus, hypothyroidism, and rare inborn errors of glycogen/lipid metabolism.

PATOPHYSIOLOGY

- Glucocorticoids—induce reversible increase in hepatocyte glycogen within 2–3 days; injectable or topical drug induces most severe VH compared to PO or topical (ocular, cutaneous, aural) routes.
- Cell expansion—causes hepatomegaly; ballooning degeneration leads to parenchymal collapse; when severe, nodularity grossly mistaken for cirrhosis.
- Variable response to glucocorticoids among dogs relates to: (1) drug type, (2) route, (3) dose, (4) treatment duration, (5) individual sensitivity; VH may follow low-dose, short-term oral treatment.
- VH may reflect: stress response, cytokines, or acute-phase response initiated by non-hepatic systemic disorders or neoplasia (especially lymphoma), without exogenous glucocorticoid exposure or adrenal disease.
- VH common in dogs with gallbladder mucocele.

SYSTEMS AFFECTED

- Hepatobiliary—normal hepatic function usually; severe degenerative VH can lead to hepatic dysfunction, jaundice, ascites, and liver failure.
- All systems affected by steroid hormones or a primary systemic disease.

INCIDENCE/PREVALENCE

- Dogs—common, often accompanies primary necroinflammatory liver disorders.
- Cats—rare; liver vacuolation with triglyceride accumulation more common (see Hepatic Lipidosis).

SIGNALMENT

Species

Dog; rarely cat

Breed Predilections

Breeds predisposed to hyperadrenocorticism develop glycogen VH (e.g., miniature poodles, Dachshunds, Boxers, Boston terriers), Scottish terriers (sex hormone adrenal hyperplasia, hyperlipidemia), and others with hyperlipidemia (miniature Schnauzers, Shetland sheepdogs) may develop mixed glycogen/lipid VH.

Mean Age and Range

- Middle-aged to old dogs—spontaneous hyperadrenocorticism ($> 75\%$ older than 9 years); chronic systemic inflammation or neoplasia.
- Dogs of any age—iatrogenic VH subsequent to glucocorticoid administration.
- Young dogs or cats—genetic glycogen storage disease.

SIGNS

General Comments

- Reflect glucocorticoids or underlying systemic illness.
- Rarely, signs of hepatic disease or failure; hepatic failure can develop with severe chronic VH.
- HE observed in some dogs with hepato-cutaneous syndrome (see Diabetic Hepatopathy).

Historical Findings

- Glucocorticoid excess—polyuria and polydipsia; polyphagia; endocrine alopecia; abdominal distention: weak muscles, loss of elasticity; skeletal muscle weakness; excessive panting; lethargy; friable skin; bruising tendencies; urinary tract infections, may be asymptomatic; corneal ulcer.
- Adrenal sex hormone hyperplasia—may display some signs of glucocorticoid excess but often fewer and less severe; endocrine alopecia may be the only sign; some dogs remain asymptomatic except for chronic progressive marked ALP activity and degenerative VH.
- Other causes—depend on system affected; chronic phenobarbital may cause severe VH.
- Sex hormone hyperplasia causing VH may increase risk for dysplastic hepatic foci and hepatocellular carcinoma (e.g., Scottish terriers).

Physical Examination Findings

- Hepatomegaly.
- Relate to steroid hormone excess or underlying disease; depends on severity and duration.

CAUSES

- Glucocorticoid administration.
- Typical hyperadrenocorticism (spontaneous).
- Atypical adrenal hyperplasia—overproduction of cortisol precursor sex hormones (spontaneous).

- Systemic disease provoking acute-phase response or stress—e.g., severe dental disease, inflammatory bowel disease, chronic pancreatitis, systemic neoplasia (especially lymphoma), chronic infections (urinary tract, skin), hypothyroidism, many others.

RISK FACTORS

- Pharmacologic doses of glucocorticoids.
- Breeds at risk for hyperadrenocorticism.
- Breeds at risk for hyperlipidemia—often also demonstrate combined glycogen VH: miniature Schnauzers, Shetland sheepdogs, Beagles.
- Dogs receiving chronic phenobarbital.

G

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

- Other diffuse hepatopathies (especially those causing hepatomegaly and increased ALP activity)—passive congestion; neoplasia (primary or metastatic to liver); necroinflammatory liver disease; anticonvulsant hepatopathy; hepatomegaly due to amyloid (rare).
- VH distinguishing features—most dogs have fold increase in ALP $>$ ALT or AST; increased cholesterol, normal serum bilirubin; normal/mild increase in TSBA; heterogeneous or homogeneous hyperechoic hepatic parenchyma on ultrasonography (nodules or “Swiss cheese” pattern); characteristic cytology: hepatocytes engorged due to expanded “rarefied” cytoplasm.

CBC/BIOCHEMISTRY/URINALYSIS

CBC

- Depends on underlying disease
- Non-regenerative anemia—anemia of chronic disease or hypothyroidism
- Relative polycythemia—steroid excess
- Stress leukogram—hyperadrenocorticism; glucocorticoid exposure; stress of illness
- Thrombocytosis—neoplasia; hyperadrenocorticism; splenic disease

Biochemistry

- ALP markedly increased; ALP glucocorticoid isoenzyme cannot differentiate cause of VH as other liver disorders also induce this isoenzyme; variable GGT, ALT, AST activity.
- Serum albumin and total bilirubin—usually normal; high bilirubin usually implicates another hepatobiliary or hemolytic process.
- Hypercholesterolemia: hyperadrenocorticism, sex hormone adrenal hyperplasia; breed-related hyperlipidemias; hypothyroidism; pancreatitis; nephrotic syndrome.

OTHER LABORATORY TESTS

- ALP glucocorticoid isoenzyme—see above, lacks specificity and thus, clinical utility.
- TSBA—may be modestly increased; ammonia tolerance test—usually normal.

GLYCOGEN-TYPE VACUOLAR HEPATOPATHY

(CONTINUED)

- Pituitary adrenal axis—ACTH-response test or LDDST, \pm HDDST, and endogenous ACTH may help differentiate non-adrenal illness, adrenal or pituitary disorders.
- Urine cortisol:creatinine ratio—at-home urine collection helps rule out hyperadrenocorticism; high ratio may reflect stress or non-adrenal illness.
- Adrenal ultrasound imaging: nodules, adrenomegaly; consider dog size and age.
- If VH confirmed (liver biopsy) and underlying cause not evident, patient asymptomatic or symptomatic for adrenal disease: assess cortisol and sex hormone panel with ACTH response test.
- Thyroid testing—rules out hypothyroidism.
- Triglycerides (fasting)—hyperlipidemia.
- cPLI—may indicate “sub-clinical” pancreatic inflammation or inflammatory bowel disease.

IMAGING

- Abdominal radiography—reveals hepatomegaly or other underlying conditions.
- Thoracic radiography—may reveal lymphadenopathy, metastatic disease, cardiac or pulmonary disorders.
- Abdominal ultrasonography—discloses hepatomegaly, diffuse hyperechoic hepatic parenchyma or multifocal nodular “mottling”; multifocal lesions suggest nodules (“Swiss cheese pattern”) formed by progressive hepatocellular ballooning degeneration; may disclose underlying primary visceral abnormalities (e.g., mesenteric lymphadenopathy, neoplasia) or adrenal disorders (size/shape): adrenals may be large with hyperadrenocorticism, sex hormone adrenal hyperplasia, chronic stress or neoplasia.

DIAGNOSTIC PROCEDURES

- Hepatic fine-needle aspiration cytology—22 gauge, 2.5–3.75 cm (1–1.5 in.) US-guided needle aspiration; target nodules and normal parenchyma.
- Cytology—glycogen vacuolation is common in many primary liver disorders. Used to rule out vacuolar change; cannot definitively confirm illness caused only by VH.
- Hepatic biopsy—verifies VH; excludes other primary hepatic disease; pursue if a systemic disorder is not discovered explaining high ALP and VH; use US-guided Tru-Cut needle biopsy to confirm VH but may miss primary hepatic disease, laparoscopy (recommended), or laparotomy (if visceral inspections and biopsies indicated).
- Cytologic features—hepatocellular cytosolic distention: “rarefaction” or granular appearance with increased cell fragility; canalicular bile casts may be observed; primary VH is not associated with inflammatory infiltrates; common association with extramedullary hematopoiesis (EMH) may be misinterpreted as suppurative inflammation.

- Tissue culture and sensitivity—if suppurative inflammation suspected, submit aerobic and anaerobic bacterial cultures.
- Coagulation assessments—PT, aPTT, fibrinogen, and mucosal bleeding time: usually normal; bench assessments have low predictive value in predicting iatrogenic hemorrhage; buccal mucosal bleeding time may be more relevant.

PATHOLOGIC FINDINGS

- Gross—variable; normal to moderate hepatomegaly; inconsistent surface irregularity; tan or pale color; confusion with cirrhosis if nodular severe degenerative VH.
- Microscopic—marked vacuolization and ballooning of hepatocytes; no consistent zonal distribution, foci of hepatic degeneration; focal aggregates of neutrophils due to EMH; severe degenerative VH leads to parenchymal collapse forming nodules surrounded by a thin partition with minimal collagen deposition.

TREATMENT

DIET

- Hyperlipidemia or pancreatitis—restrict dietary fat and fatty supplements.
- Obesity—gradual energy restriction; treat predisposing disorders.

SURGICAL CONSIDERATIONS

- Depends on underlying conditions.
- Adrenal masses may be resected.
- Hypophyseal masses—resection only by experienced surgeons; pituitary mass lesions may respond to radiation therapy.

MEDICATIONS

DRUG(S) OF CHOICE

- Depends on underlying disease.
- Pituitary-dependent hyperadrenocorticism or adrenal hyperplasia syndrome (sex hormone)—usually treated medically: op'-DDD (mitotane or Lysodren), trilostane or ketoconazole; op'-DDD preferred for sex hormone adrenal hyperplasia as Trilostane augments sex hormone accumulation; l-deprenyl and melatonin ineffective.
- Manage primary inflammatory disorders necessitating immunosuppressive or anti-inflammatory medications—use polypharmacy to minimize glucocorticoid exposure (see “Alternative Drugs”) if symptomatic or progressive VH.
- Neoplasia—tumor resection, chemotherapy or radiation, as appropriate.
- Dental disease—antibiotics and dentistry.
- IBD—hypoallergenic/hydrolyzed protein diets and immunomodulation (avoid glucocorticoids).

- Pyelonephritis, chronic dermatitis, or other infectious disorders—long-term antimicrobial treatment based on microbial culture and sensitivity tests; other appropriate medications.
- Hypothyroidism—supplemental thyroxine.

CONTRAINdications

- Avoid hepatotoxic drugs if severe VH.
- Beware of drug interactions if using ketoconazole for adrenal disease.
- Avoid drugs with hepatic ALP induction effects.

PRECAUTIONS

Glucocorticoids—caution in VH patients; use lowest effective dose regimen (e.g. alternate-day protocol if prednisone or prednisolone); special caution in hyperlipidemia: may worsen clinical signs of abdominal pain, vomiting, pancreatitis; increases insulin requirements in diabetes mellitus; may augment gallbladder mucocele formation; may provoke hepatic lipidosis in cats.

ALTERNATIVE DRUG(S)

Polypharmacy protocol—may reduce glucocorticoid usage in management of immune-mediated or inflammatory disorders; e.g. metronidazole, azathioprine, chlorambucil, cyclophosphamide, mycophenolate, or cyclosporine.

FOLLOW-UP

PATIENT MONITORING

- Hepatomegaly—abdominal palpation; imaging
- Normalizing enzymes—biochemistry
- Adrenal function—ACTH stimulation tests
- Neoplasia—physical exams and imaging
- Control of infection—repeat cultures
- Hyperlipidemia—assess gross plasma lipemia; measure triglycerides and cholesterol

PREVENTION/AVOIDANCE

- Limit glucocorticoid exposure.
- Use alternate-day therapy with prednisone/prednisolone; titrate to lowest effective dose; use alternative medications to control primary illness.

POSSIBLE COMPLICATIONS

Numerous—related to multisystemic effects of glucocorticoids and associated conditions.

EXPECTED COURSE AND PROGNOSIS

- Most patients are asymptomatic for VH despite high ALP; however, progressive degenerative hepatopathy leading to diffuse nodule formation and hepatic insufficiency may develop in chronic VH in dogs with high ALP activity.
- Laboratory and pathologic features reversible before degenerative parenchymal collapse.

(CONTINUED)

GLYCOGEN-TYPE VACUOLAR HEPATOPATHY

- Dogs with sex hormone hyperplasia, VH, and dysplastic hepatocellular foci appear at risk for development of hepatocellular carcinoma.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- Pulmonary thromboembolism and myopathy due to hyperadrenocorticism
- Pancreatitis associated with hyperlipidemia
- Gallbladder mucocele

PREGNANCY/FERTILITY/BREEDING

Reproductive failure with glucocorticoid excess—testicular atrophy; abnormal estrus

SYNOMYS

- Glucocorticoid hepatopathy
- Steroid hepatopathy
- Corticosteroid hepatopathy
- Vacuolar change

SEE ALSO

- Diabetic Hepatopathy

GRAPE, RAISIN, AND Currant Toxicosis

BASICS

OVERVIEW

Syndrome resulting from ingestion of grapes, raisins, sultanas, or Zante currants (*Vitis vinifera*).

SIGNALMENT

- Dogs are the only species in which toxicosis has been well described.
- No breed, sex, or age predisposition noted.
- Anecdotal reports of toxicosis in cats and ferrets exist, but data are lacking to confirm.

SIGNS

- Vomiting within 24 hours of ingestion; vomitus frequently contains ingested fruit.
- Diarrhea, anorexia, lethargy, and abdominal pain may occur.
- Within 24 hours to several days, dehydration with oliguria or anuria occurs.
- Death due to anuric renal failure or euthanasia.

CAUSES & RISK FACTORS

- Although amounts of raisins and grapes reported to cause toxicosis lie in the range 2.8–9.6 g/kg and 11–31 g/kg, respectively, a minimum toxic dose has not been established. Additionally, not all exposures of dogs to *Vitis vinifera* have resulted in clinical evidence of renal injury.
- Ingestion of sultanas, Zante currants, and other varieties of *Vitis vinifera* has also been associated with renal injury in dogs, but amounts associated with toxicosis have not been reported.
- Mechanism of toxicity and toxic principle are unknown. Inconsistent development of clinical signs resulting from ingestion of *Vitis vinifera* may reflect idiosyncratic reactions of individual dogs or a toxic principle that is of variable presence in the fruit due to variances in growing conditions.
- Until further toxicity data are available, all exposures of dogs to *Vitis vinifera* should merit veterinary attention.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other causes of acute renal failure—ethylene glycol, heavy metal toxicosis, nephrotoxic antibiotics (e.g., aminoglycosides), nonsteroidal anti-inflammatory drug

toxicosis, hemoglobinuria, myoglobinuria, leptospirosis, borreliosis, and vitamin D toxicosis.

CBC/BIOCHEMISTRY/URINALYSIS

- Hypercalcemia, hyperphosphatemia, high creatinine and blood urea nitrogen may develop within 24–48 hours of ingestion. Elevated creatinine and hyperphosphatemia tend to develop first, followed by elevation of BUN with calcium elevation tending to increase 48–72 hours after exposure. Differentiate from vitamin D₃ toxicosis, where calcium and phosphorus elevate first followed by elevations in BUN and creatinine as kidney injury develops.
- Hyperkalemia, hyperamylasemia, hyperlipasemia, and elevated ALT have also been reported.
- Isothrenuria, hyposthenuria, proteinuria, hematuria, and glucosuria have been reported.
- Granular casts may occur in the urine.

OTHER LABORATORY TESTS

Histopathology of kidneys reveals acute diffuse renal tubular degeneration and necrosis.

TREATMENT

- Gastrointestinal decontamination (induction of emesis, administration of activated charcoal) should follow ingestion of grapes or raisins by dogs.
- Fluid diuresis (2–3 times maintenance) for minimum of 48 hours is recommended, longer if renal failure develops. Fluid choice may vary with circumstance, but 0.9% NaCl is most commonly recommended.
- Monitor serum chemistry values, particularly renal values, for minimum of 72 hours, longer if renal failure develops.
- Correct fluid imbalances (e.g., dehydration).
- Monitor fluid in/out.
- Diuretics (e.g., furosemide, mannitol, dopamine) if oliguria or anuria develop.
- Hemodialysis or peritoneal dialysis may be required in anuric patients.

MEDICATIONS

DRUG(S)

- Emetics—3% hydrogen peroxide 2.2 mL/kg up to a maximum of 45 mL/dog

PO; may repeat once if first dose unsuccessful; apomorphine crushed and diluted with sterile saline and instilled in conjunctival sac, rinse eye after emesis, or 0.03 mg/kg IV.

- Activated charcoal—1–3 g/kg PO.

Management of Oliguric or Anuric Renal Failure

- Mannitol 0.25–0.5 g/kg of 20–25% solution IV over 15–20 minutes, repeat q4–6h or administer as CRI of 8–10% solution for 12–24 hours.
- Furosemide 2 mg/kg IV, repeat at 4 mg/kg if no diuresis within 1 hour; use with dopamine for best results.
- Dopamine 0.5–3 µg/kg/minute.

CONTRAINdications/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

- In dogs developing renal insufficiency, monitor renal values until they return to normal.
- Some dogs may develop irreversible renal injury requiring lifelong management.
- Evidence of pancreatitis developed in 3 of 43 dogs with acute renal injury following *Vitis vinifera* ingestion.

MISCELLANEOUS

ABBREVIATION

ALT = alanine aminotransferase

HAIR FOLLICLE TUMORS

BASICS

OVERVIEW

- Two main types—trichoepithelioma/trichoblastoma, which arise from keratinocytes in the outer root sheath of the hair follicle (\pm hair matrix); and pilomatrixoma, which arises from the hair matrix.
- Both types—generally benign; a few published reports of malignant pilomatrixomas.
- Approximately 5% of all skin tumors in dogs, uncommon in cats.

SIGNALMENT

- Dog and cat.
- Age—usually > 5 years.
- No sex predisposition.
- Trichoepithelioma—common in dogs; rare in cats; golden retrievers, basset hounds, German shepherds, cocker spaniels, Irish setters, English springer spaniels, miniature schnauzers, and standard poodles may be predisposed; Persian and Siamese cats.
- Pilomatrixoma—uncommon in dogs and cats; Kerry blue terriers and miniature poodles may be predisposed; no known breed predisposition in cats.

SIGNS

- Usually a solitary mass.
- Trichoepithelioma—common on the lateral thorax and dorsal lumbar area (dogs) and head (cats).
- Pilomatrixoma—common on the back, shoulders, flanks, tail, and limbs.
- Firm, round, elevated, well-circumscribed, often hairless, or ulcerated dermoepithelial masses; cut surface gray (trichoepithelioma) or lobulated with white chalky areas (pilomatrixoma).

CAUSES & RISK FACTORS

Unknown, some genetic predisposition

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Distinguish from other tumors including basal cell tumor, squamous cell carcinoma, and keratoacanthoma, and from epidermal inclusion cysts.

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Fine-needle aspiration and cytopathology
- Tissue biopsy and histopathology

PATHOLOGIC FINDINGS

- Fine-needle aspiration cytology—basaloid and ghost cells suggestive of pilomatrixoma in dogs.
- Trichoepithelioma—varies in degree of differentiation and site of origin (root sheath or hair matrix); horn cysts, lack of desmosomes, and differentiation toward hair follicle-like structures and formation of hair common.
- Pilomatrixoma—characterized by a variable proliferation of basophilic cells resembling hair matrix cells and fully keratinized, faintly eosinophilic cells with a central unstained nucleus (shadow cells); calcification common. Features of malignancy are present with the occasional malignant pilomatrixoma.

TREATMENT

Complete excision—curative with most cases

MEDICATIONS

DRUG(S)

- Isotretinoin (1 mg/kg q24h PO) was used to successfully control multiple pilomatrixomas in one dog.
- Multimodal analgesia recommended for painful lesions.

CONTRAINdicATIONS/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

- Monitor for local recurrence.
- Prognosis usually excellent; multiple reports of metastatic disease with the less common canine malignant pilomatrixomas.

H

HALITOSIS

BASICS

DEFINITION

An offensive odor emanating from the oral cavity.

PATHOPHYSIOLOGY

- The sour milk odor accompanying periodontal disease may result from bacterial populations associated with plaque, calculus, unhealthy oral cavity tissues, decomposing food particles retained within the oral cavity, and tissue necrosis.
- Contrary to common belief, neither normal lung air nor stomach aroma contributes.
- The most common cause is periodontal diseases caused by plaque bacteria.
- A bacterial biofilm forms over a freshly cleaned and polished tooth as soon as the patient starts to salivate; bacteria attach to the pellicle within 6–8 hours; within days, the plaque becomes mineralized, producing calculus; as plaque ages gingivitis may progress into periodontitis (tooth support loss), the bacterial flora changes from a predominantly non-motile gram-positive aerobic coccoid flora to a more motile, gram-negative anaerobic population including *Prophyromonas*, *Bacteroides*, *Fusobacterium*, and *Actinomyces* spp.

- The rough surface of calculus attracts more bacteria, irritating the free gingiva; as the inflammation continues, the gingival sulcus is transformed into a periodontal pocket, which accumulates food debris and bacterial breakdown products, creating halitosis.
- The primary cause of malodor is gram-negative anaerobic bacteria that generates volatile sulfur compounds, such as hydrogen sulfide, methyl mercaptan, dimethyl sulfide, and volatile fatty acids.
- Volatile sulfur compounds may also play a role in periodontal disease, affecting the integrity of the tissue barrier, allowing endotoxins to produce periodontal destruction, endotoxemia, and bacteremia.

SYSTEMS AFFECTED

Gastrointestinal—oral cavity

SIGNALMENT

Species

Dogs and cats

Breed Predilections

Small breeds and brachycephalic breeds are more prone to oral disease because the teeth

are closer together, smaller animals live longer, and their owners tend to feed softer food.

Mean Age and Range

Older animals are predisposed.

SIGNS

- If due to oral disease, ptyalism (with or without blood), pawing at mouth, anorexia may occur.
- In most cases, no clinical signs other than the odor.

CAUSES

- Eating malodorous food.
- Metabolic—diabetes, uremia.
- Respiratory—rhinitis, sinusitis, neoplasia.
- Gastrointestinal—megaeosophagus, neoplasia, foreign body.
- Dermatologic—lip-fold pyoderma.
- Dietary—fetid foodstuffs, coprophagy.
- Oral disease—periodontal disease and ulceration, orthodontic, pharyngitis, tonsillitis, neoplasia, foreign bodies.
- Trauma—electric cord injury, open fractures, caustic agents damaging oral cavity.
- Infectious—bacterial, fungal, viral infections of oral cavity.
- Autoimmune diseases of oral cavity.
- Eosinophilic granuloma complex.

DIAGNOSIS

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal. Might see changes consistent with diabetes mellitus or renal disease.

IMAGING

Intraoral radiographs are appropriate to help diagnose causes of halitosis.

DIAGNOSTIC PROCEDURES

- Hydrogen sulfide, mercaptans, and volatile fatty acids are the primary components of halitosis; an industrial sulfide monitor can be used to measure sulfide concentration in peak parts per billion.
- Use of OraStrip QuickCheck Canine provides a quick, point-of-care test that detects thiols produced by the anaerobic bacterial that cause periodontal disease and provides results in the exam room, within 10 seconds.
- Other diagnostic procedures to evaluate periodontal disease include intraoral radiography, probing pocket depths, attachment levels, and tooth mobility.

TREATMENT

APPROPRIATE HEALTH CARE

- Once the specific cause of halitosis is known, direct therapy at correcting existing pathology. Often multiple teeth are extracted when advanced periodontal disease is the cause of halitosis.

CLIENT EDUCATION

- Halitosis is generally a sign of unhealthy oral cavity and should prompt oral assessment under general anesthesia, treatment, and prevention. Initiate preventive measures to ensure good oral health (e.g., twice daily brushing and/or wiping teeth).

SURGICAL CONSIDERATIONS

Oral assessment performed under general anesthesia with intraoral radiographs, treatment including extraction of teeth with greater than 50% support loss.

MEDICATIONS

DRUG(S) OF CHOICE

- Antibiotics are not indicated to treat halitosis.
- Controlling periodontal pathogens helps control dental infections and accompanying malodor. When accompanied by follow-up homecare, has been shown to decrease pocket depth.
- Weekly application of a plaque-retardant gel, has been shown to decrease plaque.
- The use of oral care products that contain metal ions, especially zinc, inhibits odor due to the affinity of the metal ion to sulfur; zinc complexes with hydrogen sulfide to form insoluble zinc sulfide; zinc interferes with microbial proliferation and calcification of microbial deposits (by interfering with the crystal development of calculus). Topical treatment with zinc ascorbate cysteine gel usually reduces halitosis within 30 minutes.

FOLLOW-UP

PATIENT MONITORING

Evaluate for recurrence of signs.

(CONTINUED)

HALITOSIS**PREVENTION/AVOIDANCE**

Daily brushing or friction wipes to remove plaque and control dental disease and odor; periodic veterinary examinations to monitor care.

EXPECTED COURSE AND PROGNOSIS

Varies with underlying cause.

**MISCELLANEOUS****SYNONYMS**

- Bad breath
- Fetor ex ore
- Fetor oris
- Foul breath
- Malodor

H

HEAD PRESSING

BASICS

DEFINITION

Compulsive pressing of the head against a wall or other object for no apparent reason.

PATHOPHYSIOLOGY

- Alterations in behavior—caused by lesions in the prosencephalon (i.e., cerebrum, limbic system, thalamus, and hypothalamus), particularly those affecting the limbic system and frontal and temporal cortices.
- Lesions may result in compulsive pacing; when an obstacle (e.g., a wall) is reached, the animal may press its head against it for long periods of time, apparently unable to turn and move away.
- Apparent inability to voluntarily move away—may reflect impaired integration of sensory information, leading to inappropriate behavior.

SYSTEMS AFFECTED

Nervous

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

SIGNALMENT

Dogs and cats of any age, breed, and sex

SIGNS

- Head pressing—just one sign of prosencephalic disease.
- Compulsive pacing and circling toward the side of the lesion; circling can be toward either side if lesion is centrally located.
- Change in learned behavior.
- Seizures.
- Contralateral postural reaction deficits.
- Contralateral visual deficits with normal pupillary light reflexes.
- Contralateral facial hypalgesia.

CAUSES & RISK FACTORS

- Anatomic—hydrocephalus, most commonly in young toy-breed dogs; lissencephaly (Lhasa apso).
- Metabolic—hepatic encephalopathy as a result of a portosystemic shunt or severe hepatic disease; severe hyper- or hyponatremia.
- Nutritional—very unusual since most pets are fed compounded diets; thiamin deficiency can occur in cats fed a diet of raw fish, if thiamin supplementation in canned food is insufficient or in cats with severe malabsorptive syndromes; however, vestibular signs predominate.
- Neoplastic—primary (e.g., glioma, meningioma) or metastatic (e.g., hemangiosarcoma) tumors affecting the brain; more common in older animals (> 6 years).
- Immune-mediated/inflammatory—granulomatous meningoencephalitis;

necrotizing encephalitides (Maltese encephalitis, pug encephalitis); meningoencephalitis of unknown etiology.

- Infectious (dogs)—viral (rabies virus, canine distemper virus), rickettsial (*Ehrlichia canis*, Rocky mountain spotted fever), protozoal (*Toxoplasma gondii*, *Neospora caninum*), or fungal (*Blastomyces*, *Cryptococcus*); rabies is of particular importance because neurons in the limbic system are frequently infected in carnivores.
- Infectious (cats)—viral (rabies, feline infectious peritonitis, feline leukemia virus [associated immunosuppression predisposes to other encephalitides and neoplasia], feline immunodeficiency virus [can cause encephalopathy primarily and can predispose to other encephalitides and neoplasia due to immunosuppression]); *Bartonella henselae*; *Cuterebra* migration; toxoplasmosis; *Cryptococcus* and other fungal infections.
- Toxic—e.g., lead poisoning.
- Trauma.
- Vascular—intracranial hemorrhage as a result of hypertension (consider in older cats with hyperthyroidism, diabetes or chronic renal insufficiency); bleeding disorder (either primary or secondary to rodenticide toxicity); ischemia (feline ischemic encephalopathy or secondary to systemic metabolic, inflammatory, or neoplastic disease).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

A newly blind animal might bump into objects, but rapidly recognizes his environment and acts visual; an animal with prosencephalic lesion continues bumping into objects despite normal ocular exam.

CBC/BIOCHEMISTRY/URINALYSIS

- May reflect a metabolic or toxic cause.
- Hepatic encephalopathy—decreased serum albumin, blood urea nitrogen, cholesterol, and glucose concentrations, with or without elevated ALP, ALT, and bilirubin concentrations; microcytic anemia may be present; ammonium biurate crystals may be present in the urine.
- Lead toxicity—basophilic stippling of erythrocytes; presence of reticulocytes and nucleated RBCs in the absence of anemia.
- Encephalitis—findings often unremarkable, but may reflect an inflammatory process (e.g., with fungal infection).
- CNS lymphoma—may see evidence of bone marrow involvement.

OTHER LABORATORY TESTS

- Bile acid tolerance—to diagnose hepatic encephalopathy; blood ammonia concentrations may also be elevated.
- Acute and convalescent serologic titers—to diagnose rickettsial, protozoal, fungal, and viral diseases; for some infections (e.g., canine

distemper virus, *Toxoplasma*, *Cryptococcus*), also measure CSF antibody or antigen (*Cryptococcus*) titers.

- Polymerase chain reaction on CSF and serum—to diagnose rickettsial, bacterial, protozoal, fungal, and viral diseases; sensitive and specific if the infectious agent is present in CSF or serum.
- Blood lead concentration—to diagnose lead toxicity.

IMAGING

- Thoracic radiography—recommended for older patients to identify metastatic disease.
- Abdominal ultrasonography—recommended for older patients if intra-abdominal neoplasia is suspected; indicated if a portosystemic shunt or other hepatic disease is suspected.
- Rectal scintigraphy—may be used to definitively diagnose a portosystemic shunt.
- Brain CT or MRI—to identify intracranial masses, malformations, skull fractures, inflammation, and hemorrhage.
- Ultrasonography of the brain via persistent fontanels—may be used to diagnose hydrocephalus in young dogs.

DIAGNOSTIC PROCEDURES

- Fundic examination—to identify chorioretinitis (evidence of infectious/inflammatory disease) and vascular lesions.
- Blood pressure measurement to identify hypertension.
- CSF analysis—to diagnose encephalitis.

PATHOLOGIC FINDINGS

Findings at necropsy will reflect the etiology.

TREATMENT

APPROPRIATE HEALTH CARE

- Severe clinical signs—hospitalization for diagnostic workup and treatment.
- Suspected rabies—quarantine outdoor animal with no vaccination or unknown vaccination history when rapidly progressive neurologic signs are present and animal lives in a rabies-endemic area; minimize the number of people in contact with the animal, and maintain a contact log; if neurologic signs deteriorate rapidly, euthanize the animal and send it to a public health laboratory to be tested for rabies.

NURSING CARE

- When hospitalized, patients should be monitored closely for deterioration in mental status and for seizures.
- Maintenance intravenous fluids may be necessary for patients with severe prosencephalic syndrome.
- The cage may need to be padded to avoid self-trauma if constantly head pressing and pacing.

(CONTINUED)

HEAD PRESSING**H**

- Eyes should be monitored regularly for development of corneal ulcers due to self-induced trauma.
- Central intravenous catheters should be placed in the saphenous vein rather than the jugular vein if possible, to avoid increasing intracranial pressure by occlusion of the jugular veins.

ACTIVITY

N/A

DIET

- Suspected hepatic encephalopathy—appropriate low-protein diet.
- Hand-feeding may be necessary in severely encephalopathic patients; risk of aspiration if the patient fails to prehend and swallow correctly.

CLIENT EDUCATION

- Specific to the underlying condition.
- Clients should be warned about the possibility of seizures, be provided with a description of a seizure and instructions on what to do if a seizure occurs.
- Clients should be provided with a description of signs of acute decompensation due to brain herniation.

SURGICAL CONSIDERATIONS

- If signs are due to intracranial disease, elevated intracranial pressure is likely and therefore there is a risk of herniation during anesthesia, with induction and recovery from anesthesia posing the highest risk. Patients should be ventilated carefully to ensure that their partial pressure of carbon dioxide remains within normal limits (35–45 mmHg).
- Hydrocephalus can be treated by placement of a ventriculo-peritoneal shunt.
- Brain neoplasia, in particular extra-axial tumors such as meningiomas, can be treated surgically if tumor location accessible.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Different causes require different treatment; do not initiate therapy until a diagnosis has been established.
- If patient's mental status deteriorates suggesting impending brain herniation, mannitol (0.25–1 g/kg IV over 10–30 minutes) or hypertonic saline (4 mL/kg of 7.5% or 5.3 mL/kg of 3%) can be used to transiently reduce intracranial pressure; treatment can be repeated but recurrent use will simply result in dehydration.
- Furosemide (0.7 mg/kg IV) given prior to administration of mannitol can complement the use of mannitol and prolong its effect.

CONTRAINdications

N/A

PRECAUTIONS

Sedatives should be used with caution in patients exhibiting head pressing because they prevent assessment of mental status changes and might suppress respiratory drive, causing an increase in pCO_2 and thus causing an increase in intracranial pressure.

ALTERNATIVE DRUG(S)

N/A

**FOLLOW-UP****PATIENT MONITORING**

- Periodic repeat neurologic examinations to monitor progress
- See specific diseases

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

N/A

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

N/A

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

- Rabies should be considered in endemic areas.
- Fungal infections may be zoonotic if spores are released; most likely to occur if exudative skin lesions are present.

HEAD TILT

BASICS

DEFINITION

Tilting of the head away from its normal orientation with the trunk and limbs; usually associated with disorders of the vestibular system.

PATHOPHYSIOLOGY

- Vestibular system—coordinates position and movement of the head with that of the eyes, trunk, and limbs by detecting linear acceleration and rotational movements of the head; includes vestibular nuclei in the rostral medulla of the brainstem, vestibular portion of the vestibulocochlear nerve (CN VIII), and receptors in the semicircular canals of the inner ear.
- Head tilt—most consistent sign of diseases affecting the vestibular system and its projections to the cerebellum, spinal cord, cerebral cortex, reticular formation, and extraocular muscles (via medial longitudinal fasciculus); usually ipsilateral to the lesion.

SYSTEMS AFFECTED

Nervous—peripheral or CNS

SIGNS

- Ensure that abnormal head posture is true head tilt and not a head turn; i.e., turning of the head and neck to the side as if to turn in a circle.
- Head tilt may not be present if disease is bilateral.

CAUSES

Peripheral Disease

- Anatomic—congenital head tilt.
- Metabolic—hypothyroidism; pituitary chromophobe adenoma; paraneoplastic disease.
- Neoplastic—nerve sheath tumor of CN VIII; neoplasia of the bone and surrounding tissue (e.g., osteosarcoma, fibrosarcoma, chondrosarcoma, and squamous cell carcinoma).
- Inflammatory—otitis media and interna; primarily bacterial but also parasitic (e.g., *Otodectes*), and fungal; foreign body; nasopharyngeal polyp(s).
- Idiopathic—canine geriatric vestibular disease; feline idiopathic vestibular disease.
- Immune-mediated—cranial nerve neuropathy.
- Toxic—aminoglycosides, lead, hexachlorophene.
- Traumatic—fracture of tympanic bulla or petrosal bone; ear flush.

Central Disease

- Degenerative—storage disease; demyelinating disease; vascular event.
- Anatomic—hydrocephalus.
- Neoplastic—glioma, choroid plexus papilloma, meningioma, lymphoma, nerve sheath tumor, medulloblastoma, skull tumor (e.g., osteosarcoma); metastasis (e.g., hemangiosarcoma, melanoma).
- Nutritional—thiamin deficiency.
- Inflammatory, infectious—viral (e.g., FIP, canine distemper); protozoal (e.g., toxoplasmosis, neosporosis); fungal (e.g., cryptococcosis, blastomycosis, histoplasmosis, coccidioidomycosis, nocardiosis); bacterial (e.g., extension from otitis media and interna); parasitic (e.g., *Cuterebra* larvae); rickettsial (e.g., ehrlichiosis); algae (protothecosis).
- Inflammatory, non-infectious—granulomatous meningoencephalomyelitis, breed-specific meningoencephalitis (e.g., necrotizing encephalitis).
- Trauma—fracture petrosal bone with brainstem injury.
- Toxic—metronidazole.

• Inflammatory, non-infectious—granulomatous meningoencephalomyelitis, breed-specific meningoencephalitis (e.g., necrotizing encephalitis).

• Trauma—fracture petrosal bone with brainstem injury.

• Toxic—metronidazole.

RISK FACTORS

- Hypothyroidism
- Administration of ototoxic drugs
- Metronidazole treatment
- Thiamin-deficient diet
- Otitis externa, media, and interna

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Vestibular Disease

- Unilateral disease—head tilt usually toward side of the lesion; usually accompanied by other vestibular signs, e.g., abnormal nystagmus (resting, positional) with fast phase usually in the direction opposite the tilt, ventral deviation of the eye (vestibular strabismus) ipsilateral to the tilt observed with elevation of the head; ataxia and disequilibrium with tendency to fall, lean, and/or circle toward the side of the tilt.
- Bilateral disease—head tilt may be absent or mild on the more severely affected side; abnormal nystagmus may be present; physiologic nystagmus (e.g., normal vestibular nystagmus) may be depressed or absent; may have wide side-to-side swaying movements of the head (especially evident in cats); may have wide-based stance or a crouched posture with reluctance to move.
- Head tilt—localizes to peripheral (e.g., vestibular portion of cranial nerve VIII or receptors in the inner ear) or central (e.g., vestibular nuclei and their neuronal pathways) nervous system.
- Peripheral deficits—horizontal or rotatory nystagmus with fast phase opposite the head tilt; possible concomitant ipsilateral facial nerve paresis or paralysis and/or Horner's syndrome, and/or decreased tear production because of the close association of CN VIII with CN VII and the sympathetic nervous system in the petrosal bone and tympanic bulla.
- Central deficits—vertical, horizontal, or rotatory nystagmus that can change direction with position of the head; altered mentation; ipsilateral paresis and/or proprioceptive deficits; central signs related to cerebellum, rostral medulla, and pons; in some patients, multiple CN involvement.
- Paradoxical vestibular syndrome—with lesions in the caudal cerebellar peduncles, or flocculonodular lobes of cerebellum; vestibular signs (e.g., head tilt, nystagmus)

contralateral to the lesion whereas the cerebellar signs and proprioceptive deficits are ipsilateral to the lesion.

Non-vestibular Head Tilt and Head Posture

- Uncommon.
- Must differentiate from true vestibular head tilt.
- Unilateral midbrain lesions can cause severe rotation of the head (> 90°) toward the side opposite the lesion; no other vestibular signs; tilt corrects when patient is blindfolded.
- Adversive syndrome—observed with rostral thalamic or frontoparietal lobe lesions; head turn, neck curvature, and/or compulsive circling can be misinterpreted as vestibular deficits; may have postural reaction, menace, and/or sensory deficits that are contralateral to the lesion; compulsive turning is usually in large circles and without the disequilibrium and true head tilt of vestibular disease.

CBC/BIOCHEMISTRY/URINALYSIS

- Usually normal
- Mild anemia—hypothyroidism
- Leukocytosis with neutrophilia—otitis media and interna
- Thrombocytopenia—ehrlichiosis
- Hypercholesterolemia—hypothyroidism
- High serum globulin concentration—FIP

OTHER LABORATORY TESTS

- T_4 , free T_4 , FT_4 , E_QD, and endogenous TSH levels—if hypothyroidism is suspected based on physical examination and associated unilateral or bilateral involvement of CN VIII and possibly VII.
- Bacterial culture and sensitivity—sample from myringotomy or surgical drainage of tympanic bulla if otitis media/interna is suspected.
- Microscopic examination of ear swab—parasites (e.g., *Otodectes*).
- Serologic testing—*infectious causes* (e.g., canine distemper; FIP; protozoal, fungal, rickettsial diseases).

IMAGING

- Radiographs of tympanic bullae and skull—normal radiographs do not rule out bulla disease.
- CT and MRI—valuable to confirm bulla lesions, CNS extension from peripheral disease, localize tumor, granuloma, and document extent of inflammation.

DIAGNOSTIC PROCEDURES

- CSF—from cerebello-medullary cistern; for evaluating central vestibular disease; detects inflammatory process; protein electrophoresis and titers to match with serologic testing if indicated; collection may put the patient at risk for herniation if elevated intracranial pressure.
- BAER—assess cochlear portion of CN VIII and brainstem auditory pathways; particularly valuable for evaluating peripheral vestibular disease, because some diseases may cause ipsilateral deafness (e.g., otitis media/interna), whereas other diseases (e.g., canine geriatric and feline idiopathic vestibular diseases) affect only the vestibular portion of CN VIII.
- Biopsy—bone, tissue in tympanic bulla when a tumor, polyp, or osteomyelitis is suspected; brainstem mass

(CONTINUED)

HEAD TILT

(e.g., cerebello-medullary angle) difficult to approach and remove surgically.

**TREATMENT**

- Inpatient versus outpatient—depends on severity of signs (especially vestibular ataxia), size and age of patient, and need for supportive care.
- Supportive fluids—replacement or maintenance intravenous fluids may be required in acute phase when disorientation, nausea, and vomiting preclude oral intake; especially important in geriatric patients.
- Activity—restricted according to degree of disequilibrium.
- Diet—as usual unless there is thiamin deficiency (e.g., exclusively fish diet without vitamin supplementation); restrict oral intake if nausea and vomiting; caution: aspiration secondary to abnormal body posture in patients with severe head tilt and disequilibrium or brainstem dysfunction.
- Discontinue drug if toxicity suspected.
- Surgical treatment—to drain bulla with otitis media, remove nasopharyngeal polyp in cats, and resect tumor, if accessible.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Otitis media and interna—broad-spectrum antibiotic (parenteral or oral) that penetrates bone while awaiting culture results; trimethoprim-sulfa (15 mg/kg PO q12h or 30 mg/kg PO q12–24h); first-generation cephalosporins, such as cephalexin (10–30 mg/kg PO q6–8h) or amoxicillin/clavulanic acid (Clavamox dogs, 12.5 mg/kg PO q12h, or cats, 62.5 mg/cat PO q12h; Clavaseptin 12.5 mg/kg PO q12h); treatment for 4–6 weeks.
- Hypothyroidism— T_4 replacement (dogs, levothyroxine 22 μ g/kg PO q12h) should be introduced gradually in geriatric patients, especially with cardiac disease; response varies, partly depending on the duration of signs (i.e., in some patients, neuropathy is not reversible).
- Infectious CNS—specific treatment, if indicated; for bacterial diseases, antibiotic that penetrates the blood-brain barrier (e.g., trimethoprim-sulfa, 15 mg/kg PO q12h; metronidazole 15 mg/kg q12h or 10 mg/kg q8h PO or slowly IV; third-generation cephalosporin, e.g., cefotaxime 25–50 mg/kg

IV q8h); for protozoal diseases, clindamycin (12.5–25 mg/kg PO q12h); for fungal diseases, itraconazole (dogs, 2.5 mg/kg PO q12h or 5 mg/kg PO q24h; cats, 5 mg/kg PO q12h), fluconazole (dogs, 5–8 mg/kg PO q12h, 10–12 mg/kg PO q24h; cats, 50 mg/cat PO q12–24h); prognosis usually poor for protozoal, fungal, and viral diseases (e.g., FIP).

- GME—usually initially treated with steroids: dexamethasone (0.25 mg/kg PO, IM q12h for 3 days; followed by prednisone (2 mg/kg PO q24h for 1–2 weeks; then decrease slowly); depending on progress, may need stronger immunosuppression—e.g., cytosine arabinoside 50 mg/m² q12h for four treatments repeated every 3 weeks (need to monitor CBC); radiation therapy.
- Trauma—supportive care (e.g., anti-inflammatory drugs, antibiotics, intravenous fluid administration); specific fracture repair or hematoma removal is potentially difficult considering the location.
- Canine geriatric and feline idiopathic vestibular disease—supportive care only.
- Cranial nerve polyneuropathy—response to prednisone good if the patient has a primary immune disorder.
- Thiamin deficiency—diet modification and thiamin replacement.

CONTRAINdications

Drugs potentially toxic to the vestibular system—aminoglycoside antibiotics; prolonged high-dose metronidazole.

PRECAUTIONS

- Trimethoprim-sulfa administration—keratoconjunctivitis sicca (dry eye).
- Avoid administering drugs into external ear canal (especially oil-based) if tympanic membrane is ruptured.

**FOLLOW-UP****PATIENT MONITORING**

- Repeat the neurologic examination as dictated by underlying cause.
- Head tilt may persist.
- Hypothyroidism—measure T_4 concentration 4–6 hours after treatment 3–4 weeks after initiation of thyroid therapy or dosing change.
- Repeat CSF and brain imaging—with some central vestibular disorders.
- Monitor tear production (Schirmer test) with trimethoprim-sulfa administration.

POSSIBLE COMPLICATIONS

- Progression of disease
- Brain herniation

EXPECTED COURSE AND PROGNOSIS

- Prognosis for central vestibular disorders usually poorer than peripheral vestibular disorders.
- Prognosis for canine geriatric and feline idiopathic vestibular syndromes is excellent.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- Facial nerve paresis or paralysis
- Horner's syndrome

AGE-RELATED FACTORS

Canine geriatric vestibular syndrome affects older dogs.

H**SEE ALSO**

- Encephalitis
- Meningoencephalomyelitis, Granulomatous
- Nasal and Nasopharyngeal Polyps
- Otitis Media and Interna
- Vestibular Disease, Geriatric—Dogs
- Vestibular Disease, Idiopathic—Cats

HEAD TREMORS (BOBBING), IDIOPATHIC—DOGS

BASICS

OVERVIEW

- Common, very specific, benign, often self-limiting, head and neck tremors in dogs.
- Commonly called head bobbing but idiopathic head tremors is more appropriate.
- Synonyms: episodic head tremor syndrome, bobble head doll syndrome, head shaking, head tremors, head wobbling, head nodding.
- A movement disorder is suspected, but the pathophysiology remains unknown.

SIGNALMENT

- All dog breeds can be affected. • Not reported in cats. • English bulldog (EB), French bulldog, Boxer, Doberman Pinscher (DP) and Labrador retrievers are predisposed.
- Reported prevalence of 19–38% in EB.
- Reports that males are over-represented in DP and EB. • Generally starts early in life (< 3 years old), but can start at any age.

SIGNS

Historical Findings

- Acute onset of head tremor episodes.
- Possible recent stressful event (heat, gestation, whelping with lactation, vaccination, illness, etc.). • Littermates may be affected (familial form identified in DP ≤ 1 year old).

Physical Examination Findings

- None if not currently experiencing an episode. • Typical vertical or horizontal rapid (4–8 Hertz or movements per second) head tremors—episodes last from a few seconds to a few hours. • Variable tremor episode frequency, duration, and inter-episode interval. • Occasional reports of abnormal dystonic posture (subtle head tilt, stiffness, floppiness) during episodes, but not between episodes. • Occasional reports of abnormal behavior (disorientation, sleepiness, agitation) immediately prior to an episode. • All dogs are reported to be responsive to their surroundings during the episode. • Rare reports of associated generalized seizure.
- Episodes can often be interrupted by distraction or treats. • Other neurologic abnormalities (ataxia, proprioceptive deficits, paresis, etc.) consistent with concurrent, unrelated neurologic disease (cervical spondylomyopathy in DP, hemivertebrae in bulldogs) are often noted.

CAUSES & RISK FACTORS

- Unknown pathophysiology. • Anatomic, neoplastic, and traumatic causes have been ruled out by different studies. • Genetic basis suspected but unproven. • May be triggered by a recent stressful event.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Tremogenic toxin (mycotoxin, permethrins, etc.). • Corticosteroid-responsive shaker/tremor syndrome.
- Hypomyelinating/dysmyelinating congenital or degenerative disease.
- Cerebellar disease (intention tremor).
- Hypocalcemia. • Hypoglycemia.
- Hypoadrenocorticism (electrolyte imbalance). • Epilepsy (focal or generalized seizures) or reactive seizures. • Stress.
- Muscle fatigue following exercise or associated with generalized weakness from myopathy, neuropathy or neuromuscular disease. • Viewing of a video provided by the client helps greatly in identifying this typical head movement and differentiating it from other types of tremor. • History and signalment differentiate head bobbing from many of these conditions.

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal

OTHER LABORATORY TESTS

N/A

IMAGING

Magnetic resonance imaging might be considered if abnormalities other than typical head bobbing episodes noted.

DIAGNOSTIC PROCEDURES

Cerebrospinal fluid analysis and electrodiagnostic testing might be considered if abnormalities other than typical head bobbing episodes noted.

PATHOLOGIC FINDINGS

Have not been studied

TREATMENT

- No known effective treatment. • Attempts to interrupt the episodes by distracting the dog should be tried by the client. • If head bobbing episodes significantly impair crucial life functions such as eating or sleeping, or the quality of life of the dog, consult a veterinary neurologist for further recommendations.

MEDICATIONS

DRUGS

No known effective medication.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Commonly used antiepileptic drugs (phenobarbital, potassium bromide) have

multiple significant side effects and have not been proven unsuccessful at treating head bobbing. Their use is not warranted with this condition.

FOLLOW-UP

PREVENTION/AVOIDANCE

N/A

EXPECTED COURSE AND PROGNOSIS

- Self-limiting in 49% of EB in one study.
- Benign head tremor episodes may continue life-long at a variable frequency, usually decreasing over time. • Prognosis is excellent as head bobbing is not associated with a life-threatening condition.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Concurrent epilepsy may be present and may need to be addressed. • A thorough description of the idiopathic head tremor episodes needs to be obtained and variation from the typical pattern should be video-filmed and reviewed.

PREGNANCY/FERTILITY/BREEDING

Studies regarding the potential genetic transmission of this condition are under way.

ABBREVIATIONS

- EB = English bulldog • DP = Doberman pinschers

HEARTWORM DISEASE-CATS

BASICS

OVERVIEW

- Disease caused by infection with *Dirofilaria immitis*. • Microfilaremia uncommon (<20%) and if present usually transient.
- Prevalence one-tenth that of unprotected dogs. • Low average worm burden. • Worms are physically smaller but recent evidence suggests lifespan is similar to that in the dog.

SIGNALMENT

- No age or breed predisposition. • Males more commonly infected naturally and easier to infect experimentally.

SIGNS

Historical Findings

- Coughing (this is relatively uncommon with heart failure). • Cough will commonly occur early in the disease prior to an established adult infection. • Heartworm-associated respiratory disease (HARD). • Clinical signs and pulmonary pathology that occurs 2–4 months post-infection even when an adult infection is never established. • Dyspnea.
- Vomiting (undetermined cause). • PTE frequently results in acute respiratory failure and death. • Vomiting and respiratory signs predominate in chronic disease.

Physical Examination Findings

- Usually normal. • Increased bronchovesicular sounds. • An arrhythmia, murmur, or gallop rhythm should increase the suspicion of primary cardiac disease.

CAUSES & RISK FACTORS

- Outdoor cats at increased risk (2:1). • FeLV infection is not a predisposing factor.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Asthma • Cardiomyopathy • Chylothorax
- *Aelurostrongylus abstrusus* infection
- *Paragonimus kellicotti* infection

CBC/BIOCHEMISTRY/URINALYSIS

- Varies with stage of disease • Mild nonregenerative anemia • Eosinophilia inconsistent • Concurrent basophilia should increase suspicion • Hyperglobulinemia

OTHER LABORATORY TESTS

Microfilaria Concentration Tests

Very low sensitivity, high specificity

Heartworm Antigen Tests

- ELISA or immunochromatographic tests.
- Tests that detect circulating HWAg are more specific than antibody tests. • A positive antigen test result is strong evidence of adult heartworm infection. • Low worm burdens (fewer than five worms) and single-sex infections commonly result in false-negative Ag tests. • Recent data suggests that heat

treatment of samples prior to testing may significantly increase the test sensitivity. Negative result does not rule-out heartworm disease; more than 40% of cats with adult infection are antigen-negative. Many cats are symptomatic (HARD) well before an antigen test would become positive.

Heartworm Antibody Tests

- ELISA or immunochromatographic tests.
- Tests that detect circulating antibodies to immature and adult heartworm antigen are the most sensitive tests for feline heartworm disease. • A positive result does not confirm an adult infection. Usually becomes positive within 4 months of infection. • The more intense the antibody response the more likely there is an adult infection. • May become negative in adult infections perhaps associated with Ag;Ab complexing.

IMAGING

Radiography

- Enlarged (pulmonary artery, > 1.6 times the width of the ninth rib). • Blunted, tortuous pulmonary arteries. • Patchy perivascular pulmonary infiltrates. • Pleural effusion may be present. • Chylothorax has been documented with spontaneously occurring and experimentally induced heartworm infections in cats.

Echocardiography

- Dilated main pulmonary artery.
- Identification of worms in heart or main pulmonary artery; most commonly seen in the right pulmonary artery but also in right ventricle and atrium (hyperechoic “=” sign).
- Sensitive test in the hands of an experienced echocardiographer. • Excludes or confirms other primary cardiac diseases (cardiomyopathy).

TREATMENT

- There is currently no approved or recommended medical adulticide therapy.
- Surgical or catheter-based extraction may be the most reasonable option. • Symptomatic cats should be stabilized (see below) prior to consideration of worm extraction.
- Spontaneous “cure” is probably more common in cats than dogs.

MEDICATIONS

DRUG(S)

Initial Stabilization

- Supplemental oxygen. • Theophylline (sustained release formulation) 15–25 mg/kg PO q24h in the evening. • Prednisolone 1–2 mg/kg PO q12–24h for 10–14 days; then gradually reduce. • Doxycycline therapy 10 mg/kg PO q24h for 30 days (to eliminate the endosymbiont *Wolbachia*) may hasten worm death and reduce the severity of

pulmonary inflammation secondary to worm embolization. • Cautiously balanced fluid therapy if indicated. • Medical adulticide therapy is not currently recommended.

- Supportive care for PTE the same as initial stabilization (see above).

CONTRAINdications/POSSIBLE INTERACTIONS

- Aspirin therapy—no documented benefit.
- Current information does not support the use of melarsomine (Immiticide) in cats.

FOLLOW-UP

PATIENT MONITORING

Serial evaluation of clinical response, thoracic radiographs, and heartworm antigen and antibody tests is most informative.

PREVENTION/AVOIDANCE

- Ivermectin 24 µg/kg PO every 30 days.
- Milbemycin oxime 0.5 mg/kg PO every 30 days. • Selamectin 6.6–12 mg/kg cutaneously every 30 days. • Moxidectin 1–2 mg/kg cutaneously every 30 days.
- Administration of these drugs in cats is not precluded by antibody or antigen seropositivity.

MISCELLANEOUS

ABBREVIATIONS

- ELISA = enzyme-linked immunosorbent assay • FeLV = feline leukemia virus
- HARD = heartworm-associated respiratory disease • HWAg = adult heartworm antigen
- PTE = pulmonary thromboembolism

HEARTWORM DISEASE—DOGS

BASICS

DEFINITION

Disease caused by infestation with *Dirofilaria immitis*

PATOPHYSIOLOGY

- Disease severity is directly related to the number of worms, duration of infestation, host response, and host activity level.
- Endothelial damage leads to myointimal proliferation and inflammation predisposing to periarterial edema.
- Lobar arterial enlargement, tortuosity, and obstruction cause impaired compliance, loss of collateral recruitment, pulmonary hypertension, and thrombosis.
- Pulmonary damage is exacerbated after the death of adult worms and with exercise.

SYSTEMS AFFECTED

- Respiratory—pulmonary hypertension (when severe), thromboembolism, allergic pneumonitis (some occult infections), eosinophilic granulomatosis (uncommon).
- Cardiovascular—severe pulmonary hypertension causes right ventricular hypertrophy and, in some dogs, right-sided congestive heart failure (R-CHF=ascites).
- Hemic/Lymphatic/Immune—venous inflow to the heart can become obstructed by worms causing traumatic hemolytic anemia and cardiogenic shock (caval syndrome).
- Renal/Urologic—immune-complex glomerulonephritis.

INCIDENCE/PREVALENCE

Virtually 100% in unprotected dogs living in highly endemic regions.

GEOGRAPHIC DISTRIBUTION

- Most common in tropical and subtropical zones
- Common along the Atlantic/Gulf coasts and Ohio/Mississippi river basins
- Diagnosed in all 50 states
- Ubiquitous—mosquito vector

SIGNALMENT

Breed Predilections

- Medium- to large-breed dogs > small dogs
- Outdoor dogs > indoor dogs

Mean Age and Range

Infestation can occur at any age; most affected dogs are 3–8 years old

Predominant Sex

Males affected more often than females

SIGNS

Historical Findings

- Dogs often asymptomatic or exhibit minimal signs such as occasional coughing (Class I).
- Coughing and exercise intolerance associated with moderate pulmonary damage (Class II).
- Cachexia, anemia, exercise intolerance, syncope, and/or ascites (R-CHF) in severely affected dogs (Class III).

Physical Examination Findings

- No abnormalities—dogs with mild (Class I) and some with moderate infestation (Class II).
- Labored breathing and/or crackles—dogs with severe pulmonary hypertension (Class III) or pulmonary thromboembolism.
- Tachycardia, weight loss, exercise intolerance, syncope, coughing, anemia, and dyspnea (Class III).
- Ascites, jugular vein distention/pulsation, and hepatomegaly indicate R-CHF (Class III).
- Hemoptysis—occasionally.
- Pale mucous membranes, dyspnea, weak pulses, hemoglobinemia, and hemoglobinuria (caval syndrome).

RISK FACTORS

- Residence in endemic regions
- Outside habitat
- Lack of prophylaxis
- Greater than 64°F all day, every day for at least 1 month
- Greater than 80°F every day for 10–14 days.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of pulmonary hypertension and thrombosis (e.g., hyperadrenocorticism, protein-losing nephropathy or enteropathy)
- Chronic obstructive lung disease
- Pneumonia
- Allergic lung disease
- Other causes of ascites (e.g., dilated cardiomyopathy)
- Other causes of hemolytic anemia (e.g., immune-mediated).

CBC/BIOCHEMISTRY/URINALYSIS

- Anemia—absent, mild, or moderate depending on chronicity, severity of disease, and thromboembolic complications. Anemia associated with Class III.
- Eosinophilia and basophilia—vary.
- Inflammatory leukogram and thrombocytopenia associated with thromboembolism.
- Hyperglobulinemia—inconsistent finding.
- Hemoglobinemia—evident with caval syndrome and less often with thromboembolism.
- Proteinuria—common in dogs with severe and chronic infestation; caused by immune-complex glomerulonephritis or amyloidosis.
- Hemoglobinuria—caval syndrome or severe lysis with thromboembolism (Class III).

OTHER LABORATORY TESTS

- Highly specific, sensitive serologic tests that identify adult female *D. immitis* antigen; test 7 months after the end of the previous transmission season.
- Antigenemia absent in absence of adult female worms.
- Weak positive test verified by repeat testing using different test.
- Strong reaction indicates relative high worm burden or recent death of worms and is highly predictive of thromboembolic complications following adulticide therapy.
- Microfilaria identification tests are not recommended for routine heartworm screening; mainly used to

confirm weak positive antigen tests, determine microfilarial status prior to patients receiving milbemycin as heartworm preventative, and to identify microfilaria which may contribute to the development of resistance when treated chronically with macrolide preventative.

IMAGING

Radiographic Findings

- Use DV projection.
- Main pulmonary artery segment enlargement, lobar arterial enlargement, and tortuosity/pruning vary from absent (Class I) to severe (Class III).
- Right caudal artery > left caudal artery > cranial arteries.
- Parenchymal lung infiltrates of variable severity—surround lobar arteries; may extend into most or all of one or multiple lung lobes when thromboembolism occurs.
- Diffuse, symmetrical, alveolar, and interstitial infiltrates occasionally occur secondary to allergic reaction to microfilaria (allergic pneumonitis) in about 10% of occult infestations.

Echocardiographic Findings

- Often unremarkable; may reflect right ventricular dilation and wall hypertrophy, tricuspid regurgitation, pulmonary hypertension, small left heart due to under-loading (pulmonary obstruction/hypertension).
- Parallel, linear echodensities produced by heartworms may be detected in the right ventricle, right atrium, and pulmonary arteries.

DIAGNOSTIC PROCEDURES

Electrocardiographic Findings

- Usually normal.
- May reflect right ventricular hypertrophy in dogs with severe infestation.
- Heart rhythm disturbances—occasionally seen (atrial premature contractions and atrial fibrillation most common) in severe infestation.

PATHOLOGIC FINDINGS

- Large right heart
- Pulmonary arterial myointimal proliferation
- Pulmonary thromboembolism
- Pulmonary hemorrhage
- Hepatomegaly and congestion in dogs with R-CHF

TREATMENT

APPROPRIATE HEALTH CARE

- Most dogs hospitalized during adulticide administration.
- Eliminate microfilaria with monthly prophylaxis and doxycycline/minocycline; milbemycin may cause rapid decrease in microfilaria numbers and should be used with caution in that scenario; dogs should be rendered microfilaria free 3 months post diagnosis.
- Hospitalization recommended for dogs experiencing thromboembolic complications.

(CONTINUED)

HEARTWORM DISEASE—DOGS**ACTIVITY**

Severely restrict activity for 4–6 weeks after adulticide administration.

CLIENT EDUCATION

- Good prognosis for animals with mild-to-moderate disease. • Post-adulticide pulmonary complications likely in patients with moderate-to-severe pulmonary artery pathology and those with high worm burden.
- Reinfestation can occur unless appropriate prophylaxis administered.

SURGICAL CONSIDERATIONS

- Treatment of choice for caval syndrome.
- Worm removal from right heart and pulmonary artery via jugular vein, by use of fluoroscopy and a long, flexible, alligator forceps or horsehair brush, is highly effective for treating high worm burden when employed by an experienced operator.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Stabilize animals with R-CHF with diuretics, ACE inhibitor, pimobendan, sildenafil, cage rest, and moderate sodium restriction before adulticide treatment.
- Stabilize pulmonary failure with oxygen supplementation, antithrombotic agents (e.g., aspirin or heparin), or anti-inflammatory dosages of corticosteroid depending on the clinical and radiographic findings.
- Adulticide drug: melarsomine dihydrochloride (Immiticide, 2.5 mg/kg IM/dose)—injections are given into the epaxial muscles using 22-gauge needles; apply pressure over the injection site during and after needle withdrawal. • Graded-kill protocol recommended in most cases; administer one injection followed in 1 month by two injections (first injection on left or right epaxial muscles, followed by injection on the opposite side 24h later). • For Class III in small dogs or severe Class III with high worm burden administer one injection every 4–6 weeks for a total of three injections. Maintain the strictest patient confinement practical for 4–6 weeks. Perform antigen test 6 months after third injection. • Allergic pneumonitis: administer prednisone or prednisolone (2 mg/kg PO q12–24h for several days) and then immediately administer Immiticide. • Rapid microfilaricidal therapy (e.g., milbemycin or high-dose ivermectin) not recommended by authors; eliminate the microfilaria with monthly prophylaxis and doxycycline/minocycline; confirm elimination of microfilaria by testing 3 months after initiating therapy.

PRECAUTIONS

- Adulticide treatment—not indicated in patients with renal failure, hepatic failure (icterus), or nephrotic syndrome. • Caval

syndrome—remove worms surgically and stabilize patient with conservative management for at least 1 month prior to adulticide therapy.

ALTERNATIVE DRUG(S)

- Sodium heparin (75–100 units/kg SC q8h), aspirin (5–7 mg/kg PO q24h), or low molecular weight heparin (dalteparin: 100 units/kg SC q12–24h) for 1–3 weeks before, during, and for 3 weeks after adulticide administration are controversial recommendations for the most severe cases of Class III disease; therapy is combined with strict, extended cage confinement. • Sodium heparin (200–500 units/kg SC q8h) is recommended for dogs with pulmonary thromboembolism or hemoglobinuria with goal of prolonging APTT 1.5–2 times baseline. • Soft or slow kill: ivermectin (6 µg/kg weekly) and doxycycline (10 mg/kg/day) combination may result in worm eradication with 9 months of therapy (generally not recommended due to possible promotion of resistance to the macrolides).
- Doxycycline/minocycline (5–10 mg/kg PO q12h) is used prior to adulticide therapy to kill *Wolbachia*, a gram-negative, intrafilarial bacterium that is associated with post-adulticide inflammation of the lungs and kidneys.

**FOLLOW-UP****PATIENT MONITORING**

Perform an antigen test 6 months after adulticide treatment. Some dogs with persistent, low-grade antigenemia may not require retreatment. Weak antigenemia indicates most worms killed, pulmonary pathology will improve, and ivermectin prophylaxis will eventually kill remaining worms.

PREVENTION/AVOIDANCE

- Heartworm prophylaxis should be provided for all dogs at risk. Authors recommend year-round prophylaxis. Otherwise begin with mosquito season and continue for 1 month following first frost. • Antigen test prior to starting preventive treatment. • Antigen test 7 months after end of previous season.
- Ivermectin (Heartgard, Iverhart, Triheart)—a highly effective, monthly preventive that can be given safely to microfilaremic dogs.
- Milbemycin oxime (Interceptor, Sentinel, Trifexis)—highly effective, monthly prophylaxis in which acute reactions may occur when given to microfilaremic dogs.
- Moxidectin (Advantage Multi)—a topical solution administered monthly. • Selamectin (Revolution)—a highly effective monthly topical preparation. • Administer to puppies soon after 8 weeks of age as dictated by seasonal risk. • All of the prophylactic drugs can be administered safely to collies at the

appropriate dosages. • For dogs infected with adult worms and not already taking prophylactic drug, any of the above drugs can be started immediately and should be started within one month of diagnosis. The authors recommend against using milbemycin in microfilaremic dogs. • The authors do not practice initiating prophylaxis and then delaying adulticide treatment for 1 or more months. • All macrocyclic lactones with combination doxycycline/minocycline should eliminate microfilaria in 1–3 months. • Due to the recent increase in the number of lack of efficacy (LOE) reports and the concern of possible heartworm resistance to the current heartworm preventives, dogs should be rendered microfilaria free 3 months post diagnosis.

POSSIBLE COMPLICATIONS

- Post-adulticide pulmonary thromboembolic complications—may occur up to 4–6 weeks after treatment; usually more severe in dogs with Class III disease and those not properly confined. • Thrombocytopenia and intravascular coagulation. • Melarsomine adverse effects—pulmonary thromboembolism (usually 7–30 days after therapy); anorexia; injection site reaction-myositis; lethargy or depression; elevation of hepatic enzymes; paresis/paralysis/altered mentation; lack of efficacy.

EXPECTED COURSE AND PROGNOSIS

- Class I—usually uneventful with excellent prognosis
- Class III—guarded prognosis with higher risk of complications

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Wolbachia

ANESTHESIA

When anesthesia/surgery required, delay heartworm treatment until after procedure.

PREGNANCY/FERTILITY/BREEDING

- Delay adulticide treatment. • Transplacental infestation by microfilaria can occur.

H

HEAT STROKE AND HYPERTHERMIA

BASICS

DEFINITION

- Hyperthermia is defined as an elevation in body temperature above the normal range. Although published normal values for dogs and cats vary slightly, it is generally accepted that body temperatures $> 103^{\circ}\text{F}$ (39°C) are abnormal.
- Hyperthermia can be categorized into pyrogenic hyperthermia (pyrexia or fever) and non-pyrogenic hyperthermia.
- Heat stroke is a form of non-pyrogenic hyperthermia that occurs when heat-dissipating mechanisms of the body cannot accommodate excessive heat. This can lead to multisystem organ dysfunction. Temperatures of $106^{\circ}\text{F}+$ (41°C) without signs of inflammation are suggestive of non-pyrogenic hyperthermia.
- Malignant hyperthermia is an uncommon familial form of non-pyrogenic hyperthermia that can occur secondary to some anesthetic agents.
- Other causes of non-pyrogenic hyperthermia include excessive exercise, thyrotoxicosis, and hypothalamic lesions.

PATHOPHYSIOLOGY

- The hypothalamic set point is changed with true fever. This is most likely mediated via the endogenous pyrogen interleukin I.
- Non-pyrogenic hyperthermia does not change the hypothalamic set point.
- The critical temperature leading to multiple organ dysfunction is 109°F (42.7°C).
- The primary pathophysiologic processes of heat stroke are related to thermal damage, which can lead to cellular necrosis, hypoxemia, and protein denaturalization.
- Heat stroke and its sequelae can lead to SIRS.

SYSTEMS AFFECTED

- Cardiovascular—hypovolemia, cardiac arrhythmias, myocardial ischemia, and necrosis.
- Gastrointestinal—mucosal ischemia and ulceration, bacterial translocation and endotoxemia.
- Hemic/Lymphatic/Immune—hemoconcentration, thrombocytopenia, DIC.
- Hepatobiliary—hepatocellular necrosis.
- Musculoskeletal—rhabdomyolysis.
- Nervous—neuronal damage, parenchymal hemorrhage, and cerebral edema.
- Renal/Urologic—acute renal failure.

GEOGRAPHIC DISTRIBUTION

May be seen in any climate but more common in warm and/or humid environments.

SIGNALMENT

Species

- Dog and cat
- Cats uncommon

Breed Predilections

- May occur in any breed
- Longhaired animals
- Brachycephalic breeds

Mean Age and Range

- All ages but often age extremes
- Young dogs may tend to overexert
- Old dogs with preexisting disease

SIGNS

Historical Findings

- Identifiable underlying cause (warm environmental conditions, locked in car or other confined area without adequate ventilation, grooming accident associated with drying cages, excessive exercise, restricted access to water).
- Predisposing underlying disease: laryngeal paralysis, brachycephalic obstructive disease, cardiovascular disease, neuromuscular disease, previous history of heat-related disease.

Physical Examination Findings

- Panting
- Hypersalivation
- Hyperemic mucous membranes
- Pale mucous membranes
- Cyanosis
- Tachycardia
- Cardiac dysrhythmias
- Shock
- Respiratory distress
- Hematemesis
- Hematochezia
- Melena
- Petechiation
- Changes in mentation
- Seizures
- Muscle tremors
- Ataxia
- Coma
- Oliguria/anuria
- Respiratory arrest
- Cardiopulmonary arrest

CAUSES

- Excessive environmental heat and humidity (may be due to weather conditions or accidents such as enclosed in unventilated room, car, or grooming dryer cage).
- Upper airway disease.
- Exercise.
- Toxicosis (some compounds that lead to seizures, i.e., strychnine and metaldehyde).
- Anesthesia (malignant hyperthermia).

RISK FACTORS

- Previous history of heat-related disease
- Age extremes
- Heat intolerance due to poor acclimatization
- Obesity
- Poor cardiopulmonary conditioning
- Hyperthyroidism
- Underlying cardiopulmonary disease
- Brachycephalic breeds
- Thick hair coat
- Dehydration

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- If temperatures exceed 106°F (41°C) without evidence of inflammation should consider heat stroke.
- Panting and hypersalivation may not be seen with true fever as hypothalamic set point has been raised.

CBC/BIOCHEMISTRY/URINALYSIS

- May help to identify underlying disease process.
- May be beneficial in identifying sequelae to hyperthermia.
- CBC abnormalities may include stress leukogram, leukopenia, anemia, nucleated RBCs, thrombocytopenia, or hemoconcentration.
- Biochemistry profile may show azotemia, hyperalbuminemia, elevations in serum

enzymes; ALT, AST, CK, hypernatremia, hyperchloraemia, hyperglycemia, hypoglycemia, hyperphosphatemia, hyperkalemia, hypokalemia, hyperbilirubinemia.

Urinalysis may show hypersthenuria, proteinuria, cylindruria, hemoglobinuria, myoglobinuria.

OTHER LABORATORY TESTS

- Blood gas analysis may show mixed acid-base disorder, respiratory alkalosis, or metabolic acidosis.
- Lactate concentrations may be elevated due to impaired perfusion.
- Coagulation profile may indicate prolonged ACT, PT, or PTT. FDP or d-dimers may be positive. DIC may be present if PT and PTT are prolonged along with positive FDPs or d-dimers and thrombocytopenia. If available the measurement of antithrombin may be valuable.
- Thromboelastography may document hyper- or hypocoagulability.

IMAGING

- Thoracic radiographs may help identify underlying cardiopulmonary disease or predisposing factors.
- Abdominal radiographs and/or ultrasound may help identify underlying disease process.
- Computed tomography or magnetic resonance imaging may help identify hypothalamic lesion.

DIAGNOSTIC PROCEDURES

Continuous temperature monitoring

TREATMENT

- Early recognition is key.
- Immediate correction of hyperthermia; spray with water or immerse in water prior to transport to veterinary facility. Convection cooling with fans.
- Evaporative cooling such as alcohol on foot pads, axilla, and groin.
- Stop cooling procedures when temperature reaches 103°F to avoid hypothermia.
- Oxygen supplementation via oxygen cage, mask, or nasal catheter.
- Airway management in cases of laryngeal paralysis or edema.
- Ventilatory support if required.
- Fluid support with shock doses of crystalloids or colloids.
- Treat complications, seizures, DIC, renal injury, cerebral edema.
- Treat underlying disease or correct predisposing factors.

APPROPRIATE HEALTH CARE

- Patients should be hospitalized until temperature is stabilized.
- Most patients need intensive care for several days.

NURSING CARE

- External cooling; try to avoid ice as this may cause peripheral vasoconstriction and impede heat elimination. Shivering response is also undesirable as this creates heat.
- Fluid therapy; isotonic crystalloids can be administered at shock rates (90 ml/kg/hr for dogs, 45–60 mL/kg/hr for cats) based on clinical assessment. Synthetic colloids may

(CONTINUED)

HEAT STROKE AND HYPERTHERMIA

also be used to treat shock (20 mL/kg in dogs (5 mL/kg IV boluses), 5–10 mL/kg in cats (1–2 mL/kg boluses)). • Oxygen supplementation can be administered via mask, cage, or nasal cannula.

ACTIVITY

Restricted

DIET

Nothing per os until animal is stable

CLIENT EDUCATION

- Be aware of clinical signs.
- Know how to cool off animals.
- Seek veterinary care immediately.
- An episode of heat stroke may predispose pets to additional episodes.

SURGICAL CONSIDERATIONS

Tracheostomy may be required if upper airway obstruction is underlying cause or contributing factor.

**MEDICATIONS****DRUG(S) OF CHOICE**

- There are no specific drugs that are required for hyperthermia or heat stroke, therapy is dependent on clinical presentation.
- Prophylactic broad-spectrum antimicrobials may decrease the incidence of bacterial translocation. First-generation cephalosporins or potentiated penicillins (clavulanate/amoxicillin, sulbactam/ampicillin) in combination with fluoroquinolones provide excellent four quadrant coverage.
- Acute renal failure—dopamine continuous rate intravenous infusion (2–5 µg/kg/min), furosemide intravenously (2–4 mg/kg PRN) mannitol 0.5–1 g/kg as CRI.
- Cerebral edema—mannitol (1 g/kg IV over 15–30 minutes), furosemide (1 mg/kg IV) 30 minutes following mannitol infusion, corticosteroids (dexamethasone sodium phosphate (1–2 mg/kg IV), prednisone sodium succinate (10–20 mg/kg IV), methyl prednisolone (15 mg/kg IV). The use of corticosteroids is considered controversial due to adverse side effects in these patients.
- Ventricular arrhythmia—lidocaine bolus (2 mg/kg IV) followed by continuous rate intravenous infusion (25–75 µg/kg/min), procainamide (6–8 mg/kg IV).
- Metabolic acidosis—sodium bicarbonate (0.3 × BW (kg) × BE) give 1/3 to $\frac{1}{2}$ as bolus IV.
- DIC—fresh frozen plasma (20 mL/kg),

heparin doses vary widely (300–500 U/kg SC q 6–8h).

- Thrombocytopenia—severe thrombocytopenia with active bleeding can be treated with fresh whole blood, platelet-rich plasma, lyophilized platelets, or frozen platelet concentrate.
- Hemorrhagic vomiting diarrhea—broad-spectrum antibiotics, H₂-antagonists, or proton pump inhibitors in combination with sucralfate.
- Seizures—diazepam (0.5–1 mg/kg IV) or midazolam; phenobarbital (6 mg/kg IV as needed).

CONTRAINdications

- Nonsteroidal anti-inflammatory agents are not indicated in non-pyrogenic hyperthermia because the hypothalamic set point is not altered.
- The use of corticosteroids is considered controversial in heat stroke due to possible adverse effects.
- Cooling with ice, which may lead to peripheral vasoconstriction and poor heat dissipation.

PRECAUTIONS

Refer to manufacturer's recommendations.

POSSIBLE INTERACTIONS

Refer to manufacturer's recommendations.

**FOLLOW-UP****PATIENT MONITORING**

- Patients should be closely monitored during cooling-down period and for a minimum of 24 hours post-episode. Most animals must be monitored for several days depending on clinical presentation and clinical complications. Thorough physical examination should be performed daily. In addition the following parameters should be given consideration:
 - Body temperature
 - Body weight
 - Blood pressure
 - Central venous pressure
 - ACT
 - PT/PTT
 - D-dimers
 - ECG
 - Thoracic auscultation
 - Urinalysis and urine output
 - PCV, TP
 - CBC, biochemical profile
 - Venous blood gas analysis (electrolytes, lactate).

POSSIBLE COMPLICATIONS

- Cardiac dysrhythmias
- Organ failure
- Coma
- Seizures
- Acute renal failure
- DIC
- SIRS
- Sepsis/septic shock
- Pulmonary edema—acute respiratory distress (ARDS)
- Rhabdomyolysis
- Hepatocellular necrosis
- Respiratory arrest
- Cardiopulmonary arrest

EXPECTED COURSE AND PROGNOSIS

- Prognosis is dependent on underlying cause or disease process.
- Prognosis may be dependent on time lag between event and hospital admission.
- Prognosis is guarded dependent on complications that occur (renal failure and DIC) and duration of episode.
- May predispose animal to further episodes due to damage of thermoregulatory center.

**MISCELLANEOUS****SYNOMYMS**

- Heat exhaustion
- Heat prostration
- Heat-related disease
- Heat stroke

HELICOBACTER spp.

BASICS

DEFINITION

Helicobacter spp. are microaerophilic, Gram-negative, urease-positive bacteria that range from coccoid to curved to spiral.

PATHOPHYSIOLOGY

Helicobacter spp. in the Stomach

The discovery of an association of *Helicobacter pylori* with gastritis, peptic ulceration, and gastric neoplasia has fundamentally changed the understanding of gastric disease in humans. Putative mechanisms by which *H. pylori* alters gastric physiology in humans include disruption of the gastric mucosal barrier (due to secretion of phospholipases and vacuolating cytotoxins) and alteration of the gastric secretory activity (e.g., decreased somatostatin secretion leading to hypergastrinemia and hyperchlorhydria). *H. pylori* infection in humans has also been associated with increased secretion of proinflammatory cytokines, tumor necrosis factor- α , and nitric oxide. Several *Helicobacter* spp other than *H. pylori* have been isolated from the stomach of dogs and cats. Typically, multiple species of *Helicobacter* are present. To date *H. pylori*, the most important species affecting humans, has only been identified in a single colony of laboratory cats. A possible cause-effect relationship of *Helicobacter* spp. and gastric inflammation in cats and dogs remains unresolved; inflammation or glandular degeneration accompanies *Helicobacter* spp. in some but not all dogs and cats. Experiments to determine the pathogenicity of *H. pylori* in SPF cats and *H. pylori* and *H. felis* in gnotobiotic dogs demonstrated gastritis, lymphoid follicle proliferation, and humoral immune responses after infection.

HELICOBACTER spp. IN THE LIVER AND INTESTINES

The role of *Helicobacter* spp. in intestinal and hepatic disease in dogs and cats is unclear. Several *Helicobacter*-like organisms (HLOs) have been identified in the large intestine and feces from normal and diarrheic dogs and cats. *H. canis* has also been isolated from the liver of a dog with active, multifocal hepatitis.

SYSTEMS AFFECTED

Gastrointestinal—stomach: *Helicobacter* spp. may lead to gastritis in some dogs and cats; intestines: diarrhea can be observed in some dogs with *H. canis*.

Hepatobiliary—acute hepatitis has been associated with *H. canis*.

GENETICS

No genetic basis for susceptibility to *Helicobacter* spp. infection has been established.

INCIDENCE/PREVALENCE

Gastric Helicobacter spp.

- Gastric HLOs are highly prevalent in dogs and cats—evidence for HLOs has been shown in 86% of random-source cats, 90% of clinically healthy pet cats, 67–86% of clinically healthy pet dogs. • HLOs have been demonstrated in gastric biopsy specimens in 57–76% of cats and 61–82% of dogs presented for investigation of recurrent vomiting. • To date *H. pylori* has been identified only in a single colony of laboratory cats.

Enterohepatic Helicobacter spp.

- H. canis* has been isolated in 4% of 1,000 dogs evaluated. • However, only a single case of *H. canis*-associated hepatitis has been reported. • The prevalence of *H. fennelliae* and *H. cinaedi* remains undetermined.

GEOGRAPHIC DISTRIBUTION

- H. pylori* infection in human beings has a higher prevalence in less-developed countries.
- No information available for dogs and cats.

SIGNALMENT

Species

Dog and cat

Mean Age and Range

- Gastric infection with *Helicobacter* spp. appears to be acquired at a young age. • The dog with *H. canis*-associated hepatitis was 2 months old.

SIGNS

Historical Findings

- Asymptomatic presence of *Helicobacter* spp. is common. • Vomiting, anorexia, abdominal pain, weight loss, and/or borborygmus have all been reported in dogs and cats with gastric *Helicobacter* spp. • *H. canis* in dogs may be associated with diarrhea. • Vomiting, weakness, and sudden death was reported in a dog with hepatic *H. canis*.

Physical Examination Findings

- Usually unremarkable. • May have signs of dehydration from fluid and electrolyte loss due to vomiting and/or diarrhea.

CAUSES

Gastric Helicobacter spp.

- H. felis*, *H. heilmannii*, and *H. baculiformis* have been identified in cats. • *Helicobacter felis*, *H. bizzozeronii*, *H. salomonis*, *H. heilmannii*, *H. bilis*, *Flexispira rappini*, and *H. cynogastericus* have been identified in dogs.

Enterohepatic Helicobacter spp.

- H. bilis*, *H. canis*, *H. cinaedi*, and *Flexispira rappini* have been identified in feces from normal and diarrheic dogs. • *H. cinaedi* has been identified in one cat, but its significance is unknown. • *H. canis* has been reported in one dog with acute hepatitis.

RISK FACTORS

Poor sanitary conditions and overcrowding may facilitate the spread of infection.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

General Comments

There is a high prevalence of *Helicobacter* spp. in both dogs and cats. Therefore, exclusion of other causes of gastric disease and a positive identification of *Helicobacter* spp. are crucial before a diagnosis of gastrointestinal disease due to *Helicobacter* spp. can be suspected.

Gastric Helicobacteriosis

Must be distinguished from other causes of vomiting (both primary and secondary gastrointestinal diseases that can cause vomiting).

Intestinal Helicobacteriosis

Must be distinguished from other causes of diarrhea (both primary and secondary gastrointestinal diseases).

Hepatic Helicobacteriosis

Must be distinguished from other causes of hepatobiliary disease.

CBC/BIOCHEMISTRY/URINALYSIS

- May reflect fluid and electrolyte abnormalities secondary to vomiting and/or diarrhea. • May reflect changes consistent with hepatic disease in patients with *H. canis*-associated hepatitis.

OTHER LABORATORY TESTS

- Examination of impression smears of gastric mucosa or gastric washings using May-Grünwald-Giemsa, gram, or Diff-Quik stain is sensitive for *Helicobacter* spp. and can easily be performed, but this test cannot distinguish between different HLOs.

- Rapid-urease test—requires gastric biopsy specimen, but is easy to perform in patients that undergo gastroduodenoscopy. • ^{13}C -urea breath or blood test has been shown to be reliable in identifying infected dogs, but is currently not commercially available.

- Bacterial culture requires special techniques and media and is impractical. • PCR of DNA extracted from biopsy specimens or from gastric juice. • Serologic tests (ELISA) measure circulating IgG in serum, but this test cannot distinguish between different HLOs. • Histopathology enables the definitive diagnosis of gastric *Helicobacter* spp. infection, but cannot distinguish between different HLOs.

IMAGING

Abdominal radiography and ultrasonography are usually normal in patients with *Helicobacter* spp. infection alone.

DIAGNOSTIC PROCEDURES

Gastric Helicobacteriosis

In cases of *Helicobacter* spp.-associated gastritis, endoscopy may reveal superficial nodules that suggest hyperplasia of lymphoid

(CONTINUED)

follicles, diffuse gastric rugal thickening, punctate hemorrhages, and erosions.

Hepatic Helicobacteriosis

Hepatic biopsy/histopathology (Warthin-Starry staining) and culture.

PATHOLOGIC FINDINGS

- Identification of HLOs requires special staining of tissue samples with Warthin-Starry or modified-Steiner stain. Routine H&E staining may reveal larger HLOs, but smaller organisms are often missed.
- In cases of *Helicobacter* spp.–associated gastric disease: lymphocytic-plasmacytic gastritis and lymphoid follicle hyperplasia; rarely neutrophilic infiltrations. Gastric ulcers have not been reported in dogs and cats.
- In cases of *H. canis*–associated hepatitis: hepatocellular necrosis; infiltration of the hepatic parenchyma with mononuclear cells, and spiral-shaped to curved bacteria predominantly in biliary canaliculi.

TREATMENT

APPROPRIATE HEALTH CARE

- The pathogenicity of *Helicobacter* spp. in dogs and cats is still unclear. Therefore, there are no generally accepted guidelines for the treatment of *Helicobacter* spp. infections in dogs and cats.
- Currently there is no indication for treating asymptomatic animals with a *Helicobacter* spp. infection.
- Eradication of gastric *Helicobacter* spp. should only be considered in infected dogs and cats that have compatible clinical signs that cannot be attributed to another disease process.

NURSING CARE

Fluid therapy in dehydrated patients.

DIET

Easily digestible diets in patients with gastrointestinal signs.

CLIENT EDUCATION

Explain the difficulty of establishing a definitive diagnosis, the high prevalence of infections with HLOs in normal dogs and cats, the potential for recurrence, and the zoonotic potential, though minimal, of these infections.

MEDICATIONS

GENERAL COMMENTS

- A triple therapy (combination of two antibiotics and one antisecretory drug) is effective in humans with *H. pylori* infection, with cure rates of approximately 90%.
- Combination therapy may eliminate *Helicobacter* spp. infections in dogs and cats less effectively than in humans.
- Treat for 2–3 weeks.

DRUG(S) OF CHOICE

Antibiotics (Two Antibiotics with One Antisecretory Agent)

- Clarithromycin (dogs, 5 mg/kg PO q12h; cats, 62.5 mg/cat PO q12h).
- Metronidazole (dogs, 11–15 mg/kg PO q12h; cats, 12.5 mg/kg PO q12h).
- Amoxicillin (22 mg/kg PO q12h).
- Azithromycin (5 mg/kg PO q24h).
- Tetracycline (20 mg/kg PO q8h).
- Bismuth subsalicylate has mucosal protectant, anti-endotoxemic, and weak antibacterial properties; it remains unclear which property is responsible for its beneficial effects in HLO infections (0.22 mL/kg of 130 mg/15 mL solution of Pepto-Bismol PO q4–6h).

Antisecretory Agents (One with Two Antibiotics)

- Omeprazole (0.7–1 mg/kg PO q12h)
- Famotidine (0.5 mg/kg PO q12–24h)
- Ranitidine (1–2 mg/kg PO q12h)

Intestinal and Hepatic Helicobacter spp. in Dogs

A combination of amoxicillin and metronidazole at above dosages may be effective.

CONTRAINdicATIONS

Hypersensitivity to one of the antibiotics.

ALTERNATIVE DRUG(S)

Patients with HLO infections and gastritis that do not respond to antibiotic therapy usually are given immunosuppressive therapy (prednisolone, or others) for inflammatory bowel disease with gastric involvement.

FOLLOW-UP

PATIENT MONITORING

• Serologic tests are not useful to confirm eradication of gastric HLOs—serum IgG titers may not decrease for up to 6 months after a cleared infection.

• ^{13}C -urea breath and blood tests have been evaluated to monitor the eradication of HLOs in dogs and cats, but these tests are currently not commercially available.

• If vomiting persists or recurs after cessation of combination therapy, a repeat endoscopic biopsy to determine whether the infection has been successfully eradicated may be necessary.

PREVENTION/AVOIDANCE

Avoid overcrowding and poor sanitation.

EXPECTED COURSE AND PROGNOSIS

- The efficacy of therapeutic regimens currently employed in dogs and cats for eradicating *Helicobacter* spp. infections is questionable.
 - Metronidazole (20 mg/kg PO q12h), amoxicillin (20 mg/kg PO q12h), and famotidine (0.5 mg/kg PO q12h) for 14 days effectively eradicated *Helicobacter* spp. in 6 of 8 dogs when evaluated 3 days post-treatment, but all dogs were recolonized by day 28 after completion of treatment.
 - Clarithromycin (30 mg/cat PO q12h), metronidazole (30 mg/cat PO q12h), ranitidine (20 mg/cat PO q12h), and bismuth subsalicylate (40 mg PO q12h) for 4 days was effective in eradicating *H. heilmannii* in 11 of 11 cats by 10 days, but two cats were reinfected 42 days post-treatment.
 - Amoxicillin (20 mg/kg PO q8h), metronidazole (20 mg/kg PO q8h), and omeprazole (0.7 mg/kg PO q24h) for 21 days transiently eradicated *H. pylori* in 6 cats, but all were reinfected 6 weeks post-treatment.
- (Note: this dose of metronidazole has the potential for toxicity.)

HELICOBACTER spp.

H

MISCELLANEOUS

ASSOCIATED CONDITIONS

Other gastric diseases

AGE-RELATED FACTORS

Gastric HLOs appear to be acquired at a young age.

ZOONOTIC POTENTIAL

- The high prevalence of *Helicobacter* spp. in dogs and cats raises the possibility that household pets may serve as a reservoir for the transmission of *Helicobacter* spp. to human beings.
- *H. pylori*, *H. heilmannii*, and *H. felis* have been isolated from humans with gastritis.
- *H. fennelliae* and *H. cinaedi* have been isolated from immunocompromised humans with proctitis and colitis.
- *H. cinaedi* and *H. canis* have been associated with septicemia in humans.
- *H. pylori* has not been identified in pet dogs or pet cats.

PREGNANCY/FERTILITY/BREEDING

Avoid metronidazole and tetracycline in pregnant animals.

SYNONYMS

- Gastric spiral bacterial • *Gastrospirillum*

SEE ALSO

- Gastritis, Chronic • Vomiting, Chronic

ABBREVIATIONS

- ELISA = enzyme-linked immunosorbent assay
- HLO = *Helicobacter*-like organism
- PCR = polymerase chain reaction

HEMANGIOSARCOMA, BONE

BASICS

OVERVIEW

- A highly metastatic malignant tumor of the vascular endothelium.
- Primary bone HSA is rare and accounts for < 5% of all canine bone tumors.
- Difficult to differentiate metastatic from primary bone lesions based upon radiographs.
- Can arise from various appendicular sites; while the rib is most common axial location.
- Extremely rare in cats.

SIGNALMENT

- Dog and rarely cat.
- Golden retrievers, Labrador retrievers, and German shepherds predisposed.
- Typically middle-aged to older dogs; older cats.
- Possible slight predisposition for male dogs.

SIGNS

- Appendicular—pain/lameness, soft tissue swelling/mass, pathologic fracture.
- Axial—myelopathy consequent to vertebral body collapse and spinal cord compression; thoracic wall swelling with rib involvement, signs related to hemorrhagic pleural effusion if involving ribcage.

CAUSES & RISK FACTORS

Unknown

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Radiography—other primary or metastatic bone tumors (i.e., osteosarcoma, fibrosarcoma, chondrosarcoma).
- Osteomyelitis (bacterial or fungal).
- Histopathology—can be difficult to differentiate from the vascular telangiectatic subtype of OSA without immunohistochemistry.

CBC/BIOCHEMISTRY/URINALYSIS

Abnormalities less common than with splenic hemangiosarcoma but may include:

- Regenerative anemia
- Thrombocytopenia
- Leukocytosis.

OTHER LABORATORY TESTS

N/A

IMAGING

- *Radiography*—may reveal poorly marginated osteolytic lesion with minimal periosteal reaction; pathologic fractures possible.
- *Thoracic radiography*—should be used to screen for pulmonary metastasis.
- *Abdominal and cardiac ultrasonography*—should be used to screen for primary visceral tumors (spleen, liver, heart) and metastatic lesions.
- *CT scan*—can better define the extent of bone tumor for surgical excision (especially axial lesions) and provides a more sensitive assessment for pulmonary metastasis.

DIAGNOSTIC PROCEDURES

- Excisional biopsy is the preferred method for diagnosis.
- An incisional biopsy may yield a diagnosis but due to the vascular nature of the tumor, blood contamination within the specimen may preclude a diagnosis or prevent differentiation between HSA and telangiectatic OSA.

PATHOLOGIC FINDINGS

- *Gross findings*—a dark, friable mass often within the medullary cavity of the bone.
- *Histopathology*—anaplastic mesenchymal cells arranged in chords separated by a collagenous background for vascular channels and spaces filled with red blood cells, thrombi, and necrotic debris.
- Can use immunohistochemistry for von Willebrand factor (factor VIII-related antigen) or CD31/platelet endothelial cell adhesion molecule (PECAM) to confirm endothelial cell origin.

TREATMENT

- Aggressive surgical excision of primary tumor.
- Amputation is required if appendicular.
- Axial tumors may be more difficult to resect.
- Radiation therapy may be used for palliation of bone-related pain or as an adjuvant to marginal resection of axial lesions.
- Adjuvant chemotherapy is indicated due to high metastatic potential.

MEDICATIONS

DRUG(S)

- Doxorubicin: 30 mg/m² IV dogs > 15 kg; 1 mg/kg IV dogs < 15 kg q2–3 weeks for 5 cycles; cats 1 mg/kg IV q3 weeks for 5 cycles.
- Metronomic cyclophosphamide (12.5–15 mg/m² PO q24h) in combination with an NSAID (e.g., piroxicam 0.3 mg/kg PO q24h) may be used concurrent with doxorubicin and as a long-term maintenance therapy.
- Vincristine (0.5–0.7 mg/m²) and cyclophosphamide (200–250 mg/m²) q21 days can be used in rescue setting.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Doxorubicin administration can lead to gastrointestinal, bone marrow, cardiac, renal, hypersensitivity, and extravasation toxicities.
- Doxorubicin can lead to cumulative cardiotoxicity in dogs.
- Cyclophosphamide can lead to sterile hemorrhagic cystitis in dogs.
- NSAIDs can lead to gastrointestinal toxicity and liver/kidney damage.

FOLLOW-UP

PATIENT MONITORING

- Physical examination, laboratory work, thoracic radiography, and abdominal ultrasonography every 3 months after the completion of therapy.
- If treated with metronomic chemotherapy, routine monthly urinalysis recommended to screen for sterile hemorrhagic cystitis.

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

- Pathologic fracture.
- Bone lesions, especially within the rib, and visceral metastatic lesions may rupture, resulting in clinical signs related to effusion or anemia.

EXPECTED COURSE AND PROGNOSIS

- Aggressive course of disease with high risk for metastasis.
- Median survival time for bone presentation not well-defined due to rarity of cases.
- Less than 10% of patients survive 1 year following surgery alone; prognosis with addition of chemotherapy not defined but may be similar to that associated with the splenic presentation.

HEMANGIOSARCOMA, HEART

BASICS

OVERVIEW

- A highly metastatic malignant tumor of the vascular endothelium.
- The most common cardiac tumor in dogs.
- Can be a primary or metastatic site.
- Most tumors involve the right atrium or right auricular appendage.
- Metastasis can be multi-organ including lungs, kidneys, muscle, peritoneum, etc.

SIGNALMENT

- Dog and rarely cat.
- German shepherds, Labrador retrievers, golden retrievers predisposed.
- Typically middle-aged to older animals.
- Possible slight predisposition for male dogs.

SIGNS

- Signs most commonly related to pericardial effusion, cardiac tamponade, and right-sided congestive heart failure.
- *Historical findings*—include collapse, lethargy, weakness, anorexia, cough, dyspnea, vomiting, and exercise intolerance.
- *Physical examination findings*—include muffled heart and lung sounds, arrhythmias, pulse deficits, pulsus paradoxus, jugular vein distention, and hepatomegaly.

CAUSES & RISK FACTORS

- Dogs—genetic abnormalities including overexpression of the oncogene STAT3, mutations within tumor suppressor genes *p53* and *PTEN*, and overexpression of angiogenic factors such as vascular endothelial growth factor and angiopoietins.
- Cats—none identified.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other cardiac neoplasia
- Idiopathic hemorrhagic pericardial effusion
- Other causes of right heart failure or arrhythmias

CBC/BIOCHEMISTRY/URINALYSIS

- Regenerative anemia
- Thrombocytopenia
- Poikilocytosis—acanthocytes, schistocytes, spherocytes
- Leukocytosis characterized by mature neutrophilia

OTHER LABORATORY TESTS

Coagulation panel (PT, PTT, D-dimers, fibrinogen)—criteria for DIC present in up to 50% of patients.

IMAGING

- *Radiography*—thoracic radiographs may reveal the presence of a globoid cardiac silhouette, pleural effusion, and pulmonary metastasis.
- *Ultrasonography*—abdominal ultrasonography can be used to screen for visceral metastatic disease or primary splenic or hepatic lesions, omental nodules, and free abdominal fluid (hemoabdomen).

- *Echocardiography*—useful for identifying and removing pericardial effusion and determining the location and extent of tumor involvement.
- *Advanced imaging*—cardiac-gated MRI or CT scan can be used to help determine surgical resectability.

DIAGNOSTIC PROCEDURES

- Definitive diagnosis requires a tissue biopsy.
- Thoracoscopy can be used to visualize the tumor and obtain pericardial biopsies.
- Cytologic evaluation of pericardial fluid rarely provides a definitive diagnosis.
- Electrocardiography may reveal arrhythmias.

PATHOLOGIC FINDINGS

- *Gross findings*—solitary hemorrhagic, friable masses within the right side of the heart.
- *Histopathology findings*—atypical mesenchymal cells forming irregular blood-filled vascular spaces within a tumor mass. Often abundant necrosis and hemorrhage.

TREATMENT

- Periodic pericardiocentesis can provide temporary symptomatic relief from cardiac tamponade.
- Thoracoscopic pericardectomy (pericardial window) can be performed as a palliative procedure to lower the risk of life-threatening cardiac tamponade.
- Surgical tumor excision provides the best chance of long-term tumor control but is restricted to the atrial appendage and/or small areas of the right atrial wall.
- The use of doxorubicin chemotherapy in the measurable disease setting can provide clinical benefit for a median of ~4 months.

MEDICATIONS

DRUG(S)

- Doxorubicin (30 mg/m^2 IV dogs $> 15 \text{ kg}$; 1 mg/kg IV dogs $< 15 \text{ kg}$ q2–3 weeks for 5 cycles).
- Metronomic cyclophosphamide ($12.5\text{--}15 \text{ mg/m}^2$ PO q24h) in combination with an NSAID (e.g., piroxicam 0.3 mg/kg PO q24h) may be used concurrent or as an alternative to doxorubicin.

CONTRAINdicATIONS/POSSIBLE INTERACTIONS

- Doxorubicin administration can lead to gastrointestinal, bone marrow, cardiac, renal, hypersensitivity, and extravasation toxicities.
- Doxorubicin can lead to cumulative cardiotoxicity in dogs.
- Cyclophosphamide can lead to sterile hemorrhagic cystitis in dogs.
- NSAIDs can lead to gastrointestinal toxicity and liver/kidney damage.

FOLLOW-UP

PATIENT MONITORING

- Physical examinations, blood work, thoracic radiographs, and cardiac ultrasounds every 2–3 months after the completion of therapy.
- If treated with metronomic chemotherapy, monthly urinalysis recommended to screen for sterile hemorrhagic cystitis.

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

Congestive heart failure secondary to pericardial effusion and cardiac tamponade.

EXPECTED COURSE AND PROGNOSIS

- Prognosis guarded to poor, increased risk for acute death due to cardiac tamponade or fatal arrhythmias.
- Median survival < 1 month without treatment, ~ 4 months with doxorubicin, possibly longer if tumor resection performed.

HEMANGIOSARCOMA, SKIN

BASICS

OVERVIEW

- A highly metastatic malignant tumor of the vascular endothelium.
- Primary tumor develops within dermal or subcutaneous tissues.
- Accounts for ~14% of all HSA in dogs.
- Metastatic risk dependent upon grade and location within the tissues (stage).
- Subcutaneous/intramuscular lesions may represent metastasis from a primary visceral tumor.

SIGNALMENT

- Dog and cat.
- Pit bull, boxer, and German shepherd affected more commonly than other breeds.
- Dermal hemangiosarcoma—whippet, greyhound, and related breeds.
- Median age, 9 years; range, 4.5–15.6 years.

SIGNS

Dermal

- Firm, raised, dark nodules/masses on the limbs, head, face, ears, prepuce, nasal planum, and ventral abdomen.
- When caused by ultraviolet radiation on the ventral abdomen/inguinal region, often appear as several small blood blister-like nodules.

Subcutaneous/Intramuscular

- Usually solitary mass but multiple masses may occur.
- Masses are typically larger than dermal tumors.
- Firm or soft, fluctuant masses with or without associated bruising.
- Intratumoral bleeding is common.
- Pelvic limbs are commonly affected, but may arise in any location.
- In cats, the flank, ventral abdomen, inguinal region, and cervical region are most commonly affected sites.

CAUSES & RISK FACTORS

- Dermal HSA associated with ultraviolet radiation (actinic keratosis), especially in sparsely haired and lightly pigmented skin.
- Subcutaneous HSA may be secondary to prior ionizing radiation therapy.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Trauma-induced subcutaneous hematoma
- Other sarcomas
- Mast cell tumor

CBC/BIOCHEMISTRY/URINALYSIS

- Usually normal.
- Possible mild regenerative anemia and thrombocytopenia if tumor hemorrhage.

OTHER LABORATORY TESTS

Coagulation panel (PT, PTT, D-dimers, fibrinogen)—may see changes compatible

with DIC if large, bleeding subcutaneous or intramuscular tumor.

IMAGING

- *Radiography*—thoracic radiographs are used to screen for pulmonary metastatic disease characterized by coalescing miliary pattern, or nodular/generalized miliary interstitial pattern.
- *Ultrasonography*—abdominal ultrasonography should be performed to screen for metastatic (or primary) splenic or hepatic lesions, omental nodules, and free abdominal fluid (hemoabdomen).
- *Echocardiography*—can be used to identify right atrial masses (better identified when at least some degree of pericardial effusion is present).
- *Advanced imaging*—MRI/CT can be used for staging and surgical planning purposes.

Note: True dermal HSA are generally benign and may not require an extensive staging process.

DIAGNOSTIC PROCEDURES

Cytology

- Often unrewarding due to insufficient cell numbers and blood contamination.
- Neoplastic cells are spindle, oval, flamed, or stellate shape with anisocytosis and anisokaryosis, single round, oval, or pleomorphic nuclei with prominent nucleoli, low nuclear cytoplasmic ratio, and moderate-to-abundant basophilic and usually vacuolated cytoplasm.

PATHOLOGIC FINDINGS

- *Gross findings*—can include well circumscribed blood blister-like nodules confined to the dermis or more invasive and often poorly circumscribed hemorrhagic tumors within the subcutaneous and intramuscular space.
- *Histopathologic findings*—characterized by neoplastic mesenchymal cells forming irregular vascular channels with solid areas composed of severely anaplastic stromal cells.
- Allows differentiation between hemangioma and HSA and dermal versus subcutaneous/intramuscular origin.
- Some areas may not resemble vascular structures, so immunohistochemistry for von Willebrand factor (factor VIII-related antigen) or CD31/platelet endothelial cell adhesion molecule (PECAM) can be used to confirm endothelial cell origin.

Histologic Staging System

- Stage I—confined to dermis
- Stage II—subcutaneous involvement
- Stage III—intramuscular involvement

TREATMENT

Aggressive surgical excision is the first-line treatment of choice.

- Definitive radiation therapy may be used postoperatively for the control of microscopic residual tumor burden.

- Palliative (hypofractionated) radiation may be used for treatment of non-resectable macroscopic tumor burden, providing response rates of up to 60% and survival times of < 100 days.

- Doxorubicin chemotherapy has been associated with moderate response rates (up to 46%) and MST ~130 days for non-resectable tumors (subcutaneous/intramuscular).
- Metronomic chemotherapy can be used to delay time to locoregional recurrence after surgery given its anti-angiogenic effect.

MEDICATIONS

DRUG(S)

- Doxorubicin (30 mg/m^2 IV dogs $> 15 \text{ kg}$; 1 mg/kg IV dogs $< 15 \text{ kg}$ q2–3 weeks for 5 cycles).
- Metronomic cyclophosphamide ($12.5\text{--}15 \text{ mg/m}^2$ PO q24h) in combination with an NSAID (e.g., piroxicam 0.3 mg/kg PO q24h) may be used concurrent or as an alternative to doxorubicin.

CONTRAINdications/POSSIBLE INTERACTIONS

- Doxorubicin administration can lead to gastrointestinal, bone marrow, cardiac, renal, hypersensitivity, and extravasation toxicities.
- Doxorubicin can lead to cumulative cardiotoxicity in dogs.
- Evaluate cardiac function with echocardiography prior to, during, and after therapy in breeds predisposed to dilated cardiomyopathy (i.e., Great Dane, St. Bernard, Irish wolfhound) and those patients with clinical evidence of heart disease.
- Cyclophosphamide can lead to sterile hemorrhagic cystitis in dogs. Incidence with metronomic dosing not yet defined; is typically < 10% with conventional dosing.
- NSAIDs can lead to gastrointestinal toxicity and liver/kidney damage.

ALTERNATIVE DRUG(S)

Immunotherapy: A medicinal mushroom extract made from the *Coriolus versicolor* mushroom containing polysaccharide peptide may have efficacy in dogs with HSA.

FOLLOW-UP

PATIENT MONITORING

- Physical examinations, bloodwork, thoracic radiographs, and abdominal ultrasounds every 2–3 months after the completion of therapy.
- If treated with metronomic chemotherapy, routine monthly urinalysis recommended to screen for sterile hemorrhagic cystitis.

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

Tumor hemorrhage

(CONTINUED)

EXPECTED COURSE AND PROGNOSIS

- Dermal HSA—prognosis very good with treatment. MST in dogs of 987 days with surgery alone; disease-free interval in cats > 450 days with surgery alone.
- Subcutaneous HSA—higher metastatic risk but prognosis can be good with aggressive treatment. MST of 172 days for dogs undergoing surgery alone versus > 1,100 days if surgery and adjuvant doxorubicin chemotherapy.
- Intramuscular HSA—MST of 272 days with surgery and doxorubicin chemotherapy.
- High risk of locoregional recurrence and distant metastasis with stage II (SQ) and III (IM) HSA.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Other ultraviolet-induced skin tumors such as squamous cell carcinoma.

PREGNANCY/FERTILITY/BREEDING

Chemotherapy drugs may be carcinogenic and mutagenic.

ZOONOTIC POTENTIAL

N/A

PREGNANCY/FERTILITY/BREEDING

Chemotherapy drugs may be carcinogenic and mutagenic.

H

HEMANGIOSARCOMA, SPLEEN AND LIVER

BASICS

OVERVIEW

- A highly metastatic malignant tumor of the vascular endothelium.
- Accounts for up to 70% of all canine splenic tumors.
- Primary tumor rupture leads to acute hemorrhage, collapse, and often sudden death.
- Highly metastatic tumor that spreads early in the course of disease via hematogenous and intra-abdominal implantation routes.
- Metastasis can be to any organ including lungs, kidneys, muscle, peritoneum, omentum, lymph nodes, mesentery, adrenal glands, spinal cord, brain, subcutaneous tissue, and diaphragm.

SIGNALMENT

- Dog and rarely cat.
- German shepherd, Labrador retriever, golden retriever predisposed.
- Typically middle-aged to older animals.
- Possible slight predisposition for male dogs.

SIGNS

- *Historical findings*—can be variable and include weakness, lethargy, dyspnea, cough, inappetance, and weight loss.
- *Physical examination findings*—pale mucous membranes, arrhythmias, tachypnea, abdominal distension, and palpable cranial abdominal mass.

CAUSES & RISK FACTORS

- Dogs—genetic abnormalities including overexpression of the oncogene STAT3, mutations within tumor suppressor genes *p53* and *PTEN*, and overexpression of angiogenic factors such as vascular endothelial growth factor and angiopoietins.
- Cats—none identified.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Anticoagulant rodenticide ingestion.
- Other splenic and hepatic masses: hematoma, hemangioma, hepatoma, lymphoma, leiomyosarcoma, liposarcoma, splenic cyst, hepatocellular carcinoma, hepatic cyst.

CBC/BIOCHEMISTRY/URINALYSIS

- Regenerative anemia with nucleated red blood cells
- Thrombocytopenia
- Poikilocytosis—acanthocytes, schistocytes, spherocytes
- Leukocytosis characterized by mature neutrophilia
- Elevated liver enzymes

OTHER LABORATORY TESTS

Coagulation panel (PT, PTT, D-dimers, fibrinogen)—criteria for DIC present in up to 50% of patients.

IMAGING

Radiography

- Abdominal radiographs may identify a cranial abdominal mass and evidence for abdominal fluid (loss of serosal detail).
- Thoracic radiographs are used to screen for pulmonary metastatic disease characterized by coalescing miliary pattern, or nodular/generalized miliary interstitial pattern.

Ultrasonography

- Abdominal ultrasonography is used for the detection of splenic or hepatic lesions, omental nodules, and free abdominal fluid (hemoabdomen).
- Echocardiography is used to identify right atrial masses (better identified when at least some degree of pericardial effusion is present).

Advanced Imaging

MRI/CT provides high sensitivity and specificity in determining benign from malignant processes of the liver and spleen.

STAGE OF DISEASE

- Stage I—tumor confined to one organ, no rupture
- Stage II—ruptured tumor
- Stage III—measureable metastatic disease

DIAGNOSTIC PROCEDURES

- Abdominocentesis to characterize fluid accumulation—usually a serosanguineous fluid or hemorrhagic non-clotting effusion. Can compare PCV of effusion to peripheral blood PCV to confirm blood loss.
- Cytology—diagnostic yield for HSA is reported to be low (< 25%).

PATHOLOGIC FINDINGS

- *Gross findings*—solitary or multiple hemorrhagic, friable masses or nodules within the spleen and/or liver.
- *Histopathology findings*—atypical mesenchymal cells forming irregular blood-filled vascular spaces within a tumor mass. Often abundant necrosis and hemorrhage. Some areas may not resemble vascular structures, so immunohistochemistry for von Willebrand factor (factor VIII-related antigen) or CD31/platelet endothelial cell adhesion molecule (PECAM) can be used to confirm endothelial cell origin.

TREATMENT

- Balanced isotonic electrolyte solutions ± colloids to correct hypovolemic shock and reduced cardiac output.
- Fresh whole blood or packed red blood cell transfusion to replace reduced oxygen-carrying capacity from acute bleeding.

- Fresh frozen plasma if coagulopathy or signs of DIC present.

- Splenectomy or liver lobectomy are the standard of care surgical procedures and initial treatment of choice. Removes macroscopic tumor burden and lessens the ongoing risk of acute death from hemorrhage. Surgery alone is palliative, with median survival times of 1–3 months without adjuvant chemotherapy.
- The use of doxorubicin-based chemotherapy has been consistently shown to improve remission duration and survival times.
- Metronomic chemotherapy may offer benefit vs. surgery alone as a sole therapy or when used concurrent to or following doxorubicin chemotherapy.

MEDICATIONS

DRUG(S)

- Doxorubicin (30 mg/m^2 IV dogs $> 15 \text{ kg}$; 1 mg/kg IV dogs $< 15 \text{ kg}$ q2–3 weeks for 5 cycles).
- Metronomic cyclophosphamide ($12.5\text{--}15 \text{ mg/m}^2$ PO q24h) in combination with an NSAID (e.g., piroxicam 0.3 mg/kg PO q24h) may be used concurrent or as an alternative to doxorubicin.

CONTRAINdications/POSSIBLE INTERACTIONS

- Doxorubicin administration can lead to gastrointestinal, bone marrow, cardiac, renal, hypersensitivity, and extravasation toxicities.
- Doxorubicin can lead to cumulative cardiotoxicity in dogs.
- Cyclophosphamide can lead to sterile hemorrhagic cystitis in dogs.
- NSAIDs can lead to gastrointestinal toxicity and liver/kidney damage.

ALTERNATIVE DRUG(S)

- Immunotherapy:
 - Liposomal muramyl tripeptide phosphatidylethanolamine (L-MTP-PE), a synthetic macrophage activator derived from mycobacterial cell wall, when given concurrent to a doxorubicin/cyclophosphamide protocol, was associated with the longest reported survival times (MST 273 days) for this disease. This agent is not currently commercially available in the US.
 - An allogeneic HSA vaccine, when given concurrent to doxorubicin, was associated with a MST of 182 days but is not currently commercially available.

FOLLOW-UP

PATIENT MONITORING

- Physical examinations, blood work, thoracic radiographs, and cardiac ultrasounds

(CONTINUED)

HEMANGIOSARCOMA, SPLEEN AND LIVER

every 2–3 months after the completion of therapy.

- If treated with metronomic chemotherapy, routine monthly urinalysis recommended to screen for sterile hemorrhagic cystitis.

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

Death due to acute hemorrhage or fatal tachyarrhythmias.

EXPECTED COURSE AND PROGNOSIS

- Prognosis guarded to poor.
- Median survival time with surgery alone (dogs): 19–65 days.
- Median survival time with surgery plus chemotherapy (dogs): 145–179 days.
- Mean time to progression in cats: 4–5 months.

H

HEMATEMESIS

BASICS

DEFINITION

The vomiting of blood

PATHOPHYSIOLOGY

A disruption in the gastric or upper small intestinal mucosal barrier leading to inflammation and bleeding. Coagulopathies can also present with hematemesis. An animal may also vomit blood that originated in the oral cavity or respiratory system and was swallowed.

SYSTEMS AFFECTED

- Gastrointestinal—*inflammation, trauma, ulceration, neoplasia, and/or foreign body in the oral cavity, pharyngeal area, esophagus, stomach, and/or duodenum.*
- Cardiovascular—acute, severe hemorrhage may result in tachycardia, systolic heart murmur, and/or hypotension.
- Hematologic—coagulopathy with gastrointestinal hemorrhage can lead to hematemesis.
- Respiratory—respiratory hemorrhage with ingestion can lead to hematemesis.

GENETICS

N/A

INCIDENCE/PREVALENCE

True incidence unknown

SIGNALMENT

Species

Dog and, less commonly, cat

Breed Predilections

There appears to be an overrepresentation of chow chows and Siamese cats with gastric adenocarcinoma.

Mean Age and Range

All ages

Predominant Sex

Male dogs have increased incidence of gastric carcinoma

SIGNS

Historical Findings

• Vomiting with blood—blood in the vomitus may appear as fresh flecks of blood, blood clots, or digested blood, which looks like coffee grounds. • Melena can be observed. • Anorexia. • Abdominal pain (may assume the praying position).

Physical Examination Findings

- Abdominal pain
- Melena
- If patient is anemic—tachycardia, heart murmur, pallor, weakness, and/or collapse.

CAUSES

Coagulopathies

- Thrombocytopenia
- Thrombocytopathia—von Willebrand's disease, NSAIDs, drugs, uremia
- Hyperviscosity syndrome
- Disseminated intravascular coagulopathy
- Anticoagulant rodenticide toxicity
- Coagulation factor deficiency
- Liver failure
- Polycythemia

Drugs

NSAIDs, glucocorticoids

Gastrointestinal Diseases

- Inflammatory bowel disease
- Gastric, or duodenal neoplasia
- Gastric, or duodenal foreign body
- Gastric or intestinal volvulus or torsion
- Hemorrhagic gastroenteritis
- Gastroduodenal ulcers
- Gastroesophageal intussusception

Toxicity

- Heavy metal poisoning (arsenic, zinc, thallium, iron, or lead)
- Plant intoxication (dieffenbachia, sago palm, mushroom, castor bean)
- Chemical intoxication (phenol, ethylene glycol, corrosive agents, psoriasis creams—vitamin D analogues)
- Pesticide/rodenticide toxicity (cholecalciferol)
- Snake bite
- Aflatoxins
- Bee sting

Infectious Diseases

- Gastrointestinal parasitism
- Pythiosis (fungal oomycete)
- Viral, fungal, or bacterial gastroenteritis
- Virulent systemic feline calicivirus
- Rickettsial infections

Metabolic Diseases

- Renal failure
- Liver disease
- Hypoadrenocorticism
- Pancreatitis

Neoplasia

- Mastocytosis
- Gastrinoma
- Oral, nasal, respiratory (blood is swallowed and subsequently vomited), or gastrointestinal tumors
- APUDomas

Neurologic Diseases

- Head trauma
- Spinal cord disease

Respiratory Diseases

- Nasal disease—neoplasia, fungal infection
- Pulmonary and airway disease—neoplasia, severe pneumonia, fungal infection, foreign body, heartworm disease
- Mediastinal neoplasia

Stress/Major Medical Illness

- Septic or hypovolemic shock
- Severe illness
- Burns
- Heat stroke
- Major surgery
- Sustained strenuous exercise
- Trauma
- Systemic hypertension
- Thromboembolic disease
- Hypotension

RISK FACTORS

- Administration of ulcerogenic drugs—NSAIDs or glucocorticoids
- Critically ill patients
- Hypovolemic or septic shock
- Thrombocytopenia
- Concurrent administration of NSAIDs and glucocorticoids

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hemoptysis—thoracic radiographs may reveal presence of airway or pulmonary disease.
- Regurgitation or vomiting of swallowed blood from extragastrointestinal diseases (e.g., oropharyngeal, nasopharyngeal, and cutaneous diseases).
- Ingestion and vomiting of foreign materials or foods that

look like fresh or digested blood (e.g., oral iron).

CBC/BIOCHEMISTRY/URINALYSIS

- If acute (3–5 days) blood loss—nonregenerative anemia (normocytic, normochromic, minimal reticulocytosis).
- If blood loss > 5–7 days in duration—regenerative anemia (macrocytic, reticulocytosis).
- If chronic blood loss—iron-deficiency anemia (microcytic, hypochromic, variable reticulocytosis, with or without thrombocytosis).
- ± thrombocytopenia.
- ± panhypoproteinemia with alimentary hemorrhage.
- May have mature neutrophilia or left shift neutrophilia with sepsis and/or gastroduodenal ulcer perforation.
- BUN: creatinine ratio may be elevated with gastrointestinal hemorrhage, but will also be increased with dehydration.

OTHER LABORATORY TESTS

- Fecal occult blood test may be false positive if dog is not on a non-meat diet for 3 days prior to test.
- Fecal flotation—to screen for gastrointestinal parasitism.
- Coagulation profile—if a coagulopathy is suspected.
- Bile acids—if liver disease is suspected.
- ACTH stimulation—if hypoadrenocorticism is suspected.

IMAGING

- Abdominal radiography may identify a gastric or duodenal foreign body or mass, pancreatitis, pneumoperitoneum, effusion or changes consistent with kidney, pancreas, or liver disease.
- Thoracic radiographs may reveal esophageal foreign body or mass, gastroesophageal intussusception, mediastinal mass, pulmonary or airway disease, and/or pulmonary metastasis.
- Abdominal ultrasound may identify a gastric or duodenal mass, gastric or duodenal wall thickening or altered layering, gastric ulcer, and/or abdominal lymphadenopathy.
- Abdominal ultrasound can also screen for abnormalities in the pancreas, liver, kidneys, and other abdominal organs as source of hematemesis.
- Gastrointestinal scintigraphy may be used to localize gastrointestinal blood loss.

DIAGNOSTIC PROCEDURES

- Endoscopy to evaluate the mucosal appearance of the esophagus, stomach, and upper small intestinal tract once extragastrointestinal causes are ruled out.
- Biopsy mucosal lesions and submit for histopathology to determine the nature of the underlying gastrointestinal disease.
- Abdominocentesis may identify septic peritonitis.
- Obtain fine needle aspirates or biopsy specimens of cutaneous or intra-abdominal masses to identify neoplasia/disease.

PATHOLOGIC FINDINGS

- Gastroduodenal inflammation and hemorrhage.
- Ulcers may have more necrosis, microthrombi, and hemorrhage, and deeper penetration than erosions.

(CONTINUED)

HEMATEMESIS**TREATMENT****APPROPRIATE HEALTH CARE**

- Treat any underlying causes.
- Treat on an outpatient basis if the cause is identified and removed, vomiting is not excessive, and gastroduodenal bleeding is minimal.
- Inpatients—those with severe gastroduodenal bleeding, ulcer perforation, excessive vomiting, and/or shock.

NURSING CARE

- Intravenous fluids to maintain hydration.
- May need aggressive intravenous fluid treatment for shock—crystalloids and/or colloids.
- Severe hypoproteinemic patients may require colloids and/or plasma to increase vascular oncotic pressure.
- May need transfusions (whole blood or packed red blood cells) in patients with severe gastroduodenal hemorrhage.
- Patients with underlying coagulopathies may need whole blood or fresh frozen plasma to replace clotting factors.
- In severe cases of hematemesis—to stop the gastrointestinal bleeding, ice water lavage (10–20 mL/kg remaining in stomach for 15–30 minutes) or lavage with norepinephrine (8 mg/500 mL) diluted in ice water can be attempted.

DIET

- Discontinue oral intake if vomiting.
- When feeding is resumed, feed small amounts in multiple feedings.

CLIENT EDUCATION

- NSAIDs should be administered to pets only under the guidance of a veterinarian.
- Administration of NSAIDs (including COX-2 inhibitors) can result in gastroduodenal ulcerations and perforations.
- Adverse effects of NSAIDs can be reduced by giving drug with food and concurrent administration of a synthetic prostaglandin E₁ analogue (e.g., misoprostol).

SURGICAL CONSIDERATIONS

Surgical treatment is indicated if medical treatment fails after 5–7 days, hemorrhage is uncontrolled, gastroduodenal ulcer perforates, and/or potentially resectable tumor is identified.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Histamine (H₂) receptor antagonists competitively inhibit gastric acid secretion and are the initial drug of choice (ranitidine 1–2 mg/kg SC, PO, IV q8–12h, dog and cat; famotidine 0.5–1 mg/kg PO, IV q12–24h, dog and cat; nizatidine 5 mg/kg PO q24h, dog). H₂ receptor antagonists differ in potency and duration of action. Famotidine is most potent followed by ranitidine. Treat for

at least 6–8 weeks. Rebound gastric acid hypersecretion may occur when H₂ blockers are discontinued but can be minimized by tapering the dose as it is discontinued.

- H₂-receptor antagonists are less potent than proton pump inhibitors.
- Antacids neutralize gastric acid and some induce local synthesis of mucosal protectants but must be given at least four to six times/day to be effective. Owner compliance with this regimen is often poor.
- Sucralfate suspension (0.5–1 g PO q6–8h) protects ulcerated tissue (cytoprotection) by binding to ulcer sites, adsorbing pepsin and bile salts, and stimulating prostaglandin synthesis. Binding is greater in duodenal than gastric ulcers.
- Antibiotic(s) with activity against enteric gram negative bacteria and anaerobes should be given parenterally if a break in gastrointestinal mucosal barrier is suspected or aspiration pneumonia is present.
- Antiemetics (chlorpromazine 0.5 mg/kg q6–8h SC, IM, IV, dog and cat; prochlorperazine 0.1–0.5 mg/kg q6–8h SC, IM, dog and cat; ondansetron 0.5 mg/kg IV q12h, dog; 0.2 mg/kg IV q12h, cat; metoclopramide 1–2 mg/kg/24h CRI, dog and cat; maropitant 1 mg/kg SC q24h for 5 days, dog; 2 mg/kg PO q24h for 5 days, dog) are administered if vomiting occurs frequently or results in significant fluid losses.
- Proton pump inhibitors (omeprazole 1 mg/kg PO q12–24h, dog; pantoprazole 1 mg/kg IV dogs)—omeprazole is the most potent inhibitor of gastric acid secretion; treatment of choice for gastrinomas with evidence of metastasis or non-resectable disease and gastroduodenal disease that has not responded to H₂ blocker therapy.

CONTRAINdications

Avoid drugs that might damage the gastroduodenal mucosal barrier (e.g., NSAIDs and corticosteroids).

POSSIBLE INTERACTIONS

- H₂ blockers prevent uptake of omeprazole by oxyntic cells.
- Sucralfate may alter absorption of other drugs. Thus, it should be given on an empty stomach 2 hours before or after other oral drugs.
- Antacids may alter oral absorption and renal elimination of other drugs.

ALTERNATIVE DRUG(S)

Misoprostol, synthetic prostaglandin analogue, (3 µg/kg PO q8–12h) with antisecretory and cytoprotective actions helps prevent NSAID-induced ulcers. There may be some efficacy in treating gastroduodenal ulcerations from other causes.

**FOLLOW-UP****PATIENT MONITORING**

- Improvement in some cases may be assessed on resolution of clinical signs; packed cell

volume, total protein, fecal occult blood, and BUN may help to detect continued blood loss.

- Depending on the underlying cause of the hematemesis, specific laboratory or imaging tests may be necessary to monitor response to therapy.

PREVENTION/AVOIDANCE

- Avoid gastric irritants (e.g., NSAIDs, corticosteroids).
- Concurrent use of misoprostol or PPI with NSAIDs; PPI may be preferable because they are therapeutic as well.
- Administer NSAIDs with food.
- COX-2 selective or dual LOX/COX inhibitors may have less adverse gastrointestinal effects than nonselective NSAIDs.

POSSIBLE COMPLICATIONS

- Severe blood loss
- Sepsis
- Ulcer perforation

H**EXPECTED COURSE AND PROGNOSIS**

- Varies with underlying causes.
- Patients with malignant gastric neoplasia, renal failure, liver failure, pythiosis, systemic mastocytosis, sepsis, and/or gastric perforation—guarded-to-poor prognosis.
- Hematemesis secondary to NSAID administration, coagulopathies, inflammatory bowel disease, or hypoadrenocorticism—prognosis may be good to excellent, depending on severity of disease.
- Hematemesis secondary to heat stroke, toxicities, and snake bites can have variable prognoses.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Anemia

PREGNANCY/FERTILITY/BREEDING

Synthetic prostaglandins (e.g., misoprostol) cause abortion.

HEMATURIA

BASICS

DEFINITION

Blood in urine

PATHOPHYSIOLOGY

Secondary to loss of endothelial integrity in urinary tract, clotting factor deficiency, or thrombocytopenia.

SYSTEMS AFFECTED

- Renal/Urologic • Reproductive
- Hemic/Lymphatic/Immune

SIGNALMENT

Dog and cat • Familial hematuria in young animals; neoplasia in older animals • Females at greater risk for UTI

SIGNS

Historical Findings

Red-tinged urine with or without pollakiuria

Physical Examination Findings

- Palpable mass in patients with neoplasia
- Abdominal pain in some patients
- Enlarged and/or painful prostate gland in males • Petechiae or ecchymoses in patients with coagulopathy

CAUSES

Systemic

- Coagulopathy • Thrombocytopenia
- Vasculitis

Upper Urinary Tract

- Anatomic—e.g., cystic kidney disease and familial malformations • Metabolic—e.g., nephrolithiasis • Neoplastic—e.g., renal lymphoma, adenocarcinoma, and hemangiosarcoma • Infectious—e.g., leptospirosis, FIP, and bacteria
- Inflammatory—e.g., glomerulonephritis
- Idiopathic • Trauma

Lower Urinary Tract

- Anatomic—e.g., bladder malformations
- Metabolic—e.g., uroliths • Neoplasia—e.g., transitional cell carcinoma and lymphosarcoma
- Infectious—e.g., bacterial, fungal, and viral disease • Idiopathic—cats (idiopathic cystitis)
- Traumatic • Cyclophosphamide-induced hemorrhagic cystitis

Genitalia

- Metabolic—e.g., estrus • Neoplastic—e.g., transmissible venereal tumor, leiomyoma, and prostatic adenocarcinoma • Infectious—e.g., bacterial and fungal disease • Inflammatory—e.g., benign prostatic hyperplasia • Trauma

RISK FACTORS

Breed predisposed to urolithiasis (e.g., Dalmatians and urate urolithiasis), coagulopathy (e.g., Dobermanns and von Willebrand disease), or neoplasia (e.g., Scottish terriers and transitional cell carcinoma).

DIAGNOSIS

See Figure 1.

DIFFERENTIAL DIAGNOSIS

Other causes of discolored urine (e.g., myoglobinuria, hemoglobinuria, and bilirubinuria)

LABORATORY FINDINGS

Drugs That May Alter Laboratory Results

Substantial doses of vitamin C (ascorbic acid) may cause false-negative reagent test strip results; newer generations of reagent strips are more resistant to interference by reducing substances such as ascorbic acid.

Disorders That May Alter Laboratory Results

- Common urine reagent strip tests for blood are designed to detect red blood cells, hemoglobin, or myoglobin. • Low urine specific gravity (polyuric syndromes) lyses RBCs. • Bacteriuria (bacterial peroxidase) causes false-positive reagent test strip results.
- Formalin preservative causes false-negative reagent test strip results.

Valid if Run in a Human Laboratory?

Yes

CBC/BIOCHEMISTRY/URINALYSIS

- Thrombocytopenia and severe anemia in some patients. • Azotemia in some patients with bilateral renal disease. • RBCs (> 5–10 RBC/hpf) and possibly infectious agents seen in urine sediment. • Crystalluria in some patients with urolithiasis.

OTHER LABORATORY TESTS

- ACT or clotting profile to rule out coagulopathy. • Bacterial culture of urine to identify urinary tract infection.
- Examination of an ejaculate to identify prostatic disease.

IMAGING

Ultrasonography, radiography, and possibly contrast radiography are often useful in localizing the underlying cause.

DIAGNOSTIC PROCEDURES

- Biopsy of mass lesion
- Vaginourethroscopy in females or urethrocystoscopy in males and females

TREATMENT

- Hematuria may indicate a serious disease process. • Urolithiasis and renal failure may require diet modification. • Urinary tract infection may be associated with another disease, local (e.g., neoplasia and urolithiasis) or systemic (e.g., hyperadrenocorticism and diabetes mellitus), that also requires treatment.

MEDICATIONS

DRUG(S) OF CHOICE

- Blood transfusion may be necessary if patient is severely anemic • Crystalloids to treat dehydration • Antibiotics to treat urinary tract infection and septicemia
- Heparin for DIC

CONTRAINDICATIONS

Immunosuppressive drugs, except to treat immune-mediated disease.

POSSIBLE INTERACTIONS

Intravenous contrast media can cause acute renal failure.

FOLLOW-UP

PATIENT MONITORING

Depends on primary or associated diseases

POSSIBLE COMPLICATIONS

- Anemia • Hypovolemia if severe hemorrhage • Ureteral or urethral obstruction due to blood clots

MISCELLANEOUS

AGE-RELATED FACTORS

- Neoplasia tends to occur in older animals
- Immune-mediated diseases tend to occur in young adult animals

ZOONOTIC POTENTIAL

Leptospirosis

HEMATURIA

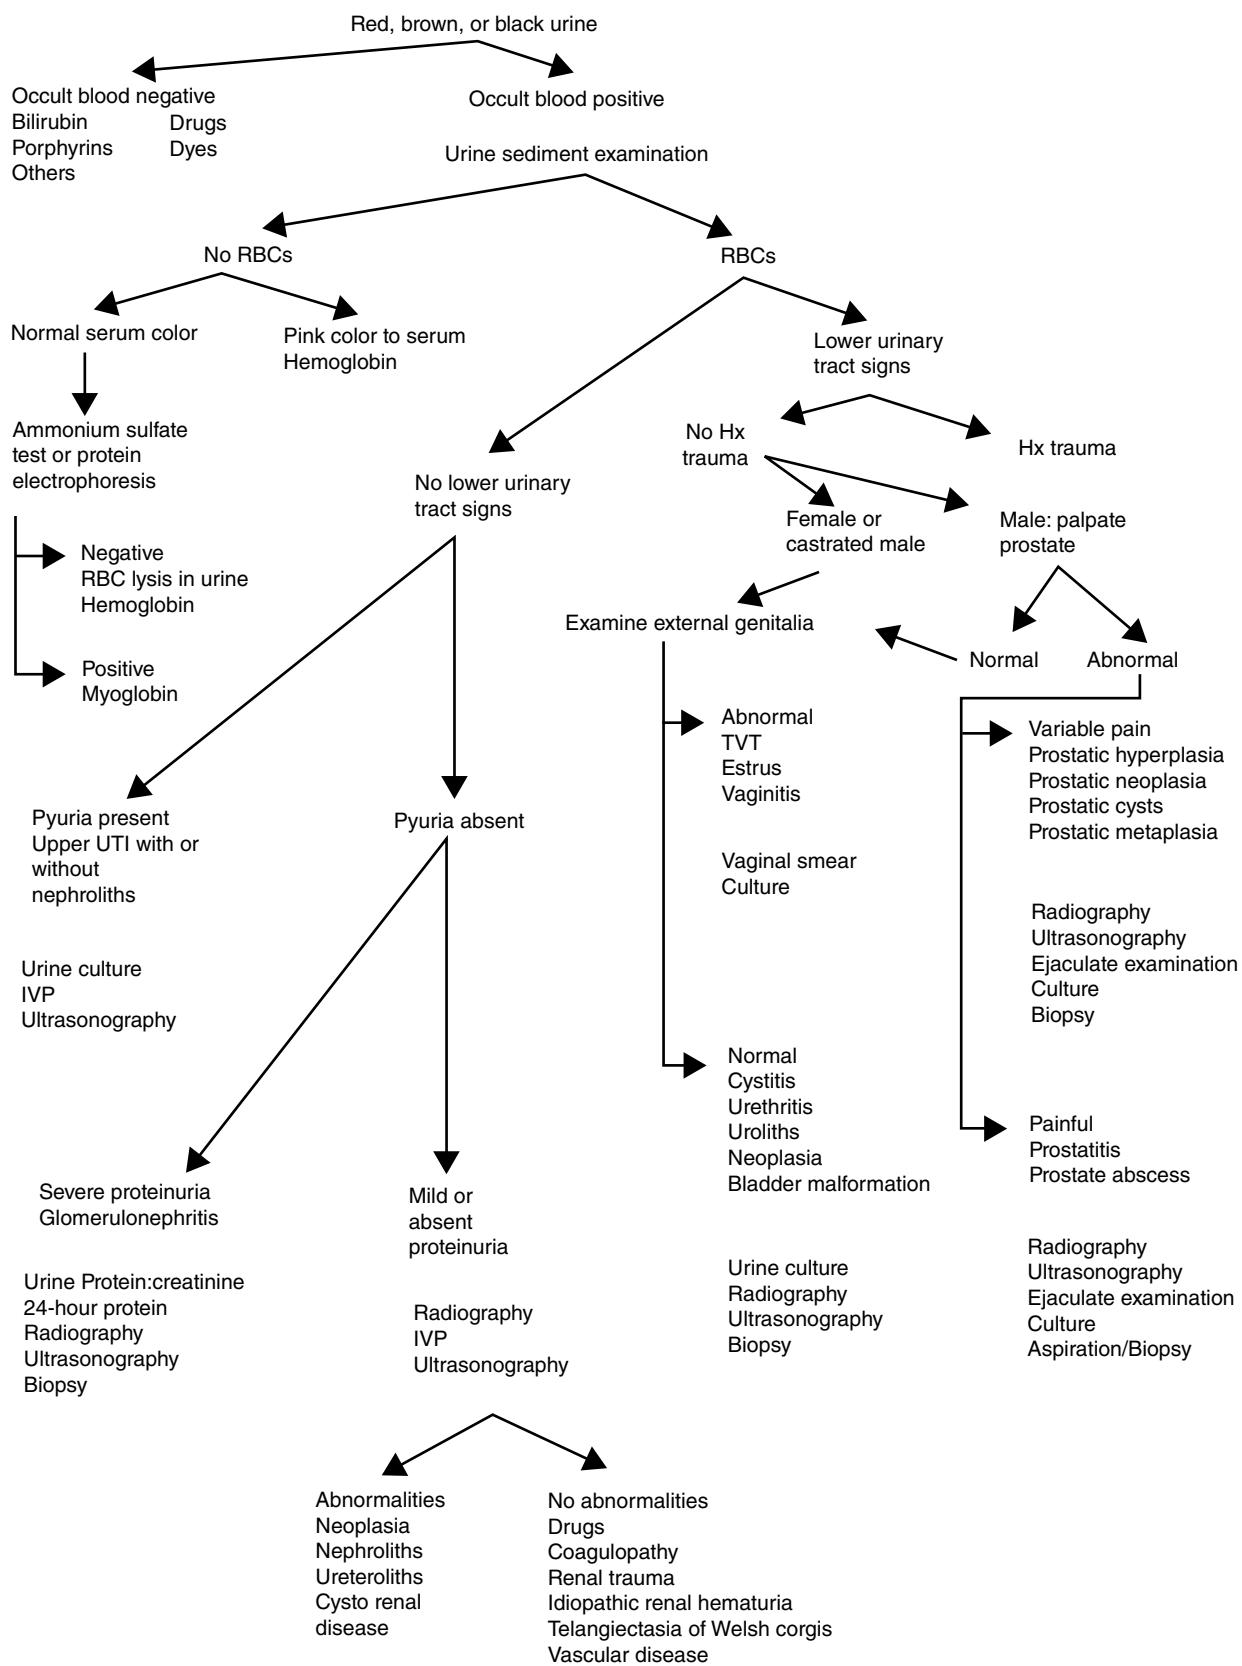

Figure 1.

Algorithm for the diagnosis of red, brown, or black urine.

HEMOGLOBINURIA AND MYOGLOBINURIA

BASICS

DEFINITION

Positive, semiquantitative urine heme (also reported as occult blood) concentration detected via routine laboratory tests (e.g., reagent test strip).

PATHOPHYSIOLOGY

- Hemoglobin released from RBC during intravascular hemolysis (hemoglobinemia) is bound (high-affinity) to haptoglobin, thereby inhibiting oxidative tissue destruction.
- Hemoglobin-haptoglobin complexes are too large to pass through normal glomerular capillaries and are removed by the reticuloendothelial system, mainly in the spleen. Haptoglobin becomes saturated when hemoglobin concentration is high; free hemoglobin (4 heme-containing chains, 64,000 daltons) rapidly dissociates into unstable dimers (32,000 daltons) small enough to pass through glomerular capillaries, resulting in hemoglobinuria (red discoloration). Free hemoglobin undergoes fluid-phase endocytosis (via megalin and tubulin receptors expressed at the apical membrane) in renal tubular epithelial cells. Globin is degraded while free heme is catabolized by heme oxygenase, resulting in lipid peroxidation and Fe deposition. In addition, an acidic intratubular environment favors hemoglobin precipitation, cast formation, and tubular obstruction.
- Methemoglobinemia causes an analogous disease process.
- In contrast, myoglobin, a single heme-containing chain (approximately 17,500 daltons), is released from muscle following decreased energy supply or injury. Interaction of heme with the protein portion (globin) allows myoglobin to carry oxygen without oxidation of ferrous (Fe^{2+}) to ferric (Fe^{3+}) iron. Myoglobin is freely and rapidly cleared by passing through the glomerular barrier (small size, no carrier protein) and plasma remains colorless. However, myoglobin accumulation in urine causes brown discoloration while an acidic environment favors precipitation, cast formation, and tubular obstruction. In addition, myoglobin enters proximal renal tubular epithelial cells via megalin and tubulin receptors, where it causes lipid peroxidation without release of free iron (via redox cycling of the heme center). Alkaline conditions prevent myoglobin-induced lipid peroxidation by (1) stabilizing the reactive ferryl myoglobin complex and (2) decreasing myoglobin precipitation in renal tubules.

SYSTEMS AFFECTED

Renal/Urologic—hemoglobin, methemoglobin, and myoglobin are

nephrotoxic, especially when decreased renal perfusion and acidic conditions are present.

SIGNALMENT

- Bedlington terrier—inherited copper toxicosis can cause hemolysis due to copper release from the liver into the blood. Although copper-associated liver disease has been reported in other breeds of dogs, only Bedlington terriers have been reported to have a hemolytic outcome.
- English springer spaniel, American cocker spaniel, English cocker spaniel, cocker spaniel—inherited phosphofructokinase deficiency may cause intravascular hemolysis with hemoglobinuria and myopathy.
- Racing sled dogs and greyhounds—exertional myopathy can result in myoglobinuria.
- Old English sheepdog—exertional lactic acidosis with hemoglobinuria.
- Neonatal isoerythrolysis in cats—(blood type B queen with type A or AB kittens) British shorthair, Cornish Rex, Devon Rex, Abyssinian, Birman, Himalayan, Persian, Scottish fold, and Somalia breeds; neonates die within 2 days.

SIGNS

General Comments

A diversity of clinical signs may be associated with specific causes; see “Causes.”

Historical Findings

Breed and drug treatment history are particularly important; see “Causes.”

Physical Examination Findings

- Signs associated with anemia (pale mucous membranes, tachycardia, lethargy, icterus).
- Signs associated with muscle damage (tenderness, bruising).

CAUSES

Hemoglobinuria

- Oxidative damage—drugs (acetaminophen, benzocaine, vitamin K₃, new methylene blue, phenacetin, phenazopyridine, monensin sodium); food (onions, garlic); heavy metals (copper, zinc).
- Physical agents—burns, heat stroke, crush injury, electric shock, IV hypotonic fluid administration, microangiopathy (e.g., disseminated intravascular coagulopathy, *D. immitis* caval syndrome).
- Toxins (loss of membrane integrity)—snake (e.g., Eastern diamondback, Eastern coral) or spider (e.g., brown recluse) venom.
- Infectious agents—babesiosis (e.g., *B. canis*), leptospirosis (e.g., *L. icteroheemorrhagica*), cytauxzoonosis (e.g., *C. felis*), mycoplasmosis (e.g., *M. hemofelis*).
- Immune-mediated—idiopathic immune-mediated hemolytic anemia, incompatible blood transfusion, isoerythrolysis (e.g., type B queen with type A or AB kittens).

- Deficiencies—hypophosphatemia (e.g., following insulin treatment in diabetes mellitus patients).

- Genetic associated—PK deficiency, copper toxicity.

- Other—retroperitoneal hemorrhage.

Myoglobinuria

- Myositis—*infectious* (e.g., toxoplasmosis, neosporosis), eosinophilic (German shepherd dog, other breeds), *immune-mediated*.
- Genetic-associated—X-linked muscular dystrophy (e.g., golden retriever, Weimaraner, rottweiler, Samoyed, Groenendael shepherd, miniature schnauzer); glycogenoses (storage diseases)—Type II (spitz), Type III (German shepherd dog), Type VII (springer spaniel colony, one American cocker spaniel); mitochondrial abnormalities (Clumber spaniel, Sussex spaniel, possibly Old English sheepdog).
- Toxins (loss of membrane integrity)—snake (e.g., coral) or spider (e.g., brown) venom.
- Physical—ischemia, crush injury, compartment syndrome.
- Excessive body temperature (e.g., heat stroke, prolonged seizures).
- Extreme exercise.

RISK FACTORS

- Genetic predisposition (see “Signalment”)
- Exposure to specific drugs or toxins
- Certain infectious agents
- Extreme physical exertion
- Heat stroke
- Snake or spider venom

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Urine reagent test strip heme (occult blood) pads detect RBC, hemoglobin (or methemoglobin), and myoglobin; the following assist with differentiation:
 - Clear plasma/serum with RBC or RBC ghost cells in urine sediment suggests hematuria.
 - Hemolyzed plasma/serum (not related to collection) suggests hemoglobinuria.
 - Chocolate-colored whole blood suggests methemoglobinuria.
 - Clear plasma/serum with an increased CK concentration and clinical evidence of muscle damage suggests myoglobinuria.
 - False-positive results (see “Laboratory Findings”).

LABORATORY FINDINGS

Drugs That May Alter Laboratory Results

- Vitamin C (ascorbic acid) administration may cause false-negative reagent test strip results.
- Hemoglobin-based oxygen carriers (Oxyglobin) administration causes positive reagent test strip results.

(CONTINUED)

HEMOGLOBINURIA AND MYOGLOBINURIA

H

Disorders That May Alter Laboratory Results

- Hyposthenuria (low urine specific gravity) may cause *in vitro* RBC lysis (no intact RBC in sediment) with a positive reaction.
- Bacteriuria may cause a false-positive result (bacterial peroxidase).
- Oxidizing reagents (e.g., from disinfectants) may cause a false-positive result.
- Free hemoglobin from transfused blood or blood products may cause a positive reaction.
- Formalin causes false-negative results.

Valid if Run in Human Laboratory?

Yes

CBC/BIOCHEMISTRY/URINALYSIS

- Proteinuria.
- Intravascular hemolysis—decreasing PCV (may be accompanied by leukocytosis), blood smear abnormalities (RBC parasites, Heinz bodies, RBC ghost cells [complement mediated]), bilirubinemia, increased ALT activity, bilirubinuria.
- Rhabdomyolysis—increased CK and AST activities.

OTHER LABORATORY TESTS

- Ammonium sulfate precipitation test—mix 5 mL urine with 2.8 g ammonium sulfate and centrifuge; hemoglobin precipitates, myoglobin remains in solution. Dark precipitate is suggestive for hemoglobinuria, dark supernatant is suggestive of myoglobinuria, and if both are dark, hemoglobin and myoglobin are present.
- New methylene blue stained blood smear to detect Heinz bodies.
- Methemoglobin detection confirms toxin as oxidant.
- Haptoglobin concentration is decreased with intravascular hemolysis.
- Increased serum copper or zinc concentration.
- DNA test for PFK deficiency.

IMAGING

Abdominal radiography or ultrasonography—coins, hardware or other metal objects in the gastrointestinal tract; abnormal liver size in patients with copper-associated hepatopathy.

DIAGNOSTIC PROCEDURES

- Liver biopsy to measure copper concentration
- Forced exercise (e.g., Old English sheepdog)

TREATMENT

- Copious fluids to maintain renal function (50% of sodium as sodium bicarbonate if acidosis is present to avert precipitation and peroxidation).
- Avoid stress in anemic patients.
- Avoid hyperventilation in PFK-deficient patients.
- Exercise-induced hematuria has a benign, self-limiting course.
- See suspected causes for specific treatment.

MEDICATIONS

DRUG(S) OF CHOICE

Vary with underlying cause.

CONTRAINDICATIONS

See list of causes for contraindicated drugs.

ALTERNATIVE DRUG(S)

N/A

FOLLOW-UP

PATIENT MONITORING

PCV, pO₂, urinalysis, serum creatinine, ALT (copper-associated), CK (myopathy-associated).

POSSIBLE COMPLICATIONS

Renal damage (failure) may develop.

MISCELLANEOUS

HEMOTHORAX

BASICS

OVERVIEW

- Accumulation of blood in pleural space.
- Can develop acutely due to trauma or a coagulopathy, or chronically over time.
- Cardiovascular and respiratory systems commonly affected.

SIGNALMENT

Any age, breed, or sex of dogs and cats

SIGNS

- Peracute to acute onset—hypovolemic signs can occur before sufficient blood volume accumulates in the pleural space to impair respiration. • Respiratory distress, tachypnea. Honking cough in dogs with rodenticide poisoning. Ecchymoses along ventral cervical and thoracic inlet areas. • Pale mucous membranes. • Weakness and collapse.
- Weak, rapid pulse. • Ventral thoracic dullness; dorsal hyperresonance if concurrent pneumothorax.

CAUSES & RISK FACTORS

- Trauma—bleeding artery or vein of the thoracic wall, mediastinum, or thoracic spine; damaged heart, lungs, thymus, or diaphragm; herniated abdominal viscera (liver or spleen).
- Neoplasia—involving any structure adjacent to the pleural cavity. • Coagulopathies—can be congenital or acquired; rodenticide ingestion common; liver failure; cholangiohepatitis with concurrent small bowel disease. • Lung lobe torsion. • Acute thymic hemorrhage in young animals.
- *Dirofilaria immitis*, *Spirocerca lupi*, *Angiostrongylus vasorum*.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Pulmonary contusion. • Pneumothorax.
- Diaphragmatic hernia. • Flail chest.
- Non-hemorrhagic pleural effusions—chyothonax; pyothorax; modified transudates; transudates. • Congestive heart failure.

CBC/BIOCHEMISTRY/URINALYSIS

- PCV and hemoglobin—reflect blood loss after initial fluid compartment shifts have occurred. • Platelet count may be low (~100,000) with acute blood loss. • Very low platelet count (<20,000) consistent with spontaneous bleeding. • Peripheral smear evaluation—less than 3–5 platelets/hpf indicates thrombocytopenia. • Chemistry panel may reveal low glucose, BUN, albumin, and cholesterol with liver failure.

OTHER LABORATORY TESTS

Fluid Analysis

- Hemorrhage-produced effusion—PCV and protein content similar to that of the peripheral

blood; platelets commonly seen on cytology. • Inflammation- or vascular-congestion related effusion—PCV < 8%. • Neoplasia or lung lobe torsion—PCV can be low or mid-range. • Cytologic examination—often fails to identify malignant causes.

Coagulation Tests

- Prolonged ACT or PT/PTT suggestive of coagulopathy. • Prolonged PT, APTT, and low platelet count—suggestive of DIC.
- Positive D-dimer aids in detecting DIC.
- Specific factor analysis—needed to diagnose congenital defect or acquired coagulopathy.
- Buccal mucosal bleeding time—identifies platelet function defect or vasculitis.

IMAGING

• Radiology—reveals pleural effusion varying from a diffuse increase in radiopacity to ventral leafing, interlobar fissures, and localized pleural densities. • Can see associated lesions (e.g., rib fractures, pneumothorax or pneumomediastinum, mediastinal hemorrhage, pulmonary contusions, diaphragmatic lesions, and masses). • Lobar consolidation with vesicular gas pattern suggestive of lung lobe torsion.

• Ultrasound—confirm pleural effusion; look for masses, lung lobe torsion, and herniation of liver, gallbladder, spleen, or bowel. • In stable patients without a coagulopathy—evacuation of pleural space may allow better radiographic visualization of masses or other pathology.

DIAGNOSTIC PROCEDURES

- Thoracentesis (contraindicated if clotting abnormality). • Surgical exploration—may be necessary to establish a diagnosis; if imaging does not suggest the appropriate side to enter, the left side is recommended or use median sternotomy. Preoperative computed tomography can be helpful.

TREATMENT

- Acute—judicious use of IV fluids. Try to get systolic blood pressure above 90 mm Hg using synthetic colloids, crystalloids and/or hypertonic saline to correct hypovolemia.
- Coexisting pneumothorax—generally requires needle thoracentesis or tube thoracostomy. • Plasma, specific clotting factors, and/or blood transfusion can be needed to restore clotting factors or provide RBCs for oxygen transport. • Pulmonary contusion—may require ventilator support.
- Severe or recurrent thoracic hemorrhage—may require surgical exploration. • Oxygen therapy. • Maintenance of body heat. • Most coagulopathic cases have respiratory difficulty associated with soft tissue bleeding rather than pleural hemorrhage and therefore rarely require evacuation of pleural fluid to resolve tachypnea. • Autotransfusion.

MEDICATIONS

DRUG(S)

- Hypovolemia—see Shock, Hypovolemic.
- Vitamin K₁—5 mg/kg SC loading dose (using a small gauge needle) followed by 1.5–2.5 mg/kg PO q12h for 21–30 days. Takes 12 hours or more to carboxylate clotting factors and restore activity.
- Analgesics—systemically or as nerve blocks for trauma. • Broad-spectrum antibiotics—when indicated.

CONTRAINdications/POSSIBLE INTERACTIONS

Avoid aspirin and other NSAIDs.

FOLLOW-UP

PATIENT MONITORING

- Clinical signs, respiratory rate and effort, heart rate. • Temperature. • Urine production. • Relief from pain. • Follow-up radiographs at 48-hour intervals until stable.
- Coagulation panel in 48 hours if coagulopathy diagnosed, and 48 hours after discontinuing vitamin K supplementation.

POSSIBLE COMPLICATIONS

- Pyothorax. • Sepsis. • Entrapment and constriction of lungs by scar tissue and fibrosis.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Peritonitis—with penetrating wounds (e.g., gunshot) into the abdomen. • Esophageal perforation.

SEE ALSO

- Rodenticide Toxicosis—Anticoagulants
- Disseminated Intravascular Coagulation
- Lung Lobe Torsion • Pleural Effusion
- Pulmonary Contusions

ABBREVIATIONS

- ACT = activated clotting time • APTT = activated partial thromboplastin time
- DIC = disseminated intravascular coagulation • NSAID = nonsteroidal anti-inflammatory drug • PCV = packed cell volume • PT = prothrombin time • PTT = partial thromboplastin time • RBC = red blood cell

Consulting Editor Lynelle R. Johnson

HEMOTROPHIC MYCOPLASMOSIS (ALSO HEMOPLASMOSIS)

BASICS

OVERVIEW

Red blood cell destruction and anemia caused by parasite attachment to the external surface of RBCs, nutrient scavenging by parasite from RBC, and immune response by the host.

SIGNALMENT

- Dog and cat.
- Acute disease most common in young cats, chronic form most common in adults.
- In cats, more common in males.
- Acute disease in splenectomized dogs, chronic disease in non-splenectomized dogs.
- Kennel-raised beagles are at increased risk for infection.
- No sex prevalence in dogs.

SIGNS

Cats

- For *M. haemofelis* infection:
 - Variable disease severity ranging from inapparent infection (chronic disease) to marked anemia and death (acute disease).
 - Intermittent fever (only 50% of the time) during the acute phase, depression, weakness, anorexia, anemia, pale mucous membranes, splenomegaly, and (occasionally) icterus.
- For *Candidatus M. haemominutum* infection:
 - Usually results in inapparent infection.
 - Minimal or no decrease in hematocrit.
- For *Candidatus M. turicensis*:
 - Limited information regarding natural infection.
 - Moderate anemia following experimental infection.

Dogs

- Mild or inapparent signs (e.g., pale mucous membranes and listlessness)—except when dogs have been splenectomized or splenic function is altered.
- High prevalence of chronic, inapparent infection in kennel-raised Beagles, which may be a threat to the validity of research results.

CAUSES & RISK FACTORS

- Caused by bacteria previously classified in the genus *Haemobartonella*, but these organisms are now recognized to be mycoplasmas (hemotropic mycoplasmas or hemoplasmas) based on genetic determinations.
- *Mycoplasma haemofelis* (previously classified as the large form of *Haemobartonella felis*), *M. haemominutum* (previously classified as the small form of *H. felis*), and *M. haemocanis* (previously classified as *H. canis*).
- *M. haemofelis* infection in cats generally causes more severe disease than does *M. haemominutum* infection.
- Cats—anemia more severe if FeLV-infected.

- Dogs—likelihood of severe anemia greatly increased if splenectomized or with pathologic changes in the spleen.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of hemolytic anemia, including AIHA, babesiosis (not in cats in the United States), cytauxzoonosis (cats only), Heinz body hemolytic anemia, microangiopathic hemolytic anemia, pyruvate kinase deficiency, and phosphofructokinase deficiency (dogs only).
- Differentiated from AIHA only by recognition of parasites in blood (stained blood film or species-specific PCR-based assays)—both disorders (IMHA and/or *M. haemofelis* infection) may be Coombs' test positive.
- *Babesia* and *Cytauxzoon* species are protozoal organisms that differ in morphology from these mycoplasmal organisms.
- New methylene blue stains used to identify Heinz bodies.
- Enzyme assays or specialized DNA tests used to diagnose pyruvate kinase and phosphofructokinase deficiencies.

CBC/BIOCHEMISTRY/URINALYSIS

- Anemia, most often present with reticulocytosis in animals with clinically important infections—may appear poorly regenerative if a precipitous decrease in PCV has occurred early in the disease or if there are other concurrent disorders (e.g., FeLV or FIV infections in cats).
- Autoagglutination may be seen in feline blood samples after they cool to below body temperature.
- Variable total and differential leukocyte counts of little diagnostic assistance.
- Slight hemoglobinuria rarely observed; no hemoglobinuria reported.
- Hyperbilirubinemia may be measured and/or seen clinically at times but is seldom severe.
- Substantial bilirubinuria seen in some dogs.
- Abnormalities related to anemic hypoxia may be shown by clinical chemistry profiles, but profile can be normal.
- Hypoglycemia possible in moribund cats or if slow to separate blood cells from plasma or serum.

OTHER LABORATORY TESTS

- Routine blood stains (e.g., Wright-Giemsa) to identify organisms in blood films, which must be examined for organisms before treatment is begun.
- Organism may detach from RBCs in stored blood collected with EDTA.

- Reticulocyte stains cannot be used because punctate reticulocytes in cats appear similar to the parasites.

- Organisms must be differentiated from precipitated stain, refractile drying or fixation artifacts, poorly staining Howell-Jolly bodies, and basophilic stippling.

- Feline organisms—small blue-staining cocci, rings, or rods on RBCs, often many parasites for *M. haemofelis*; small rods or coccoid organisms in low numbers for *Candidatus M. haemominutum*; parasites not conclusively seen in blood for *Candidatus M. turicensis*.

- Canine organisms—commonly form chains of organisms that appear as filamentous structures on the surface of RBCs.
- Parasitemia is cyclic and thus organisms not always identifiable in blood (especially in cats).
- PCR-based assays can detect parasites in blood below the number required to make a diagnosis by a stained blood film.

DIAGNOSTIC PROCEDURES

- In patients with nonregenerative anemia, bone marrow biopsy should be performed to detect other disorders (e.g., myeloproliferative disorders).
- PCR testing of blood donor cats and dogs is strongly recommended.

TREATMENT

- Without therapy, mortality with *M. haemofelis* infection may reach 30% in cats.
- Outpatient treatment unless severely anemic or moribund.
- Blood transfusions required when the anemia is considered life-threatening.
- IV administration of glucose-containing fluid recommended in moribund animals.

MEDICATIONS

DRUG(S)

- Doxycycline (5 mg/kg PO q12h), tetracycline (20 mg/kg PO q8h), or oxytetracycline (20 mg/kg PO q8h) should be given for a minimum of 3 weeks and up to 6 weeks for elimination.
- Preliminary findings indicate that enrofloxacin (5 mg/kg PO q24h) for 2 weeks may be efficacious in cats.
- Glucocorticoids, such as prednisolone (1–2 mg/kg PO q12h), may be given to severely anemic animals; gradually decrease dosage as the PCV increases.

HEMOTROPHIC MYCOPLASMOSES (ALSO HEMOPLASMOSES) (CONTINUED)

CONTRAINdications/POSSIBLE

INTERACTIONS

- Esophageal strictures have been reported in cats following doxycycline administration.
- Tetracycline antibiotics may produce fever or evidence of gastrointestinal disease in cats.
- Enrofloxacin at dosages above 5/mg/kg/day may cause retinotoxicity.
- Chloramphenicol should not be used to treat cats because it causes dose-dependent erythroid hypoplasia.

FOLLOW-UP

- Examine animal after 1 week of treatment to confirm that PCV has risen.
- Alert owners that cats may remain carriers even after completion of treatment but seldom relapse with disease once PCV returns to normal.
- Cats have protective immunity against *Mycoplasma haemofelis* reinfection for some period of time.

MISCELLANEOUS

ABBREVIATIONS

- AIHA = autoimmune hemolytic anemia
- HIV = human immunodeficiency virus
- PCR = polymerase chain reaction

Authors Joanne B. Messick and John W. Harvey

Consulting Editor Alan H. Rebar

BASICS

OVERVIEW

- Amyloidosis—disorders of diverse etiology sharing common feature of deposition of extracellular insoluble fibrillar β -pleated proteinaceous matrix with distinctive staining properties and fibrillar ultrastructure.
- Amyloid—derived from diverse primary proteins, sometimes an acute phase reactant.
- Amyloid may accumulates as a focal or systemic process secondary to inflammatory or lymphoproliferative disorders or as a familial genetic disorder.
- Familial amyloidosis—certain kindreds of purebred cats; certain breeds and kindreds of dogs; syndromic inflammatory disorders.
- Multiple organs commonly involved; clinical signs often reflect renal involvement.
- Liver amyloid accumulation—insidious; associates with variable liver enzymes, severe hepatomegaly, coagulopathies, liver rupture leading to hemoabdomen (cats), or liver failure.

SIGNALMENT

- Dogs—Chinese Shar-Pei with cyclic “Shar-Pei fever syndrome”; Akita with cyclic fever and polyarthropathy; Collie with “Gray Collie syndrome”; usually develop renal signs first although some develop hepatic insufficiency.
- Cats—Oriental shorthair, Siamese, Devon rex, domestic shorthair cats; usually < 5 years of age when first symptomatic (hepatic signs and coagulopathies predominate); familial in Abyssinians (renal signs predominate). Upper respiratory viral infection proposed to trigger amyloidosis in Siamese.

SIGNS

Historical Findings

- Episodic fever and swollen hocks—Shar-Pei
- Episodic polyarthropathy, pain, and signs of meningitis—Akita
- Acute lethargy, cyclic
- Anorexia and vomiting, episodic
- Polyuria and polydipsia

Physical Examination Findings

- Pallor
- Abdominal effusion—hemorrhage or ascites
- Jaundice: unusual
- Hepatomegaly with amyloid deposition
- Edema: due to hypoalbuminemia secondary to pathologic proteinuria
- Joint pain: Akita, Shar-Pei syndromes
- Non-localized pain, meningeal pain, and abdominal discomfort: with different inflammatory disorders promoting amyloid

CAUSES & RISK FACTORS

- Familial immunoregulatory disorders
- Chronic infections—coccidioidomycosis; blastomycosis; tick-borne diseases
- Cyclic neutropenia—Gray Collie syndrome

- Bacterial endocarditis
- Chronic inflammation (e.g., SLE).
- Neoplasia

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Chronic hepatic inflammation
- Infiltrative hepatic neoplasia
- Primary or rodenticide induced coagulopathy
- Glomerulonephritis
- Pyelonephritis
- SLE
- Abdominal trauma
- Peritonitis
- Meningitis
- Immune-mediated or infectious polyarthropathy

CBC/BIOCHEMISTRY/URINALYSIS

- Anemia secondary to hepatic hemorrhage or liver lobe rupture or chronic inflammation.
- Leukocytosis with a left shift during febrile episodes in Shar-Pei and Akita.
- Normal or high: liver enzymes, total bilirubin, and serum bile acids; may be normal with severe hepatic amyloid deposition.
- Azotemia with severe renal infiltration: glomeruli targeted in dogs (proteinuria), renal interstitium targeted in cats (azotemia).
- Proteinuria: dogs—glomerular amyloid.
- Dilute urine—renal involvement or failure.
- Feline systemic amyloidosis—involves multiple organ systems: thyroid, cardiac, renal, intestine, pancreatic, bone marrow, lymph nodes, adrenals.

OTHER LABORATORY TESTS

- Coagulation tests—normal to prolonged clotting times, hyperfibrinogenemia.
- Synovial fluid—dogs with joint swelling or pain: suppurative nonseptic inflammation.
- CSF—if meningeal pain, increased protein and suppurative inflammation.

IMAGING

- Abdominal radiography—hepatomegaly; variable renal size; abdominal effusion.
- Abdominal ultrasonography—hepatomegaly: hypoechoic parenchyma (diffuse amyloid); variable renal size with normal or equivocally hypoechoic parenchyma (renal amyloid); inconsistent mesenteric lymphadenopathy; thickened gut wall (amyloid deposition); abdominal effusion.

DIAGNOSTIC PROCEDURES

- Fine-needle aspiration cytology—may disclose amorphous fibrillar material.
- Liver or other tissue biopsy.
- Abdominocentesis—hemorrhagic (esp. cats) or transudative effusion (diffuse hepatopathy).

PATHOLOGIC FINDINGS

Gross

Liver—normal to pale color; large, firm to friable; hemorrhages (subcapsular hematomas, capsular tears) to overt rupture.

Microscopic

- Liver—diffuse acellular amorphous material in the space of Disse, associated with hepatic cord atrophy; may primarily involve blood vessels in portal triads (Abyssinian cats).
- Cats with systemic amyloidosis may have amyloid deposited in many organs and endocrine tissue.
- Amyloid stains amorphous pink with routine hematoxylin and eosin; may stain turquoise blue with Masson's trichrome; Congo red staining with bright field: amyloid is salmon pink but with polarized light is birefringent (β -pleated sheet structure refracts polarized light) and apple green.

TREATMENT

- Warn client that hepatic amyloidosis is difficult to treat; guarded to poor prognosis.
- Dictated by severity of clinical signs.
- No curative treatment; manage underlying disease; colchicine as described below may reduce organ amyloid deposition.
- Fluids—for dehydration.
- Blood transfusion—for acute blood loss; essential in cats with hepatic amyloid induced liver lobe rupture.
- Diet—individually tailored to organ function.
- Liver failure—consider measures appropriate for hepatic encephalopathy as appropriate.
- Pathologic proteinuria—see Nephrotic Syndrome.
- Surgical intervention—hepatic lobe resection as emergency measure for catastrophic bleeding from fractured liver lobe in cats; histologic features may describe centrilobular necrosis due to anemia-induced hypoxia; amyloid may be overlooked without special stains.

MEDICATIONS

DRUG(S)

- Colchicine—dogs: 0.03 mg/kg PO q24h; may block amyloid deposition in early disease or control deposition in chronic disorders in dogs; modulates expression of adhesion molecules and chemotactic factors; causes microtubule polymerization by binding to tubulin blocking cell mitosis in cells such as neutrophils. Effects attenuate inflammatory response triggering acute phase protein (amyloid precursor) production. Monitor

HEPATIC AMYLOID

(CONTINUED)

CBC for bone marrow toxicity; observe patient for enteric side effects (vomiting, diarrhea [bloody]), beware of toxicity if co-administered with p450 blocking drugs (e.g., ketoconazole, omeprazole, cimetidine). Use colchicine without added probenecid. Limited experience in cats.

- DMSO—Controversial treatment; use medical grade only; dogs: 80 mg/kg given as no more than a 33% solution in sterile water, PO, three times a week; may promote dissolution of amyloid fibrils or provide anti-inflammatory or anti-amyloid effect. Side effects: garlic odor and objectionable taste. Sterile solutions have also been prepared and administered SQ. In humans this treatment given PO daily (3–20 g/patient) has benefit in polysystemic amyloidosis but not renal amyloidosis associated with renal failure.

POSSIBLE INTERACTIONS

- Colchicine combined with probenecid may cause vomiting as probenecid prolongs residence time of colchicine.
- Colchicine toxicity if co-administered with p450 cytochrome inhibitor drugs.

H

FOLLOW-UP

- Shar-Pei—with hepatic amyloid may survive > 2 years; most have episodes of fever and cholestasis; some resolve clinical signs and diminish hepatic amyloid with colchicine.
- Akitas with cyclic clinical signs—grave prognosis.
- Cats surviving liver hemorrhage eventually succumb to renal failure and other polysystemic effects of deposited amyloid.

HEPATIC ENCEPHALOPATHY

BASICS

DEFINITION

- Hepatic encephalopathy (HE) defines a broad spectrum of neurobehavioral signs.
- Associated with: (1) acute liver failure, (2) portosystemic bypass without intrinsic liver disease (portosystemic vascular anomaly [PSVA] shunt), (3) hepatic fibrosis/cirrhosis associated with portal hypertension and acquired portosystemic shunts (APSS).
- Direct metabolic/physiologic dysregulations responsible for HE are potentially reversible.

PATHOPHYSIOLOGY

- Multifactorial origin.
- Ammonia best studied toxin; ammonia and glutamate function as neurotoxins adversely affecting astrocytes (site of ammonia detoxification to glutamine). Hyperammonemia causes astrocyte swelling and oxidative stress.
- Complex pathophysiology—energy failure (neuroglycopenia), altered cerebral pH, calcium ion flux, abnormalities of glutamatergic, GABAergic and catecholaminergic neurotransmission; perturbed aromatic amino acid metabolism (preferential systemic utilization of branched chain gluconeogenic amino acids), increased cerebral levels of endogenous benzodiazepine-like substances; inflammatory cytokines, oxidative injury; each factor contributes to electrophysiologic derangements. An altered blood-brain barrier likely contributes to pathophysiologic changes.
- Neurobehavioral abnormalities predominate with most signs attributed to gut-derived substances (bacterial and protein metabolism), particularly ammonia.

SYSTEMS AFFECTED

- Nervous—abnormal cerebral function predominates; decreased awareness and function progresses to somnolence, coma, or agitation progressing to seizures; aggression and seizures more likely in cats with PSVA.
- GI—vomiting, diarrhea, and anorexia.
- Renal/urologic—ammonium biurate urolithiasis; renal pelvic and cystic calculi.

GENETICS

- PSVA—polygenic inheritance of extrahepatic PSVA in small breed dogs (see Portosystemic Vascular Anomaly, Congenital).
- Certain chronic hepatopathies have increased prevalence in some breeds (see Chronic Hepatitis; Copper Associated Hepatopathy).

INCIDENCE/PREVALENCE

Uncommon disorder

SIGNALMENT

Species

Dog and cat

Breed Predilections

- PSVA—usually purebred dogs; increased occurrence in certain breeds (see Portosystemic Vascular Anomaly, Congenital) and mixes of these.
- Chronic hepatitis and copper associated hepatopathy more common in certain breeds (see topics).

Mean Age and Range

- PSVA—usually young animals
- Acquired liver disease with APSS—any age

Predominant Sex

None

SIGNS

General Comments

- Neurologic—usually coordinates with meal ingestion (particularly high protein, e.g., red meat); systemic infection; GI hemorrhage; dehydration; azotemia; constipation; catabolism; hemolysis; blood transfusion; certain drugs.
- Temporary resolution of signs with: dietary protein restriction, ± antibiotic or lactulose treatment, ± resolution of associated conditions.
- Prolonged recovery from sedation or anesthesia—reduced elimination of drugs removed by first pass extraction.
- Ammonium biurate obstructive uropathy.

Historical Findings

- Episodic abnormalities.
- Learning disabilities (difficult to train).
- Lethargy/Somnolence → coma.
- Anorexia/Vomiting; ptalism especially cats.
- Polyuria and polydipsia.
- Disorientation—aimless wandering; compulsive pacing; head pressing.
- Amaurotic blindness.
- Seizures—neurologic prodrome.
- Signs more frequent in cats than in dogs—ptalism; seizures; aggression; disorientation; ataxic stupor.
- More frequent in dogs than cats—compulsive behavior, e.g., head pressing, circling, aimless wandering, vocalizing; vomiting; diarrhea; PU/PD; hematuria, pollakiuria, and dysuria-ammonium biurate urolithiasis.

Physical Examination Findings

- PSVA—cats may have normal size, but most have stunted stature; microhepatia; and golden-copper colored iris (non-blue-eyed and non-Persian cats; no green iris color).
- PSVA dogs may have normal size, but are usually stunted; microhepatia, increased incidence of cryptorchidism (one study).
- Acquired liver disease—depends on chronicity and formation of APSS; ascites common in dogs with HE due to acquired liver disease and vacillates in severity; variable coagulopathies (uncommon).
- Lower urinary tract signs—obstructive uropathy due to ammonium biurate urolithiasis; imparts orange/brown color to urine.

CAUSES

- PSVA—congenital malformations.
- APSS—secondary to splanchnic portal hypertension (cirrhosis, sinusoidal fibrosis; intrahepatic AV malformation, intolerant to PSVA shunt attenuation); see Hypertension, Portal; Portosystemic Shunting, Acquired.
- Acute hepatic failure—induced by drugs, toxins, or infection (see Hepatic Failure, Acute; Hepatotoxins).

RISK FACTORS

- Alkalosis, hypokalemia, hypoglycemia.
- Certain anesthetics and sedatives.
- Certain drugs: e.g., methionine, tetracycline, antihistamines.
- Enteric bleeding—most common acute precipitating cause of HE.
- Transfusion—stored blood products may contain high concentrations of ammonia; incompatible blood transfusions; heme potently provokes HE.
- Infections.
- Constipation.
- Catabolism—disorders causing muscle wasting; large amounts of ammonia are transiently detoxified by storage in muscle.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Lead toxicosis
- Urinary tract infection—other urolithiasis
- Intestinal parasitism
- Primary gastrointestinal disease
- Hypoglycemia: many causes
- Toxoplasmosis
- Congenital CNS disease or malformation—hydrocephalus; storage diseases
- CNS neoplasia
- Acute ethylene glycol or xylitol toxicosis
- Infectious diseases—rabies; canine distemper
- Thiamin deficiency—Wernicke's encephalopathy (especially cats)
- Drug intoxications; recreational human drugs

CBC/BIOCHEMISTRY/URINALYSIS

CBC

PSVA and APSS—RBC microcytosis; mild non-regenerative anemia; poikilocytosis (cats); target cells (dogs); APSS—± jaundice.

Biochemistry

- Low BUN and creatinine—reflect PU/PD, high GFR, and reduced hepatic synthesis.
- Hypoglycemia—young toy breed dogs with PSVA; fulminant hepatic failure; cirrhosis.
- Low cholesterol—common; PSVA and APSS; fulminant hepatic failure.
- Liver enzymes—variable with APSS depending on cause; ALP usually high in young patients with PSVA owing to bone isoenzyme.

H

HEPATIC ENCEPHALOPATHY

(CONTINUED)

- Bilirubin—normal with PSVA but may be high with APSS depending on cause.
- Hypoalbuminemia—common with APSS but inconsistent and mild with PSVA.

Urinalysis

- Low concentration—common with PSVA.
- Ammonium urate crystalluria—causing hematuria, pyuria, and proteinuria due to mechanical inflammation and infection secondary to metabolic calculi.

OTHER LABORATORY TESTS

- Blood ammonia—sensitive but inconsistent indicator of HE; fasting hyperammonemia unreliable; blood ammonia values less reliable than TSBA owing to analytic/methodologic issues and because samples cannot be mailed for analysis; ammonia tolerance testing—most reliable method for detecting ammonia intolerance (administer NH₄Cl; **caution:** may induce HE).
- TSBA—confirms hepatic insufficiency or shunting associated with HE.
- Coagulation tests—PSVA: abnormalities usually not associated with bleeding; APSS: increased PT, APTT, PIVKA, and low fibrinogen reflect severity of liver dysfunction, synthetic failure, DIC, and vitamin K adequacy.
- Protein C: low activity in dogs with substantial shunting, liver failure, PLE, DIC.
- Abdominal effusion—acquired liver disease; hepatic AV malformation; pure or modified transudate.
- Liver zinc values—often low (< 120 µg/g dry weight liver tissue).

IMAGING

See Portosystemic Vascular Anomaly, Congenital; Portosystemic Shunting, Acquired

DIAGNOSTIC PROCEDURES

- Hepatic aspiration—cannot differentiate disorders causing portosystemic shunting.
- Liver biopsy—open surgical wedge biopsy or laparoscopic sampling (cup biopsy forceps) to collect tissue from several liver lobes.
- Tru-Cut needle biopsy: may inadequately sample tissue.

PATHOLOGIC FINDINGS

- Gross—liver changes reflect underlying disorder; rare brain herniation in acute HE.
- Microscopic—liver lesions: define causal hepatic disorders and identify portal hypoperfusion associated with portosystemic shunting; CNS lesions: polymicrocavitation and Alzheimer type II astrocyte changes—**inconsistent** in dog.

TREATMENT

APPROPRIATE HEALTH CARE

- Depends on underlying condition.
- PSVA—surgical correction preferred; chronic medical treatment possible for some.

NURSING CARE

- Depends on underlying condition; eliminate factors promoting HE.
- Improve dietary protein tolerance by concurrent oral or rectal (enema) treatments (see "Medications") and altered protein intake (type, quantity).
 - If hepatic coma—discontinue oral medications.
 - Avoid risk factors.
 - Fluids—balanced crystalloids but avoid lactate if fulminant hepatic failure, if hypoglycemic supplement fluids with 2.5–5.0% dextrose; provide 20–30 mEq/L potassium chloride (not to exceed 0.5 mEq/kg/h) titrated according to needs; sodium-restricted fluids with acquired liver disease associated with ascites, and/or marked hypoalbuminemia.
 - B-soluble vitamins (2 mL/L fluids).

ACTIVITY

Keep patient warm, inactive, and hydrated.

DIET

- Adequate calories—avoid catabolism and maintain muscle mass (site for temporary ammonia detoxification/storage).
- Dietary protein restriction—cornerstone of medical management; use commercially formulated diets for liver disease or moderate renal insufficiency; dogs: dairy and soy protein best sources; 2.5 g protein /kg bodyweight; cats: pure carnivores must have meat-derived protein; 3.5 g protein/kg bodyweight.
- Good-quality vitamin supplements—vitamin metabolism perturbed with liver disease and losses in urine. S-adenosylmethionine preferred to methionine supplementation: 20 mg/kg PO/d.
- Ensure thiamin repletion—avoids Wernicke's encephalopathy; 50–100 mg daily for 3 days in cats, then in water-soluble vitamins in fluids; **caution:** anaphylactoid reactions may occur with injectable thiamin.
- Partial parenteral nutrition—if short-term inappetence; may reduce muscle catabolism.
- Total parenteral nutrition if > 5 days inappetence and enteral route unavailable; use of branched-chain amino acid solutions remains controversial.

CLIENT EDUCATION

- HE—often episodic; relapse if underlying disorder cannot be eliminated.
- Train owner to administer enemas and to judiciously adjust medications PRN.
- PSVA—surgical ligation may be curative but also may cause adverse complications (see Portosystemic Vascular Anomaly, Congenital); postoperative clinical signs may persist requiring chronic nutritional and medical management.
- APSS—depends on underlying cause.

SURGICAL CONSIDERATIONS

- See Portosystemic Vascular Anomaly, Congenital
- APSS—do not ligate

MEDICATIONS

DRUG(S)

- Medications increasing dietary protein tolerance alter enteric flora or condition, reduce production/availability of substances provoking HE.
 - Antibiotics—spectrum altering intestinal flora (aerobic and anaerobic) or their products; first choice antimicrobial selections: systemic metronidazole (7.5 mg/kg q12h) or amoxicillin (esp. cats, 12.5–25 mg/kg PO q8–12h); combined with lactulose; **caution** if using neomycin (10–22 mg/kg PO q12h) as chronic administration may result in renal and otic toxicity (approximately 3% absorbed systemically).
 - Local antimicrobials used in enemas: same dosages as oral but do not administer by both oral and rectal routes.
 - In humans, rifaximin (semisynthetic rifamycin derivative) is as effective as lactulose and neomycin in treatment of HE and has a favorable safety and tolerability profile, but is expensive. There is no data accumulated for its utility for HE in animals. Suggested dose in dogs 5 mg/kg PO q24h or q12h.
 - Nonabsorbable-fermented carbohydrates—lactulose, lactitol, or lactose (milk products, if lactase deficient); decrease production/absorption of ammonia; promote a cathartic effect; trap nitrogen in bacteria; lactulose most commonly used (start at 0.5–1.0 mL/kg q8–12h and titrate up to therapeutic goal of passage of 2 or 3 soft stools/day); may also administer as enema for acute hepatic encephalopathy and coma *after* cleansing enemas remove debris.
 - Probiotics with nonabsorbable-fermented carbohydrates may be advantageous for altering gut flora to diminish HE toxin production (remains controversial).
 - Enemas—*cleansing enemas* (warmed polyionic fluids) mechanically clean colon (10–15 mL/kg, until clear return); *retention enemas* deliver fermentable substrates or directly alter colonic pH and organisms: diluted lactulose, lactitol, or lactose (1:2 in water); neomycin in water (do not exceed PO dose, do not dose PO and rectally); diluted Betadine (1:10 in water, *rinse well in 15 min*); diluted vinegar (1:10 in water).
 - Zinc supplementation—two urea cycle enzymes require zinc; measure baseline plasma zinc, (dose 1–3 mg/kg elemental zinc PO using zinc acetate); titrate dose using sequential plasma zinc measurements: avoid > 800 µg/dL.
 - Cerebral edema—complicates acute HE; head-up posture (15–20° incline); mannitol (1 g/kg diluted in saline, over 30 min); nasal oxygen; N-acetylcysteine (140 mg/kg IV diluted 1:2 in saline given through non-pyrogenic filter; then 70 mg/kg q8h);

(CONTINUED)

HEPATIC ENCEPHALOPATHY

glucocorticoids controversial, may promote enteric bleeding.

- Salvage therapy for intractable HE (experimental)—L-ornithine—L-aspartate (humans, rats: 180–300 mg/kg/day divided into three doses); L-carnitine (100 mg/kg PO or IV), may attenuate hepatic encephalopathy-associated hyperammonemia.
- If epileptic seizure activity—Keppra (levetiracetam) is the preferred anticonvulsant as it is minimally metabolized in liver and largely excreted in urine; secondary anticonvulsants include: zonisamide (caution: sulfa drug, rare idiopathic hepatotoxicity) and lastly, KBr (complicated by fluid therapy) as preferred anticonvulsants to phenobarbital.

CONTRAINDICATIONS

Avoid drugs metabolized by the liver.

PRECAUTIONS

- Use anesthetics, sedatives, tranquilizers, potassium-wasting diuretics, analgesics, and highly protein-bound drugs cautiously.
- If possible, avoid drugs reliant on hepatic metabolism, biotransformation, or excretion.
- Consider altered pharmacokinetics; reduced first-pass extraction due to portosystemic shunting; low albumin reduces protein binding increasing free drug-receptor interaction.

POSSIBLE INTERACTIONS

Drugs that affect or depend on hepatic metabolism—e.g., cimetidine, chloramphenicol, barbiturates, ketoconazole.

**FOLLOW-UP****PATIENT MONITORING**

- Re-evaluate patient's at-home behavior, demeanor, body condition and weight.

- Monitor albumin and glucose—in patients with non-correctable disorders; adjust nutrition.

- Monitor electrolytes—especially potassium; avoid hypokalemia as it aggravates hyperammonemia.

PREVENTION/AVOIDANCE

Avoid dehydration, azotemia, hemolysis, constipation, enteric bleeding, endoparasitism, infusion of stored blood, ammonium challenge, urinary tract infections (especially with urease-producing organisms, e.g., *Staphylococcus*), hypokalemia, hypomagnesemia, and alkalemia.

POSSIBLE COMPLICATIONS

Permanent neurologic damage (rare)

EXPECTED COURSE AND PROGNOSIS

- Depends on underlying disorder.
- Acute or chronic hepatic failure—may be fully or partially reversible, or patient may die.

**MISCELLANEOUS****AGE-RELATED FACTORS**

PSVA—surgical outcome may be good in young and old patients; medically treat HE before anesthesia/surgery.

H

HEPATIC FAILURE, ACUTE

BASICS

DEFINITION

- Severe acute hepatic injury incapacitating the ability to meet synthetic, metabolic, and detoxification needs.
- Sudden loss of > 75% of functional hepatic mass due to acute, massive hepatic necrosis.
- May lead to catastrophic multi-organ dysfunction/failure in a previously healthy individual; may rapidly progress to death.

PATOPHYSIOLOGY

- Necrosis—secondary to insufficient perfusion, hypoxia, hepatotoxins or their adducts (drugs, other xenobiotics, toxins), heat excess, or infectious agents.
- Severity of hepatic dysfunction depends on insult type and lobular (zonal) distribution.
- Reduced perfusion or hypoxia usually affect zone 3 (pericentral or centrilobular region).
- Ingested toxins—affect zone where toxin is metabolized or adducts formed, or where there is specific organelle tropism or propensity for oxidative injury (copper accumulation increases zone 3 vulnerability).
- Accompanied by enzyme leakage and markers of impaired liver function, hyperbilirubinemia and acute onset splanchnic hypertension due to sinusoidal or centrilobular collapse.
- Lethal organ failure associated with coagulopathy, enteric hemorrhage, acute onset hepatic encephalopathy (HE).
- Hepatic failure—associates with a myriad of metabolic derangements: i.e., altered glucose homeostasis, protein synthesis (albumin, transport proteins, procoagulants, and anticoagulants), and detoxification capabilities.

SYSTEMS AFFECTED

- Hepatobiliary—hepatocellular necrosis; hepatic failure, and jaundice.
- Nervous—HE; cerebral edema.
- Gastrointestinal—vomiting; diarrhea; melena; hematochezia due to acute splanchnic hypertension ± coagulopathy.
- Hemic/Lymphatic/Immune—pro- and anticoagulant factor imbalances; DIC.
- Renal/Urologic—renal tubule damage from certain toxins or physiologic vasoconstriction; tubular injury: i.e., copper associated hepatopathy, leptospirosis, xylitol toxicity, NSAID toxicity.
- Hyperdynamic circulatory status: low systemic and pulmonary vascular resistance, increased cardiac output and metabolic rate, systemic hypotension; this associates with endotoxemia, TNF- α , dehydration, and splanchnic hypertension.

INCIDENCE/PREVALENCE

- Variable depending on pre-existent liver disease: i.e. hepatocellular copper accumulation, chronic immune-mediated

hepatitis or cholangitis.

- Panlobular hepatic necrosis leading to acute liver failure is uncommon; examples: idiosyncratic drug toxicity: dogs—zonisamide, phenobarbital, primidone, diphenhydantoin, NSAIDs (e.g., carprofen), xylitol; cats—diazepam; dogs or cats—sulfa-antibiotics; primary toxins: dogs and cats—primary copper accumulation, acetaminophen; dogs—zonisamide, xylitol, cycad (sago palm), blue-green algae, *Amanita* mushrooms, aflatoxin; infectious disease: dogs—leptospirosis, infectious canine hepatitis.

More common in dog than in cat

Breed Predilections

Breeds with apparent predisposition to chronic hepatitis and copper associated hepatopathy (e.g., Labrador retriever, Doberman pinscher) may have higher risk. e.g., Labrador retrievers and NSAID toxicity enhanced by copper associated hepatopathy.

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

- Acute-onset nonspecific clinical signs; lethargy, inappetence, GI disturbances (vomiting, small intestinal diarrhea may be bloody), PU/PD.
- Tender hepatomegaly.
- Bleeding tendencies.
- Jaundice.
- Hepatic encephalopathy.
- Seizures.

CAUSES

Drugs

- See Hepatotoxins.
- Drug related toxicities may be *intrinsic* (direct) or *idiosyncratic* (unpredictable, unrelated to dose) presenting consequent to immune-mediated hypersensitivity or metabolic injury.

Biologic Toxins

See Hepatotoxins

Infectious Agents

See Hepatotoxins

Thermal Injury

- Heat stroke
- Whole-body hyperthermia
- Cancer treatment

Hepatic Hypoxia

- Thromboembolic disease, shock, DIC.
- Acute circulatory failure from any cause.
- Acute centrilobular necrosis (zone 3).

RISK FACTORS

- Administration of any potentially hepatotoxic substance or drug.
- Exposure to environmental toxins (e.g., *Amanita* mushroom, foodborne aflatoxin, cycad [sago palm] ingestion, blue-green algae, artificial sweetener xylitol (gum, candy)—dogs.

- Enzyme inducers (e.g., phenobarbital)—may increase risk for certain toxicities by enhancing xenobiotic toxin formation: e.g., acetaminophen toxicity is greatly enhanced by phenobarbital.
- Indiscriminate substance ingestion—puppies; polyphagic animals.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Severe acute pancreatitis or gastroenteritis—differentiated via laboratory tests and imaging.
- Acutely decompensated chronic liver disease—distinguished by review of medical records, blood tests, abdominal ultrasonography, and liver biopsy.

CBC/BIOCHEMISTRY/URINALYSIS

- Anemia and panhypoproteinemia—bleeding, marrow toxicity, direct enteric toxicity.
- Thrombocytopenia—bleeding, DIC, or portal hypertension.
- Liver enzyme activity—high acute ALT and AST; smaller increases ALP and GGT.
- Hypoglycemia—grave prognosis (cats esp.).
- Hypocholesterolemia—impaired synthesis or enteric loss with hemorrhage.
- Normal to low BUN concentration: reduced urea cycle function, PU/PD.
- Hyperbilirubinemia: initially absent.
- Bilirubinuria may precede hyperbilirubinemia—always abnormal in cats.
- Ammonium urate crystalluria signifies hyperammonemia, hepatic insufficiency or portosystemic shunting.
- Acquired Fanconi's syndrome—granular casts and renal glucosuria indicate proximal tubule injury (e.g., carprofen, copper, leptospirosis, other toxicities especially in dogs).

OTHER LABORATORY TESTS

- TSBA—high values indicate hepatic dysfunction, cholestasis, or portosystemic shunting.
- Plasma ammonia concentration—high values coincide with high TSBA, confirm hepatic insufficiency; hyperammonemia inconsistent but reflected by ammonium biurate crystalluria; hyperammonemia may reflect concurrent myonecrosis.
- Coagulation tests—coagulation factor deficiencies, platelet dysfunction, low fibrinogen, low antithrombin or protein C activity, and DIC suggest severe liver failure, decompensated DIC, or enteric losses with hemorrhage.

IMAGING

- Abdominal radiography—may identify a normal to slightly large liver ± effusion.
- Abdominal ultrasonography—may disclose non-hepatic disorders (e.g., pancreatitis), altered circulation (ratio hepatic vein:portal vein), altered liver echogenicity or surface contour reflecting chronic injury (e.g., remodeling implicated by heterogeneous liver texture, nodularity, or hepatofugal portal

(CONTINUED)

blood flow); rule out biliary obstruction as source of hyperbilirubinemia. • Brain MRI—may disclose early cerebral edema.

OTHER DIAGNOSTIC PROCEDURES

- Liver biopsy—confirms necrosis and characterize lesion zonal distribution.
- Fine-needle liver aspirate may identify hepatocellular degeneration, copper accumulation, dysplastic hepatocytes observed with cycad (sago palm) or aflatoxin ingestion; canalicular cholestasis. Many toxins lead to microvesicular hepatocellular lipid vacuolation.

PATHOLOGIC FINDINGS

- Gross—slightly large, mottled liver.
- Microscopic—confirms necrosis; zonal involvement; may assist in determining underlying cause: hypoxia leading to zone 3; certain toxins cause zone 1 or 3 necrosis; reticulin staining confirms zonal involvement, confirms retention or loss of reticulin substructure that orchestrate organized regeneration.

TREATMENT

APPROPRIATE HEALTH CARE

Inpatient—intensive care required.

NURSING CARE

- **Caution:** Delay inserting central catheters until bleeding diatheses controlled with vitamin K₁, fresh frozen plasma, or fresh whole blood. No advantage to prophylactic FFP administration as this may contribute to onset of HE and cerebral edema. • Fluids—non-lactate-containing; initially at a resuscitation rate; monitor peripheral blood pressure and pulse oximetry. Mixed acid-base disturbances common. • Colloid replacement—with low oncotic pressure from bleeding and protein loss; plasma always preferred; synthetic colloids are second line. Avoid dextran 70 and Hetastarch (as these may promote bleeding) and human albumin (may induce fatal acute allergic reaction).
- Potassium, phosphate, glucose—supplement as appropriate; low phosphate, potassium and glucose aggravate HE and other clinical signs, complicating critical supportive care. • Fluid regimen—adjust for maintenance needs after achieving normovolemia; typically provide one-third of normal maintenance rate with polyionic crystalloids if concurrently giving slow CRI of synthetic colloid. Avoid colloids if possible as these leak from the microvasculature (exacerbated with some toxicities that affect endothelium) and disturb signaling that triggers albumin and transporter protein synthesis. • Supplemental oxygen—if pulse oximetry $\leq 90\%$ saturation. • If suspect cerebral edema: use 30° head up elevation, consider mannitol, other interventions.

- Predisposition to infection from enteric bacterial translocation—cover with broad-spectrum antimicrobials; patient may not manifest fever or leukocytosis with infection. Sepsis/SIRS—major risks for cerebral edema. • Early administration of N-acetylcysteine may improve microvascular perfusion, tissue oxygenation, and mitigate oxidative damage; dosing: see below.

ACTIVITY

Restricted activity—conserves energy and metabolites for healing and regeneration.

DIET

- Intractable vomiting— withhold PO food until controlled; use antiemetics (see below).
- When enteric nutrition contraindicated (somnolent patient) use total or partial parenteral nutrition until enteral feeding route established; < 5 days advised. • If enteric nutrition chronically compromised, establish total parenteral nutrition (TPN) feeding catheter; use TPN formula with normal nitrogen content unless HE; branched-chain amino acids remain controversial. • Enteral feeding—small volume, frequent meals; optimize digestion and assimilation, minimize enteric toxin formation contributing to HE.
- Diet composition—use normal protein (nitrogen) content in tolerant patients; moderate protein restriction if HE (2.5 g protein/kg bodyweight) but strive to maintain a positive nitrogen balance for hepatic regeneration. • Supplemental vitamins are essential—water-soluble (2-fold normal); vitamin K₁ (0.5–1.5 mg/kg SC or IM, three doses at 12-h intervals, then once-to-twice weekly); vitamin E (10 IU/kg PO or by injection q24h). • Probiotic/Prebiotic yogurt: may protect against enteric bacterial translocation; tolerated dairy protein source if HE; controversial.

CLIENT EDUCATION

- Acute hepatic failure is a serious condition.
- Some patients succumb despite optimal treatment. • Cause of panlobular injury (e.g., exposure to a drug or toxin) should be investigated but may remain unconfirmed.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUG(S) OF CHOICE

Drugs for Vomiting

- Metoclopramide—1–2 mg/kg/day CRI for intermittent mild vomiting; contraindicated if spironolactone used for ascites mobilization.
- Ondansetron—0.5–1.0 mg/kg IV q24h.
- Chlorpromazine—0.5 mg/kg SC, IM, or rectally, q8–24h) for severe vomiting; ensure volume expansion first as causes alpha blockade vasodilation.

HEPATIC FAILURE, ACUTE

- Maropitant—1.0 mg/kg SC q24h.
- Histamine H₂-blocker—famotidine (0.5–1.0 mg/kg IM or SC q12–24h) if enteric bleeding; reserve cimetidine (0.5 mg/kg q8–12h) for purposeful P450 cytochrome inhibition.
- Omeprazole (0.5–1.0 mg/kg PO q12–24h) or pantoprazole may induce P450 cytochrome-associated drug interactions; 24–48 h delay in onset of action.

Drugs for Hepatic Encephalopathy

- Lactulose—0.5–2.0 mL/kg PO q8h; or rectally if PO hazardous; goal is soft feces.
- Probiotic yogurt (see above).
- Metronidazole—7.5 mg/kg PO q12h or rectally if PO hazardous.
- Rifaximin—5–10 mg/kg PO or rectally q12h (non-absorbed antibiotic alters enteric flora).
- Neomycin—22 mg/kg PO or rectally q12h; **caution:** may be ototoxic and renal toxic if increased absorption with reduced gut integrity.

H

Treatment of Cerebral Edema Associated with Hepatic Encephalopathy

- Mannitol—1 g/kg over 10–20 min, filtered; if brisk diuresis does not occur (~1 h), check for excessive volume expansion (plasma osmolality, blood pressure) and renal function.
- Furosemide—0.5–1.0 mg/kg IV q8–24h increases free water excretion and reduces CSF production; monitor hydration and serum potassium; avoid dehydration and hypokalemia that provoke or worsen HE.
- *Vasopressin V₂ antagonists* (aquaretics) may assist with management of diuretic resistant ascites. Tolvaptan successful in dogs with experimentally induced (rapid pacing) congestive heart failure. Human dose in cirrhosis is 7.5 mg/day; tolvaptan is metabolized exclusively in the liver primarily by cytochrome P450; dose undetermined in dogs with liver disease.

Drugs for Coagulopathy

Fresh whole blood or fresh frozen plasma—if clinically significant bleeding.

Free Radical Scavengers and Antioxidants

- For ongoing damage (membrane injury), reperfusion injury, and hypoxia.
- Vitamin E—10 IU/kg PO q24h.
- N-acetylcysteine—140 mg/kg IV or PO; IV use 10% solution diluted 1:2 in saline, administer via 0.25 μm non-pyrogenic filter; follow with 70 mg/kg q6–12h.
- S-adenosylmethionine (SAMe) as a GSH donor, use proven bioavailable product)—20 mg/kg PO q24h on empty stomach; multiple benefits: essential intermediary metabolites, GSH synthesis, promotes liver regeneration, antifibrotic, anti-inflammatory.

HEPATIC FAILURE, ACUTE

(CONTINUED)

Hepatoprotectants

- Silibinin (milk thistle), efficacy reported for *Amanita* toxicity and certain other toxins; use product complexed with polyunsaturated phosphatidylcholine (PPC), 2–5 mg/kg PO q24h.
- Ursodeoxycholic acid—if chronic liver injury or high bile acids persist, 10–15 mg/kg divided q12h PO, best absorbed if given with food.

Blocking Enterohepatic Circulation

Cholestyramine: 30–40 mg/kg mixed with water PO q24h; bile acid binding resin that can absorb certain toxins in the alimentary canal that undergo enterohepatic circulation diminishing their systemic availability, e.g., anecdotal, sago palm (cycad toxin).

CONTRAINDICATIONS

- Ideally, drugs biotransformed primarily in the liver, altering liver perfusion, or metabolizing enzyme activity should be avoided; may be difficult as many drugs are metabolized in hepatic pathways or eliminated in bile.
- Vitamin C—100–500 mg q24h, *avoid* if high liver iron or copper concentrations; ascorbate may augment transition metal-associated oxidative injury; no substantiation for vitamin C administration in liver failure.

PRECAUTIONS

Administration of stored whole blood or packed RBCs may precipitate or exacerbate HE in dogs with hepatic failure because of spontaneously generated ammonia during storage.

POSSIBLE INTERACTIONS

Compromised hepatic metabolism

ALTERNATIVE DRUG(S)

Case-based considerations

FOLLOW-UP

PATIENT MONITORING

- Temperature, pulse, respiration, and mental status—q1–2h until stable.
- Maintain

vigilance for infection, especially catheter-induced.

- Bodyweight—twice daily guides fluid therapy; bodyweight and condition used to assess nitrogen and energy allowances.
- Acid-base, electrolyte balances (especially potassium and phosphate), and glucose—q12–24h for the first 72 h.
- Sequential measurements of: liver enzymes, bilirubin, cholesterol, and fibrinogen q2–3 days provide evidence of recovery.

PREVENTION/AVOIDANCE

- Vaccinate dogs against infectious canine hepatitis virus.
- Avoid indiscriminate ingestion of hepatotoxins and environmental exposure.
- Consider drugs as potential toxins.

POSSIBLE COMPLICATIONS

- Hypoglycemia
- Uncontrolled GI bleeding and DIC
- HE, cerebral edema, brain herniation
- Chronic hepatic insufficiency, cirrhosis, fibrosis from postnecrotic scarring
- Acute renal failure
- Death

EXPECTED COURSE AND PROGNOSIS

Prognosis—depends on extent of liver injury, etiopathogenesis, supportive nursing care.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Pancreatitis
- Sepsis/Endotoxemia/Shock
- Bleeding diathesis; severe enteric hemorrhage; DIC
- Renal failure
- Hepatic encephalopathy

ZOONOTIC POTENTIAL

- Toxins (?)
- Leptospirosis

SYNOMYMS

- Acute hepatic necrosis
- Fulminant hepatic failure

HEPATIC LIPIDOSIS

BASICS

DEFINITION

- Feline hepatic lipidosis—> 80% of hepatocytes accumulate substantial triglyceride vacuoles that distend the cytosolic compartment, causing canalicular compression, severe cholestasis, and liver dysfunction.
- Untreated—leads to progressive metabolic dysregulation and death.
- Develops secondary to a primary disease or condition causing anorexia or catabolism.

PATHOPHYSIOLOGY

- Cats have a unique propensity to accumulate triglyceride filled hepatocellular vacuoles.
- Causal factors—energy and protein deficits; increased peripheral fat mobilization; increased hepatic triglyceride synthesis; impaired hepatic β -oxidation of fatty acids; reduced hepatocellular triglyceride exportation.
- Cytosolic triglyceride vacuoles displace organelles to cell periphery, associate with organelle dysfunction, and canalicular compression.
- Hepatic failure—with rare overt HE.

SYSTEMS AFFECTED

- Hepatobiliary—severe intrahepatic cholestasis, hepatic dysfunction or failure
- Gastrointestinal—anorexia; vomiting
- Musculoskeletal—peripheral tissue wasting
- Nervous—HE, ptalism, moribund condition
- Hemic/Lymphatic/Immune—abnormal RBC shapes (poikilocytes), Heinz body hemolysis
- Renal/Urologic—potassium wasting; renal tubule triglyceride accumulation

INCIDENCE/PREVALENCE

Most common severe feline hepatopathy in North America causing jaundice.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

Cat, rarely dog (toy breed puppies; also see Glycogen Storage Disease).

Breed Predilection

N/A

Mean Age and Range

Middle-aged adult cats: 8 (1–16 years)

Predominant Sex

N/A

SIGNS

Historical Findings

- Anorexia, hyporexia, weight loss, sarcopenia
- Jaundice
- Lethargy, weakness progressing to collapse
- Vomiting, diarrhea, or constipation

- Ptyalism: may reflect food aversion or HE
- Neck ventriflexion: weakness, electrolyte depletion: potassium, phosphate; thiamin deficiency
- Abnormalities due to underlying disease

Physical Examination Findings

- Jaundice
- Hepatomegaly
- Dehydration
- Weakness—neck ventriflexion, recumbency
- Ptyalism
- Collapse/Obtunded
- Others, depending on underlying or primary disease; HE (rarely overt)

CAUSES

"Idiopathic" Hepatic Lipidosis

“Idiopathic” = inappropriate terminology; antecedent health problems are discoverable in > 85% of cases causing anorexia or malassimilation; remainder have food deprivation.

Secondary Hepatic Lipidosis

- Primary liver disease—PSVA; CCHS; EHBDO; cholelithiasis; neoplasia
- Gastrointestinal—obstruction; neoplasia (lymphosarcoma); IBD; pancreatitis
- Urogenital disease—renal failure, CIN, lower urinary tract syndrome
- Neurologic conditions: cannot eat
- Infectious diseases—toxoplasmosis; FIP; FIV- or FeLV-related disorders
- Hyperthyroidism
- Vitamin B₁₂ deficiency (may predispose cats to HL)
- Many other systemic conditions or toxins
- Rapid weight loss protocol

RISK FACTORS

- Obesity
- Anorexia, negative nitrogen balance
- Catabolism or rapid weight loss
- Vitamin B₁₂ deficiency

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Primary liver disease—CCHS, cholelithiasis, EHBDO, or neoplasia (esp. lymphosarcoma) important considerations differentiated by abdominal ultrasonography, liver aspiration, and liver biopsy.
- PSVA—rarely confused; diagnosis by ultrasound or colorectal scintigraphy, and lab testing.
- Hepatic toxoplasmosis or FIP—liver biopsy, serology, immunohistochemistry.
- Pancreatitis—differentiated by ultrasonography, serum tests (low fPLI rules down likelihood of pancreatic inflammation, high values with local inflammation or pancreatitis; inconsistent amylase, lipase), pancreatic aspiration cytology, gross inspection, biopsy.

- Gastrointestinal disease—IBD differentiated by endoscopic or full-thickness bowel biopsies; obstruction differentiated by abdominal survey or contrast radiography and ultrasonography.

- Toxicities—suspected based on history (e.g., oral diazepam, acetaminophen, methimazole).
- Hyperthyroidism—serum thyroid panel.

CBC/BIOCHEMISTRY/URINALYSIS

- Hematology—poikilocytes common; non-regenerative anemia; hemolytic anemia: severe hypophosphatemia or Heinz bodies (low GSH); leukogram reflects underlying disorder.
- Biochemistry—hyperbilirubinemia; high ALP, ALT activity; normal or mild increase in GGT if no primary necro-inflammatory disorder of biliary or pancreatic tissue; low BUN; normal creatinine; variable glucose (hypoglycemia rare); variable cholesterol, albumin, globulins (high globulins with inflammatory disease); hypokalemia (associated with failure to survive, refeeding phenomenon); severe hypophosphatemia (< 2 mg/dL) complicates initial 72 h of feeding (refeeding syndrome).
- Urinalysis—lipiduria and unconcentrated urine common; ammonium biurate crystalluria not seen; renal potassium wasting (some cats).

OTHER LABORATORY TESTS

- Prolonged coagulation times—PT, APTT, ACT, esp. PIVKA in > 50% tested cats; fibrinogen usually normal; abnormalities correct with parenteral vitamin K₁ therapy.
- Hyperammonemia—uncommon.
- Serum bile acids—high before hyperbilirubinemic; redundant test if hepatobiliary jaundice.
- B₁₂ deficiency—may increase susceptibility to HL and appears to compromise recovery.

IMAGING

Survey Abdominal Radiography

- Hepatomegaly
- May note features of underlying disorder

Abdominal Ultrasonography

- Diffuse hyperechoic hepatic parenchyma reflects hepatic lipid vacuolation.
- Look for primary disease causing HL.

DIAGNOSTIC PROCEDURES

- Fine-needle liver aspiration cytology: > 80% hepatocytes with severe cytosolic vacuolation; biopsy rarely needed to confirm HL
- Definitive diagnosis HL—based on history, clinical features, high ALP, diffuse hyperechoic hepatic parenchyma, severe hepatocyte lipid vacuolation on aspiration cytology; cannot rule out underlying primary hepatic disorders (e.g., CCHS, EHBDO, PSVA) with these tests.
- Liver biopsy—definitive diagnosis of underlying “primary” liver disorders; *done only if poor response to therapy or high GGT*.

H

HEPATIC LIPIDOSIS

(CONTINUED)

Caution: stabilize cat before anesthesia and biopsy to reduce risk of death.

- Vitamin K₁ (0.5–1.5 mg/kg SC or IM) three doses at 12-h intervals, at least 12 h *before*: aspiration sampling, liver biopsy, jugular vein catheterization, or feeding appliance insertion to reduce risk of severe iatrogenic bleeding.

PATHOLOGIC FINDINGS

- Gross—diffuse hepatomegaly, smooth surface; friable greasy consistency, yellow/pale color with reticulated appearance; sample floats in formalin.
- Microscopic—diffuse, severe hepatocellular vacuolation; large (macrovesicular) or small (microvesicular) vacuolation.
- Oil Red O—on frozen tissue confirms lipid; but not typically necessary.

TREATMENT

APPROPRIATE HEALTH CARE

- Inpatient—necessary for recumbent cats or those with neck ventriflexion (indicates severe electrolyte disturbance: potassium or phosphate, or thiamin deficiency).
- Discharge for home care after stabilization and enteral feeding route established, and demonstrated to be problem free.
- Frequent reevaluations—imperative.
- Outpatient—reduces stress and thereby facilitates recovery in some cats.

NURSING CARE

- Balanced polyionic fluids—*avoid* lactate and dextrose supplementation. Acetate may not be metabolized quickly; 0.9% NaCl preferred.
- Potassium chloride supplementation is important, use sliding scale (see Hypokalemia).
- Phosphate supplements usually needed (see Hypophosphatemia) at initial feeding (refeeding syndrome).
- Magnesium supplements rarely needed; low Mg may rarely complicate potassium repletion.

Correct Hypophosphatemia

- Serum phosphate < 2.0 mg/dL reflects refeeding syndrome; may provoke: anorexia, vomiting, weakness, myonecrosis, ileus, hemo-lysis, and neurologic signs confused with HE.
- Treatment—potassium phosphate initial dose 0.01–0.03 mmol/kg/h IV (commercial parenteral phosphate = 3 mmol/mL phosphate = 93 mg/mL elemental phosphorus); monitor serum phosphate q6h; discontinue when stable phosphate > 2 mg/dL. **Caution:** reduce IV potassium chloride supplement to avoid iatrogenic hyperkalemia.

Correct Hepatic GSH Depletion

- Low liver GSH is confirmed in HL; routine GSH measurements are not available;

increased risk for oxidant injury from primary diseases, lipid accumulation; or hypophosphatemia-induced energy deficit (low ATP).

- Crisis intervention for low hepatic GSH or Heinz body anemia—NAC (140 mg/kg IV, then 70 mg/kg IV, 10% solution diluted 1:2 in saline; administer through 0.22–0.25 micron non-pyrogenic filter; administer over 20 minutes).
- When enteral feeding established, change to SAMe: 200 mg/cat PO q24h, use form with confirmed bioavailability/efficacy; need for dosing on empty stomach complicates use.

ACTIVITY

Activity may augment gastric motility when gastroparesis complicates feeding (chronic vomiting); early recovery phase cats too weak.

DIET

- Nutritional support—cornerstone of recovery.
- High-protein, high-calorie feline diet essential.
- Energy—50–60 kcal/kg ideal weight/day; gradual transition to full energy requirement over 3–5 days; feed multiple small meals/day.
- Forced alimentation usually required.
- Forced oral feeding may cause food aversion.
- Tube feeding—initially by nasogastric tube transitioned to esophageal tube after hydration and electrolyte status improves, and vitamin K₁.
- Avoid laparotomy for gastric feeding tube insertion; cats with HL have high mortality.
- Cautiously offer PO food daily to assess interest in food.
- Human stress formula enteral diets (not recommended)—require supplemental arginine (or citrulline), and taurine.

SUPPLEMENTS

- Supplements improve survival in severely affected cats.
- Medical grade L-carnitine (250–500 mg/day). Carnitine supplements have wide variability in bioavailability; Carnitor (liquid medical grade carnitine) recommended. Carnitine has been confirmed to increase and sustain fatty acid oxidation in overweight cats undergoing weight loss, as in HL (see Suggested Readings).
- Taurine (250–500 mg/day).
- Thiamin (50–100 mg/day).
- Vitamin B₁₂ (initially, 1 mg IM or SC once); determine chronic vitamin B₁₂ needs by sequential B₁₂ values (weekly intervals).
- Water-soluble vitamins in fluids (2 mL/L).
- Vitamin E (10 IU/kg/day) in food.
- Thiol donors (NAC, SAMe): as above.
- Potassium gluconate (for hypokalemia), reduces fluid potassium supplements.
- Marine oil in food (2000 mg q24h).

CLIENT EDUCATION

- Warn client—sequential biochemical assays needed to assess recovery.

- Educate client about feeding tube use/care and may be retained for 4–6 months.
- Advise client—recurrence unlikely; liver function will not be chronically compromised.

SURGICAL CONSIDERATIONS

- Avoid surgical interventions until hydration, electrolyte depletions, Vit. K₁ deficiency, Heinz body anemia alleviated.
- Exploratory laparotomy and liver biopsy (if indicated)—inspect for underlying disorders; biopsy pancreas, stomach, and small bowel.

MEDICATIONS

DRUG(S)

- Vitamin K₁—recommended for all cats with suspected HL; see dose above, avoid overdosage: oxidant hemolysis and liver injury.
- Drugs to ameliorate HE (see Hepatic Encephalopathy) usually not needed.
- Emesis control—metoclopramide: for vomiting, nausea, and gastroparesis (0.2–0.5 mg/kg SC q8h, 30 min before feeding, or as a CRI IV drip at 0.01–0.02 mg/kg/h or 1–2 mg/kg/day); dolasetron (0.5–0.6 mg/kg q24h IV, SC, PO); or maropitant (1 mg/kg IV, SC, PO q24h, 5 days max); famotidine: to avert damage to lower esophagus if vomiting (0.5–1.0 mg/kg q12–24h).
- Systemic antibiotics—as appropriate for concurrent infections.

CONTRAINdications/ PRECAUTIONS

- Adjust dosages of medications relying on hepatic metabolism or excretion.
- Avoid benzodiazepines and barbiturates—interact with neuroreceptors provoking HE.
- Appetite stimulants (e.g., diazepam, oxazepam, cyproheptadine, mirtazapine)—do not provide dependable energy intake; some produce sedation; diazepam rare fulminant hepatic failure.
- Avoid injectable medications with a propylene glycol carrier; may lead to hemolysis in cats with low GSH.
- Ursodeoxycholic acid—likely not beneficial; may be injurious in HL; may promote taurine deficiency due to conjugation.
- Dextrose supplements—may provoke hepatic triglyceride accumulation.
- Avoid tetracyclines or stanazolol—these promote triglyceride deposition leading to HL.
- Avoid propofol—(phenol derivative) may provoke hemolysis 12 h after infusion in cats with Heinz body anemia; some HL cats recover slowly; alternatively use gas anesthesia.

(CONTINUED)

HEPATIC LIPIDOSIS**FOLLOW-UP****PATIENT MONITORING**

- Body weight, condition, hydration, electrolytes; judicious adjustment of energy, fluid, and electrolyte provisions important.
- Serum bilirubin—declines within 2 weeks of adequate management; predicts recovery.
- Liver enzyme activity—slow to normalize; do not predict recovery.
- Discharge for home care—when vomiting is controlled, gastroparesis resolved, bilirubin declining, patient ambulatory, and tube-feeding apparatus is problem-free.
- Tube feeding—discontinued only after confirmed voluntary food consumption.

PREVENTION/AVOIDANCE

- Obesity—prevent; weight reduction must not exceed 2.0% bodyweight per week.
- Caution owner to verify food intake during weight loss regimens and during at-home stress.

POSSIBLE COMPLICATIONS

- Feeding tube malfunction or obstruction—tube obstructions relieved with: papaya juice, carbonated soft drink, or pancreatic enzyme slurry; 15-min dwell time, warm water flush.
- Rare HE after dietary support introduced.
- Hepatic failure can lead to death.
- Untreatable underlying causal disorder.

EXPECTED COURSE AND PROGNOSIS

- Optimal response to tube feeding and nutritional supplements—recovery in 3–6 weeks.

- Therapy as described—85% recovery of severely affected animals.
- Underlying disease influences outcome.
- HL rarely recurs.
- HL does not cause chronic liver dysfunction.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- Primary liver disorders
- Pancreatitis
- Malassimilation: various causes
- Diabetes mellitus
- Neoplasia—hepatic and systemic
- Hepatic encephalopathy (rare)
- Systemic illness limiting nutrition intake

SYNOMYMS

H

HEPATIC NODULAR HYPERPLASIA AND DYSPLASTIC HYPERPLASIA

BASICS

OVERVIEW

Hepatic Nodular Hyperplasia (HNH)

- Benign parenchymal feature in middle-aged to older dogs; non-encapsulated, ≤ 2 cm (rarely up to 5 cm), expansile nodule of hepatocellular hyperplasia, maintaining a modified lobular architecture with recognizable central and portal elements that are irregularly spaced, organized hepatic cord structure 1 cell wide, without marginal parenchymal collapse or fibrosis (is not a regenerative nodule), smooth margins; hepatocyte phenotype may be similar to surrounding parenchyma but may contain glycogen or lipid vacuoles.
- May associate with increased liver enzymes in elderly dogs, especially ALP.
- Clinical concern derives from association with increased liver enzyme activity and US detection of hepatic nodules or hepatic nodularity during exploratory surgery.
- Variable US appearance.
- Biopsy specimens must include affected and unaffected liver for appropriate interpretation.
- Nodular hyperplasia may be mistaken for regeneration secondary to chronic hepatitis or hepatocellular neoplasia (adenoma) with needle core biopsies or when only nodular tissue without normal hepatic tissue is sampled.

Hepatocellular Dysplastic Hyperplasia (HDH)

- Potentially pre-neoplastic proliferative hepatocellular foci in dogs with glycogen-type VH; non-encapsulated, variably sized, reduced reticulin substructure, expansile nodules of non-vacuolated hepatocytes forming wide (2 cells wide, normal = 1 cell width) disorganized hepatic cords, an irregular (serrated) margin interfacing with adjacent "normal VH" affected hepatocytes, and lacking remodeled marginal lesions (fibrosis, parenchymal collapse).
- Associates with VH-related increased liver enzymes, dominated by increased ALP activity.
- Recognized as an antecedent hepatic lesion in dogs developing hepatocellular carcinoma (e.g., Scottish terriers, also other breeds) and is seemingly associated with increased sex hormone concentrations (androgens, progestins).
- Variable US appearance depending on size, number, distribution.
- May be mistaken for nodular regeneration without special stains to detail reticulin substructure and collagen fibril deposition.

SIGNALMENT

HNH

- Age-related lesion.

• Nodules develop by 6–8 years of age; one study documented lesions in all geriatric dogs > 14 years of age.

HDH

- Associated with glycogen-type VH
- Reflect adrenal hyperplasia syndromes

SIGNS

Physical Examination Findings

- HNH does not cause clinical illness.
- Large nodules that rupture and bleed or nodules impairing hepatic sinusoidal perfusion likely represent misdiagnosed hepatic adenomas or well-differentiated hepatocellular carcinoma.
- HDH is associated with glycogen-type VH syndromes (see Glycogen-Type Vacuolar Hepatopathy).

CAUSES & RISK FACTORS

- HNH etiology—unknown; metabolic factors, prior injurious events. In humans associated with infarcts but no evidence of this in dogs.
- HDH etiology—may represent hormonal influence promoting neoplastic transformation (sex hormone-related adrenal hyperplasia).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Necroinflammatory liver disease—regenerative nodular hyperplasia involves the entire liver; formation of irregular nodules of variable size that are segregated by parenchymal collapse, often marginated by fibrous connective tissue; demonstrate loss of lobular architecture, sinusoidal fibrosis, reduced reticulin substructure, and wide disorganized hepatic cords.
- Neoplasia. Hepatic adenoma—mass lesions with margins reflecting expansile compression on normal adjacent liver, encapsulated, hepatic cords double wide, disorganized, reduced reticulin substructure, and minimal atypia. Hepatocellular carcinoma—single or multiple confluent or separate mass lesions, margins reflecting irregular expansile compression on normal adjacent liver, partially encapsulated, variable width of disorganized hepatic cords > 2 cells, multiple phenotypes differing from adjacent normal tissue, variable atypia (may be well differentiated), may display pseudoglandular pattern associated with giant canaliculi, well-vascularized with arterial twigs; retention of some normal lobular elements possible (primarily at the periphery).

CBC/BIOCHEMISTRY/URINALYSIS

- CBC—no association with HNH; for HDH see Glycogen-Type Vacuolar Hepatopathy.
- Biochemistry profile—increased serum ALP activity may be encountered with HNH and

HDH; may range 2.5 to 16-fold normal; higher with HDH and VH syndrome, see Glycogen-Type Vacuolar Hepatopathy); usually normal total protein, albumin, bilirubin, and cholesterol.

- Urinalysis—no consistent findings.

OTHER LABORATORY TESTS

TSBA—usually normal, unless lesions are diffuse and severe.

IMAGING

- Abdominal radiography—no abnormalities except hepatomegaly with HDH due to VH.
- Abdominal US—variable echogenicity relating to histologic features, nodule number and size, and associated VH. HNH often not noted until liver grossly inspected at surgery or laparoscopy.

DIAGNOSTIC PROCEDURES

- Aspiration cytology—may yield normal hepatocytes, hepatocytes with cytosolic rarefaction and fragility consistent with VH (glycogen retention), or cells with discrete lipid (triglyceride) vacuoles (HNH); occasional binucleate hepatocytes may reflect cell proliferation or other concurrent disease (common in PSVA/MVD); hepatocytes may be small with size variation in HDH. Liver biopsy—collection of a needle biopsy specimen may not clearly differentiate HNH lesion because of small specimen size; definitive diagnosis requires targeted sampling of a large-enough tissue specimen to include lesion and adjacent normal hepatic tissue. HDH may be recognized on needle samples.
- Recommended biopsy methods—laparoscopy, open wedge biopsy during laparotomy, or multiple 14-g needle samples.
- Special stains—reticulin staining illustrates hepatocyte reticulin substructure, lobular collapse/remodeling, and changes associated with nodule margins. Masson's trichrome staining illustrates collagen deposition and remodeling typical of regenerative nodules secondary to chronic liver injury; PAS staining with and without amylase pre-digestion confirms excess glycogen in vacuolated hepatocytes (See Glycogen-Type Vacuolar Hepatopathy).

PATHOLOGIC FINDINGS

- HNH gross—single or multiple mass lesions, rarely > 2 cm in diameter; color similar to adjacent normal hepatic tissue or paler if vacuolated with glycogen or lipid.
 - HDH gross—single or multiple lesions, usually small, may appear darker colored compared to adjacent tissue.
- Microscopic—see previously.

TREATMENT

- Usually none required; rupture of large nodules indicates hepatocellular carcinoma misdiagnosis; may necessitate blood

HEPATIC NODULAR HYPERPLASIA AND DYSPLASTIC HYPERPLASIA

transfusion and emergency mass excision. Palliate or alleviate underlying cause of VH. • HDH: recommend biochemical assessments for rising ALP or ALT that may indicate transformation of mass lesion to a neoplastic phenotype; US inspection of adrenal glands for adrenomegaly or nodules, US surveillance for expanding mass lesions that should be surgically removed; assess pituitary adrenal axis for typical or atypical hyperadrenocorticism; if increased sex hormones $> 2.5 \times$ upper reference interval consider adrenal modulation with agent that does not increase sex hormones.

MEDICATIONS

DRUG(S)

- HDH: if increased sex hormones, progressive VH, nodule formation, increasing ALP, or confirmed hepatocellular carcinoma (after mass resection) consider adrenal modulation with a drug that does not increase sex hormone concentrations (Lysodren or Mitotane); Trilostane increases sex hormone concentrations and would be inappropriate.
- Scottish terrier syndrome does not respond to adrenal modulation; instead use surveillance to detect emerging hepatocellular carcinoma.

FOLLOW-UP

PATIENT MONITORING

- Quarterly biochemical profiles
- Sequential abdominal US to evaluate progression of hepatic nodules
- See Glycogen-Type Vacuolar Hepatopathy for related disorders

POSSIBLE COMPLICATIONS

Distinction of HNH from neoplastic foci is not possible based only on clinical, laboratory, or imaging data although lesions > 2 cm are unlikely to be this diagnosis.

EXPECTED COURSE AND PROGNOSIS

More extensive numbers of nodules may develop in some dogs with HNH and HDH; HDH predicts risk for primary hepatocellular neoplasia which requires surveillance and surgical treatment.

Consulting Editor Sharon A. Center

HEPATITIS, CHRONIC

BASICS

DEFINITION

- Hepatic injury associated with active necroinflammatory liver injury.
- Nonsuppurative inflammation—most common; lymphocytes, plasma cells, macrophages, occasional neutrophils.
- Chronicity—progressive remodeling, regenerative nodule formation, fibrosis, eventuating in cirrhosis (see Fibrosis and Cirrhosis of the Liver).

PATHOPHYSIOLOGY

- Multitude of initiating events cause hepatic injury that alter hepatic architecture, damage membranes and/or organelles, and activate cytokine and cell-mediated immune responses; hepatic components become targeted foci. • Initial injury may include infectious agents, toxins, or therapeutic agents but cause often remains undetermined.
- Inflammatory cells, including predominantly lymphocytes (T-cells, NK T-cells), Kupffer cells (hepatic macrophages resident in the lumen of sinusoids), and neutrophils are initial effector cells; INF-g, TNF-a, FasL, IL-4, and numerous chemokines and oxidative free radicals are commonly involved.
 - Oxidant injury an important pathomechanism of membrane and organelle injury.
 - Initial zone of injury demarcates area of necroinflammatory response—zone 1 (periportal) common in many forms of idiopathic hepatitis whereas zone 3 incriminates Cu associated injury, NSAID and other toxins, or repeated ischemic/hypoxic insult.
 - Lesions progression is variable and may include portal and periportal lymphoplasmacytic infiltrates, interface hepatitis with piecemeal necrosis of the limiting plate and variable lobular necroinflammatory activity. Chronic inflammation—progressive fibrosis with bridging between involved zones.
 - Bridging fibrosis and regenerative nodules distort lobular architecture leading to cirrhosis.
 - Progressive development of cholestasis.
 - Cirrhosis and hepatic failure—late stage.
 - Cirrhosis—consequence of chronic fibrogenesis and hepatic regenerative response; typified by: regenerative nodules; reduced functional hepatic mass; collagen deposition along sinusoids and/or around portal triads that compromises sinusoidal perfusion.
 - Fibrosis—usually reflects chronic injury; associated with release of cytokines/mediators that stimulate ECM production or accumulation.
 - Cirrhosis/fibrosis—leads to hepatic dysfunction, sinusoidal hypertension; intrahepatic shunting in collagenized sinusoids or through recanalized vascular pathways within fibrotic partitions between regenerative nodules.
 - Sinusoidal hypertension—leads to (1) hepatofugal portal

venous flow (away from the liver), (2) mesenteric splanchnic hypertension, (3) formation of APSS, (4), episodic HE, (5) splanchnic pooling of blood, decreased effective blood volume, renal sodium and water retention that culminate in ascites formation, (6) portal hypertensive enteric vasculopathy predisposing to enteric bleeding.

SYSTEMS AFFECTED

- Hepatobiliary—inflammation; necrosis; cholestasis; fibrosis.
- GI—emesis; diarrhea; anorexia, portal hypertension leads to ascites formation and propensity for enteric bleeding (portal hypertensive gastroenteric vasculopathy).
- Neurologic—HE.
- Hemic—RBC microcytosis reflecting APSS; bleeding tendencies: failed factor synthesis or activation or thrombocytopenia; coagulopathy (advanced stage).
- Renal/Urologic—PU/PD; isosthenuria; ammonium biurate crystalluria (advanced stage).
- Endocrine/Metabolic—hypoglycemia if end-stage liver failure (provoked by prolonged inappetence).
- Respiratory—tachypnea if tense ascites; bicavity effusion (leakage across diaphragm (rare), pulmonary edema (rare)).
- Nervous—HE (advanced stage).

GENETICS

- Breed or familial predisposition for chronic hepatitis—Doberman pinscher, Labrador retriever, West Highland white terrier, and Dalmatians may develop chronic hepatitis related to low tolerance to Cu levels in commercial diets; Cocker spaniel, standard poodle, Maltese, Skye terrier, others.
- Inherited copper associated hepatopathy only proven in the Bedlington terrier—autosomal recessive, genetic test available.

INCIDENCE/PREVALENCE

N/A

SIGNALMENT

Species

Dog

Breed Predilection

See under genetics

Mean Age and Range

Average age 6–8 years (range 2–14 years)

Predominant Gender

Inconsistent among reports for any breed

SIGNS

General Comments

- Initially—vague and nonspecific.
- Later—relate to complications of portal hypertension (e.g., HE, ascites, gastroduodenal bleeding), and impaired hepatic function.

Historical Findings

- May be no signs in early disease.
- Lethargy.
- Anorexia, weight loss, vomiting, reduced body condition.
- Polyuria and polydipsia.
- Jaundice (late stage).
- Ascites (late stage, signifies onset of portal hypertension and development of APSS, fibrosis, cirrhosis)

- Hepatic encephalopathy (late stage, cirrhosis)

Physical Examination Findings

- May be no signs in early disease.
- Lethargy, poor coat, declining body condition.
- Variable jaundice.
- Liver size—normal to small, depends on chronicity.

Late Stage Physical Findings

- Ascites.
- Hepatic encephalopathy.
- Obstructive uropathy: ammonium biurates.
- Bleeding tendencies—variable, uncommon.

CAUSES

- Chronic necroinflammatory, oxidant, or immune-mediated liver injury has many causes.
- Infectious—canine hepatitis virus; leptospirosis, enteric portal bacteremia or endotoxemia affiliated with IBD; accidental parenteral administration of intranasal *Bordetella* vaccine.
- Immune-mediated—autoimmune with positive ANA; acquired immune sensitization, nonsuppurative inflammation.
- Toxic—copper associated hepatopathy; acute or chronic exposure to drugs—predictable or idiosyncratic toxicity: e.g., azole antifungals, trimethoprim-sulfa, zonisamide, phenobarbital, primidone, phenytoin, CCNU, NSAIDs (esp. carprofen); repeat exposure to environmental or food-borne toxins, e.g., dimethylnitrosamine, aflatoxin, cycad, cyanobacteria.

RISK FACTORS

- Immunostimulants (vaccinations?) and molecular mimicry of cell epitopes by infectious agents or infection of sinusoidal endothelium may promote inflammatory reactions associated with chronic hepatitis.
- Cu associated hepatopathy—neopeptope formation from oxidant injury.
- Hepatic iron accumulation: supplementation.
- Drugs—inducers or inhibitors of microsomal enzymes or conditions diminishing hepatic antioxidant status may augment liver damage from certain toxins.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Acute hepatitis—history; liver biopsy.
- Congenital portosystemic shunt (PSVA)—abdominal ultrasonography; radiographic or multisector CT contrast venography (latter preferred); colorectal scintigraphy; liver biopsy.
- Primary hepatic neoplasia—radiography or ultrasonography; cytology; biopsy.
- Metastatic neoplasia or carcinomatosis.
- Chronic pancreatitis.
- Causes of abdominal effusion—hypoalbuminemia; right heart failure; carcinomatosis (see Hypertension, Portal); bile peritonitis.
- Other causes of portal hypertension—see Hypertension, Portal.
- Jaundice—EHBO; bile peritonitis, hemolysis.

(CONTINUED)

CBC/BIOCHEMISTRY/URINALYSIS**Hemogram**

CBC—nonregenerative anemia; RBC microcytosis if APSS; variable leukogram, thrombocytopenia; low total protein if chronic disease

Biochemistry

High liver enzymes; variable total bilirubin, albumin, BUN, glucose, and cholesterol; hepatic failure suggested by low albumin, BUN, glucose, and cholesterol, in the absence of other explanations

Urinalysis

Variable urine concentration; bilirubinuria; ammonium biurate crystalluria if APSS

OTHER LABORATORY TESTS

- TSBA—variable depending on extent of hepatic remodeling, sinusoidal hypertension, and cholestasis.
- Ammonia intolerance—reflects APSS; insensitive to cholestatic changes.
- Coagulation tests—reflect panlobular injury and/or chronicity; early disease has no abnormalities but perhaps high fibrinogen; advanced stage or severe panlobular injury may note prolonged PT, APTT, and PIVKA, low fibrinogen, increased FDP or D-dimers (**note:** some D-dimer tests are too sensitive for differential diagnostic utility); coagulation tests reflect severity of liver dysfunction, synthetic failure, DIC, and vitamin K adequacy (see Coagulopathy of Liver Disease); low protein C activity suggests APSS or hepatic failure.
- Abdominal effusion—chronic liver disease or portal hypertension: pure or modified transudate.
- Liver zinc values—low with chronic disease and especially if APSS.
- Serologic tests—for possible infectious agents, e.g., leptospirosis, rickettsial diseases, *Borrelia*, *Bartonella*, endemic fungal agents.
- ANA titer—for potential autoimmune-mediated disease; **note:** low level positive titers are nonspecific.
- Immunohistochemical staining of liver sample—confirm infectious agent or origin of infiltrative cells.

IMAGING**Abdominal Radiography**

- Microhepatia—suggests late-stage disease
- Abdominal effusion—obscures image
- Ammonium biurate calculi—radiolucent unless combined with radiodense minerals

Ultrasonography

- Liver size depends on disease stage; microhepatia in late stage.
- Normal to variable parenchymal and biliary tract echogenicity; may note nodularity and irregular liver margins.
- APSS—tortuous vessels caudal to left kidney or near splenic vein with Doppler color flow interrogation.
- Abdominal effusion—visualize small pockets; US facilitates sampling.
- Uroliths (tiny to large)—renal pelvis or urinary bladder; may signify ammonium biurate urolithiasis.
- Rule out—EHBD (jaundice,

high enzymes); identify mass lesions, cholelithiasis; GB mucocele; cholecystitis, choledochitis; cystic lesions (abscess). Enables fine needle aspiration—cytology and cholecystocentesis for bile collection.

Colorectal/Splenoportal Scintigraphy

- 99M-Technetium pertechnetate isotope time activity curve displays first isotope distribution: delivery to liver = no shunting, delivery to heart = shunting.
- CRS—sensitive and noninvasive, detects portosystemic shunting but cannot differentiate PSVA from APSS.
- SPS—offers no diagnostic advantage, is invasive and requires US-guided splenic injection.

DIAGNOSTIC PROCEDURES**Aspiration Cytology**

Fine-needle aspiration cytology—*cannot define* fibrosis or nonsuppurative inflammation; *cannot* recommend therapy. May identify hepatic vacuolation and canalicular cholestasis: common changes observed in canine liver disorders; neoplasia; infectious agents. Cannot definitively diagnose chronic hepatitis, hepatic fibrosis, or copper associated hepatopathy with cytology.

Liver Biopsy

- Liver biopsy—needed for definitive diagnosis; acquire biopsies from multiple lobes.
- Tru-Cut needle biopsy—18G needle core too small for accuracy; use 14–16 G.
- Laparoscopy—best biopsy method; permits gross visualization, documents APSS, biopsy access to multiple liver lobes and focal lesions.

Bacterial culture

Aerobic and anaerobic and sensitivity of liver and bile; use bile containing particulate debris for best sample—bacteria are found tangled with biliary precipitates.

Metal analyses

Determine copper, iron, and zinc concentrations (dry matter basis). Low zinc commonly associated with portosystemic shunting; high iron common in necroinflammatory disorders, contributes to oxidative injury; copper analysis results may reflect sampling of regenerative nodules or fibrotic regions or regions of parenchymal extinction, leading to low measurements compared to intact parenchyma. Digital scanning of biopsy slide stained with rhodanine can accurately quantify liver copper concentration.

PATHOLOGIC FINDINGS

- Gross—early: no gross change; late stage: microhepatia with irregular surface or margins (fine or coarse nodules), tortuous APSS.
- Microscopic—nonsuppurative inflammation involving zone of necroinflammatory injury; variable cholestasis and biliary hyperplasia; piecemeal and/or bridging necrosis; interface hepatitis; disruption of limiting plate in zone 1 lesions; in late-stage disease: bridging between or

HEPATITIS, CHRONIC

within zones; regenerative nodules, and transition to cirrhosis.

Histopathology

- Immune-mediated hepatitis—periportal, lobular, or centrilobular lymphoplasmacytic infiltrates, hepatic cord disorganization, sinusoidal fibrosis (space of Disse), biliary hyperplasia (ductular reaction).
- Cu hepatopathy: initially centrilobular, may evolve to immune-mediated hepatitis.
- Cirrhosis—diffuse lesion; fibrosis associated with nodular regeneration and hepatic lobule distortion; periportal/sinusoidal fibrosis.

**TREATMENT****APPROPRIATE HEALTH CARE**

- Inpatient—for diagnostic testing and therapy in overtly ill dogs.
- Outpatient—if condition is stable at diagnosis; slowly titrated onto medical therapy.

NURSING CARE

- Depends on underlying condition.
- Fluid therapy—balanced polyionic fluids supplemented to correct electrolyte aberrations or hypoglycemia; restrict sodium if ascites.
- Water-soluble vitamins (2 mL/L fluids).
- Ascites: managed with sodium-restricted diet, enforced rest, diuretics (furosemide combined with spironolactone); see Cirrhosis and Fibrosis of the Liver.
- Therapeutic abdominocentesis—aseptic procedure for removing large-volume symptomatic ascites compromising food intake, ventilation, or sleep; if diuretics and sodium restriction ineffectual.
- For diuretic-resistant ascites: calculate sodium intake against measured renal sodium excretion (collect urine over 12 hours, measure sodium and creatinine in well-mixed sample, and in sera); guides adjustments in management (i.e., increase sodium restriction vs. increase diuretic).

ACTIVITY

Keep patient warm, inactive, and hydrated; inactivity may promote hepatic regeneration, euglycemia, and ascites mobilization.

DIET

- Adequate calories and protein—avoid catabolism to maintain muscle mass (attenuates hyperammonemia); monitor body condition.
- Dietary protein—restrict quantity ONLY if signs of HE (see Hepatic Encephalopathy) or observed ammonium biurate crystalluria; feed balanced diet; if HE, avoid fish and red meat source protein (dogs).
- Meal frequency—feed several small meals per day to optimize nutrient assimilation.
- Sodium restriction—with ascites or severe hypoalbuminemia: < 100 mg/100 kcal or < 0.2% dry matter basis formula.
- Good-quality vitamin supplement—vitamin metabolism perturbed with liver

H

HEPATITIS, CHRONIC

(CONTINUED)

disease and losses in urine; avoid copper supplements if copper associated hepatopathy.

- Thiamin—ensure repletion to avoid Wernicke's encephalopathy; 50–100 mg PO q24h; caution: anaphylactoid reactions may occur with injectable thiamin.
- Partial parenteral nutrition—may consider, if short-term inappetence to minimize catabolism.
- Total parenteral nutrition—if inappetence lasts > 7 days; branched-chain amino acids remain controversial in dogs with liver dysfunction.
- Fat restriction rarely needed.

CLIENT EDUCATION

- Control rather than cure is the expected goal; medications usually will be required for life; disease is cyclic; quarterly evaluations important.
- Inform client of the lack of long-term veterinary studies proving efficacy of single or polypharmacy approaches; recommendations derived from clinical experience, studies in humans, and animal disease models.
- Antifibrotics may reduce fibrosis but limited evidence; fibrosis diminished by control of inflammation and underlying primary process.
- Attenuate factors provoking HE—dehydration; azotemia, infection; catabolism; hypokalemia; alkalemia; high protein meals; endoparasitism; enteric bleeding; certain drugs.

SURGICAL CONSIDERATIONS

- APSS—do not ligate nor band the vena cava.
- Cirrhosis—high anesthetic risk; gas anesthesia preferred—isoflurane or sevoflurane.

MEDICATIONS

DRUG(S) OF CHOICE

- Treatments for specific etiologies: chelate Cu if copper associated hepatopathy); withdraw potentially hepatotoxic drugs.
- No clinical trials prove efficacy of specific regimens to date.

Copper Chelation

See Copper Associated Hepatopathy

Immunomodulation

- *Prednisolone/prednisone*—2–4 mg/kg daily PO; taper to lowest effective dose (e.g., 0.25–0.5 mg/kg PO q48h); for data on survival effect see reference. If ascites: use dexamethasone to avoid mineralocorticoid effect (to account for increased potency, divide prednisone dose by 8–10 for dexamethasone dose), SID q2–4 days; for data on canine survival influence see reference.
- *Azathioprine*—in dogs: 1–2 mg/kg PO q24h; use loading SID dose for 3–5 days then titrate to q48h; contraindicated in cats (toxic); in dogs: combined with prednisone, antioxidants, antifibrotics (PPC), and possibly cyclosporine. During chronic therapy, titrate dose by 25–50% reduction after 2–6 months

based on sequential biochemistries showing improvements (e.g., declining total bilirubin and liver enzyme activity); monitor CBC and biochemistry profile q7–10 days for first month to ensure absence of hematopoietic, hepatic, and pancreatic toxicity; if acute hematopoietic toxicity, stop therapy, allow recovery, then reintroduce at 25% dose reduction; if insidious chronic hematopoietic toxicity (after months) or acute cholestatic liver or pancreatic injury, discontinue therapy.

- *Mycophenolate mofetil*—similar mechanism of effect as azathioprine; dose: 10–15 mg/kg PO q12h; eliminated by hepatic glucuronidation and renal excretion; monitor as for azathioprine and titrate dose similarly. May have fewer side effects than azathioprine.
- *Microemulsified cyclosporine*—5 mg/kg PO q24h; limited long-term experience; variable response.

Ursodeoxycholic Acid

Immunomodulatory, hepatoprotectant, antifibrotic, choleretic, anti-endotoxic, antioxidant; dose 7.5 mg/kg PO q12h; administered with food for best assimilation; tablets have best bioavailability; may prepare aqueous solution; safe; maintain indefinitely.

Antifibrotics

- Immunomodulators, SAMe, silibinin, vitamin E: also are considered antifibrotics as these interrupt signaling processes promoting activation of sinusoidal myofibrocytes and collagen production.
- *Polyunsaturated phosphatidylcholine* (PPC)—antifibrotic, immunomodulatory, antioxidant, hepatoprotectant effects; dose: 25 mg/kg/day PO with food. Use PhosChol® form (preformed active ingredient: dilinolylphosphatidylcholine); beneficial in some forms of liver disease (humans, animal models); may provide a corticosteroid-sparing effect allowing reduced glucocorticoid dosing; safely prescribed without liver biopsy.
- *Colchicine*—imparts anti-inflammatory, antifibrotic, and immunomodulatory effects; 0.25–0.03 mg/kg PO q24–48h; controversial evidence for benefit reducing fibrosis in human liver disorders; mechanism of action is via polymerization of microtubules curtailing collagen formation; metaphase arrest may provoke GI and bone marrow toxicity; neurologic adverse effects described in humans; avoid form complexed with probenecid (prolongs drug retention time); used when fibroplasia is the overriding histologic feature but not in ductal plate malformations.
- *Silibinin with PPC*—hepatoprotectant (studied against numerous toxins), antifibrotic, and antioxidant effects, may also promote hepatocellular regeneration; no meta-analysis in humans confirms beneficial influence in chronic hepatitis that does not have a viral cause. Even that category remains controversial. 2–5 mg/kg/day PO (PPC complexed form only). May alter

glucuronidation of some drugs, unclear if causes drug interactions.

Antioxidants

- *Vitamin E*— α -tocopherol, 10 IU/kg PO q24h.
- *S-Adenosylmethionine (SAMe)*—use bioavailable proven GSH donor) 20 mg/kg/day enteric-coated tablet PO given on empty stomach for best absorption.
- *Avoid vitamin C (ascorbate)*—if high tissue copper or iron concentration, augments oxidant injury associated with transition metals.
- *Zinc (zinc acetate)*—antioxidant; antifibrotic, blocks enteric copper uptake, required for urea cycle enzymes. Elemental zinc 1.5–3 mg/kg PO daily supplement if low liver zinc concentration (< 120 μ g/g dry weight liver; adjust dose using sequential plasma zinc concentrations (avoid plasma \geq 800 μ g/dL).

Hepatoprotectants

- Ursodeoxycholate, vitamin E, SAMe provide hepatoprotectant effects in addition to other benefits.
- *Silibinin*—efficacy unclear, use PPC complexed form (bioavailable), 2–5 mg/kg PO q24h.

Bleeding Tendencies

See Coagulopathy of Liver Disease

Gastrointestinal Signs/Hemorrhage

- *Histamine type-2 receptor antagonists*—famotidine 0.5–2 mg/kg PO, IV, SC q12–24h.
- *HCl pump inhibitors*—omeprazole 1.0 mg/kg q24h PO or pantoprazole 1 mg/kg q24h IV. Omeprazole may induce P450 cytochrome-associated drug interactions and may have a 24–48 h delayed onset of action.
- Some clinicians recommend chronic treatment with HCl pump inhibitors to minimize gastrointestinal bleeding and ulceration that may become a chronic problem.
- *Sucralfate*—gastroprotectants 0.25–1.0 g/10 kg PO q8–12h; titrate to effect, beware of drug interactions as sucralfate may bind other medications, reducing bioavailability.
- Eliminate endoparasitism.

Specific Conditions

Ascites

- Restrict activity and sodium intake; combine with diuretic therapy.
- *Dietary sodium restriction*—(0.2% dry matter basis or < 100 mg/100 kcal).
- *Diuretics*—slowly mobilize effusion with combination of: furosemide (0.5–2 mg/kg IV, SC, PO q12h) and spironolactone (0.5–2 mg/kg PO q12h; loading spironolactone is important, use doubled dose once); recheck and adjust dose at 4- to 7-day intervals by 25–50%. Titrate dose to response, may use q48h or intermittently to mobilize recurrent ascites.

(CONTINUED)

- *Therapeutic large volume abdominocentesis*—if ascites is nonresponsive to mobilization in 7–14 days with concurrent diuretics and sodium restriction; may require fluid support as a result of intravascular to abdominal fluid shift causing postcentesis hypotension syndrome and acute renal failure.
- *Consider vasopressin V₂ antagonists* (aquaretics) with low-dose diuretics for treatment of resistant ascites; tolvaptan has been used experimentally in dogs at 10 mg/kg without adverse effects to mobilize water.

HE

See Hepatic Encephalopathy

CONTRAINDICATIONS

- NSAIDs—avoid; potentiate enteric bleeding; may worsen ascites; potentially centrilobular hepatic necrosis-hepatotoxic metabolites.
- Avoid drugs requiring hepatic metabolism whenever possible.

PRECAUTIONS

- Diuretics—dehydration, hypokalemia, alklosis worsen HE.
- Glucocorticoids—increased susceptibility to infection, enteric bleeding, sodium and water retention, protein catabolism and HE.
- Avoid drugs or reduce dose if first-pass hepatic extraction, if require hepatic conjugation or biotransformation e.g. metronidazole—reduce conventional dose to 7.5 mg/kg PO q12h (often used for HE).
- Zinc overdose may cause hemolysis.

ALTERNATIVE DRUG(S)

- Dexamethasone—if ascites, replace prednisone or prednisolone with this drug to remove mineralocorticoid effect); divide pred. dose by 7–10, administer q3–4 days; taper dose to observed efficacy.
- Mycophenolate: alternative for azathioprine.

**FOLLOW-UP****PATIENT MONITORING**

- At-home behavior, body condition, muscle mass, weight—adjust protein and energy intake to nitrogen tolerance and apparent energy needs.
- CBC, biochemistry, and

urinalysis—monthly or quarterly, depends on patient status; look for signs of drug toxicity, disease remission, synthetic function, ammonium biurate urolithiasis, and urinary tract infections.

- Serial monitoring of TSBA—usually does not add prognostic or diagnostic information.
- Abdominal girth: reflects ascites volume.
- Azathioprine, mycophenolate, colchicine—monitor for possible bone marrow toxicity (serial CBCs), GI toxicity, and other effects.

POSSIBLE INTERACTIONS

- Avoid medications that alter hepatic biotransformation or excretion pathways (e.g., cimetidine, quinidine, ketoconazole).
- Avoid concurrent treatment with metoclopramide if spironolactone used for diuresis (causes aldosterone release).

POSSIBLE COMPLICATIONS

HE, septicemia, bleeding—may be life-threatening; DIC—may be a terminal event.

EXPECTED COURSE AND PROGNOSIS

- Chronic hepatitis can be a cyclic disease with occasional flare-ups indicated by sequential assessment of liver enzymes.
- Some dogs achieve solid long-term remission.
- Some dogs with Cu associated hepatopathy can achieve permanent remission of apparent “immune-mediated” inflammation upon effective Cu chelation and appropriate nutritional management.
- Presence of ascites indicates severe disease with shorter survival.
- Severe disease complicated by development of APSS have HE and ascites may require occasional hospitalizations for adjustment of nutritional and medical interventions.
- Sodium restriction and diuretics may require titration to achieve optimal control of ascites.

**MISCELLANEOUS****ZOONOTIC POTENTIAL**

- Dogs with leptospirosis-associated chronic liver disease (rare) may shed organisms.

HEPATITIS, CHRONIC

- *Bartonella*; rickettsial agents (endemic vectors).

H

HEPATITIS, GRANULOMATOUS

BASICS

DEFINITION

- Uncommon necroinflammatory hepatitis.
- Characterized by histiocytes/macrophages, lymphocytes, plasma cells, and variable neutrophilic infiltrates forming granulomas that efface normal hepatic structure.
- May reflect infectious agents, immune-mediated or immunoregulatory disorder, or a proliferative/neoplastic histiocytic syndrome.
- May localize to the liver or involve multisystemic disease (spleen, lymph nodes, bone marrow).
- Copper associated hepatopathy— involves unique “copper granulomas” distinct from this syndrome; having histologically stainable copper-protein aggregates.

H

PATHOPHYSIOLOGY

- May initiate by infection with: bacteria (eubacterial, mycobacterial, chlamydial), viral, parasitic, protozoal, or fungal agents.
- May reflect immune-mediated or immunoregulatory disorders, or an adverse drug or xenobiotic interaction (herbal, holistic supplements).
- May reflect proliferative histiocytic syndromes or histiocytic neoplasia.
- Hepatocyte necrosis—reflects insufficient perfusion and hypoxia (sinusoidal invasion or collapse), cytokines or cytotoxic cell injury (histiocytes, lymphocytes), hepatotoxins including: xenobiotics (drugs, toxins, bacterial products, herbal or holistic remedies).
- Severity of hepatic dysfunction—reflects lobular distribution and density of infiltrates.
- Toxins—affect zone where they are metabolized (adducts formed), where there is specific organelle tropism or oxidative injury.
- Zone 3 copper accumulation—can augment zone 3 (centrilobular region) injury.
- Liver injury is accompanied by enzyme leakage reflecting regional involvement; hyperbilirubinemia occurs with diffuse injury, canalicular damage, or biliary tree involvement; sinusoidal injury can cause sinusoidal hypertension leading to splanchnic hypertension, ascites, and development of acquired portosystemic shunts (APSS).
- Severe diffuse lobular involvement can lead to liver failure, coagulopathy, enteric hemorrhage from acute portal hypertension, and acute-onset hepatic encephalopathy (HE).
- Hepatic failure—associated with a myriad of metabolic derangements, i.e., altered glucose homeostasis, protein synthesis (albumin, transport proteins, procoagulants, and anticoagulants), and detoxification capabilities; often lethal.

SIGNALMENT

- No breed, sex, or age predilection

- More common in dog than in cat

SIGNS

Historical Findings

- Nonspecific clinical signs, lethargy
- Anorexia, vomiting, diarrhea, weight loss
- Polyuria or polydipsia

Physical Examination Findings

- Normal liver size to severe hepatomegaly
- Abdominal pain: vague, due to hepatic capsule distention
- Distended abdomen—ascites; hepatomegaly
- ± Splenomegaly—granulomatous process
- ± Lymphadenopathy
- ± Jaundice
- ± Fever
- ± Tachypnea: abdominal distention, pulmonary disease involvement
- Late stage: bleeding tendencies, ascites, HE

CAUSES & RISK FACTORS

- Systemic fungal infection—histoplasmosis; blastomycosis; coccidioidomycosis; pythiosis
- Bacterial infection—Brucella; Nocardia, Borrelia, *Propionibacterium acnes*, mycobacteria; Bartonella
- Rickettsial infections
- Parasitism—visceral larval migrans; liver flukes, schistosomiasis; dirofilariasis
- Virus—FIP
- Protozoal—Toxoplasma; visceral Leishmania
- Neoplasia—histiocytic neoplasia, lymphoma
- Hemophagocytic histiocytic sarcoma
- Reactive or proliferative histiocytosis
- Immune-mediated disease
- Drug reactions
- Xenobiotics: holistic or herbal remedies
- Treats or food products from countries with unregulated manufacturing processes
- Idiopathic

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Widely disparate features initiate pursuit of diagnostic considerations; drug history must be carefully reviewed; consideration of splenic and/or bone marrow involvement necessary to rule out histiocytic neoplasia.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC—inflammatory or stress leukogram; nonregenerative anemia (chronic inflammation); spherocytes: microangiopathic, immune-mediated anemia, or histiocytic hemophagocytic syndrome; moncytosis with chronic inflammation/infection.
- Biochemistry—high liver enzymes; variable: bilirubin, hypoglycemia; hypoalbuminemia, low BUN; high or low total proteins; high globulins; may note electrolyte abnormalities with fluid and acid-base disturbances,

hypcholesterolemia with hemophagocytic histiocytic sarcoma.

- Urinalysis—may be normal or demonstrate: bilirubinuria, proteinuria, RBCs, WBCs, cellular and other casts.

OTHER LABORATORY TESTS

- Serum bile acid concentrations—often high with massive hepatic involvement or APSS.
- Coagulation assays—normal, except with end-stage liver failure.
- Acute phase proteins may be increased: certain globulins, fibrinogen, C-reactive protein, protein C, antithrombin.
- Serologic tests—titers must be evaluated with caution in regard to infectious agents; consider convalescent titers; increased IgM titers to toxoplasmosis support active infection, serology for *Bartonella* should be considered.
- Molecular diagnostic tests: PCR or fluorescent *in situ* hybridization (FISH: for eubacterial organisms, other) on liver tissue can confirm certain infectious agents not visualized on histopathology; mycobacterial PCR and Bartonella PCR are necessary.
- Antinuclear antibody titer—positive with SLE but low positive titers are nonspecific.
- Bacterial cultures—liver tissue, bile, or blood; mycobacterial cultures grow slowly (months); mycobacteria may be better detected using PCR; tissue staining (Ziehl-Neelsen, Fite Faraco for mycobacteria) should be done; however, staining in humans with granulomatous mycobacteria is often negative.

IMAGING

- Abdominal radiography—may identify a normal to large liver, abdominal mass; ascites may obscure details.
- Abdominal ultrasonography—liver size and parenchymal pattern (diffuse vs. focal); defines mass lesions; other visceral lesions may include splenomegaly and lymphadenopathy; confirms abdominal effusion; US imaging enables diagnostic sample collection.

OTHER DIAGNOSTIC PROCEDURES

- Aspiration sampling—hepatic parenchyma; other visceral lesions (esp. spleen, bone marrow) and abdominal effusion.
- Liver biopsy—definitive diagnosis of granulomatous reaction but usually does not define cause. Copper-specific stain and copper quantification in liver (dry weight basis) should be completed; copper concentration may be calculated from digitally scanned biopsy stained with rhodanine (Cornell University).
- *Special Tissue Stains for Infectious Agents:* Gram stain, Modified Steiner's, Ziehl Neelsen and Fite Faraco (mycobacteria), periodic acid-Schiff, Grocott's methenamine silver (GMS).
- Consider bone marrow aspirate/core: histiocytic neoplasm, lymphoma, infectious disease.

(CONTINUED)

HEPATITIS, GRANULOMATOUS**PATHOLOGIC FINDINGS**

- Gross—hepatomegaly; normal or finely irregular surface; firm texture; blunted margins; may have abdominal effusion.
- Microscopic—pyogranulomatous reaction, variable zonal orientation and infiltration.

**TREATMENT**

- Inpatient vs. outpatient—dictated by severity of clinical signs.
- Fluid therapy—balanced polyionic solution for dehydration; may require dextrose (2.5–5%); judicious potassium supplements.
- Nutritional support essential; provide positive nitrogen balance; do not restrict protein if lacking signs of hepatic encephalopathy.
- Inform client that the causes of this syndrome (e.g., FIP, neoplasia) are often difficult to confirm and treat.
- If granulomatous response associates with copper, see Copper Associated Hepatopathy.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Remove drug, herbal, or holistic therapies considered possible causes of granulomatous hepatic reaction.
- Depends on cause; see specific chapters for infectious disorders.
- Immunomodulation—if immune-mediated mechanisms suspected and survey for infectious etiology negative.
- Idiopathic disease (no underlying cause or possible markers of immune-mediated process)—glucocorticoids combined with azathioprine or mycophenolate has been proven successful. **Caution:** may exacerbate undetected infectious conditions.

- Vomiting—antiemetics (e.g., metoclopramide 0.2–0.5 mg/kg PO or SC q6–8h; ondansetron 0.5–1.0 mg/kg 30 minutes before feeding, q12–24h); maropitant (1.0 mg/kg SC, PO, maximum 5 days).
- Gastrointestinal bleeding—H₂-receptor antagonist: famotidine 0.5–2 mg/kg PO, IM, SC q12–24h or omeprazole 1.0 mg/kg PO q24h; sucralfate gastroprotection.

POSSIBLE INTERACTIONS

- Consider potential drug-associated pathologies because of the broad spectrum of possible causes.
- Consider adjusting drugs requiring hepatic activation, biotransformation, or elimination.
- Immunosuppression—may worsen clinical signs in primary infectious disorders.

**FOLLOW-UP****PATIENT MONITORING**

- Routine monitoring: fluids, acid-base and electrolyte balance, and general response.
- Sequential hematologic, biochemical, imaging, and serologic evaluations.

POSSIBLE COMPLICATIONS

- Chronic hepatitis, fibrosis or cirrhosis
- Hepatic failure
- Coagulopathy

EXPECTED COURSE AND PROGNOSIS

- Depends on primary cause.
- Prognosis usually guarded at best, owing to multisystemic nature of this syndrome.

**MISCELLANEOUS****ZOONOTIC POTENTIAL**

- Brucellosis—main causal agent of concern.
- Blastomycosis, coccidioidomycosis, Bartonellosis, Leishmania—not directly

contagious; pet may serve as environmental exposure sentinel.

SEE ALSO

- Bartonellosis
- Leishmaniasis
- Blastomycosis
- Coccidioidomycosis
- Histoplasmosis
- Pythiosis
- Feline Infectious Peritonitis (FIP)
- Leptospirosis
- Lupus Erythematosus, Systemic (SLE)
- Mycobacteria

HEPATITIS, INFECTIOUS (VIRAL) CANINE

BASICS

OVERVIEW

- Viral disease of dogs (Canidae) caused by CAV-1 serologically homogeneous and antigenically distinct from respiratory CAV-2.
- Infection—targets parenchymal organs (especially liver), eyes, and endothelium.
- Oronasal exposure—viremia (4–8 days); virus shed in saliva and feces; initial dispersal to hepatic macrophages (hepatocellular Kupffer cells) and endothelium; replicates in Kupffer cells; damages adjacent hepatocytes producing massive viremia when released.
- Adequate antibody response clears organs in 10–14 days; virus persists in renal tubules and may be shed in urine for 6–9 months.
- Chronic hepatitis—after infection in dogs with only partial neutralizing antibody response.
- Cytotoxic ocular injury—anterior uveitis; leads to classic “hepatitis blue eye”. Develops in ~1% of dogs after MLV vaccine.
- Virus can be shed for 6–9 mths in urine.

H

SIGNALMENT

- Dogs and other Canidae
- No breed or sex predilections
- Most common in dogs < 1 year of age

SIGNS

- Depend on immunologic status of host and degree of initial cytotoxic injury.
- Peracute—fever; CNS signs; vascular collapse; DIC; death within hours.
- Acute—fever; anorexia; lethargy; vomiting; diarrhea; hepatomegaly; abdominal pain; abdominal effusion; vasculitis (petechia, bruising); DIC; lymphadenopathy; rarely, nonsuppurative encephalitis.
- Uncomplicated—lethargy; anorexia; transient fever; tonsillitis; vomiting; diarrhea; lymphadenopathy; hepatomegaly; abdominal pain.
- Late—20% of cases develop anterior uveitis and corneal edema 4–6 days post-infection; recover within 21 days; may progress to glaucoma and corneal ulceration. May be the only clinical feature of inapparent infection.

CAUSES & RISK FACTORS

- CAV-1
- Unvaccinated dogs susceptible

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Canine herpesvirus (neonatal)
- Other infectious hepatopathies
- Leptospirosis
- Granulomatous hepatitis
- Toxic hepatitis

- Fulminant infectious disease—e.g., parvovirus, canine distemper

CBC/BIOCHEMISTRY/URINALYSIS

- CBC—schistocytes; leukopenia during acute viremia, followed by leukocytosis with reactive lymphocytosis and nucleated RBCs.
- Biochemistry—liver enzyme activity high initially, begin to decline within 14 days; low glucose and albumin reflect fulminant hepatic failure, vasculitis, and endotoxemia; low sodium and potassium levels reflect GI losses; hyperbilirubinemia if survive several days.
- Urinalysis—proteinuria (glomerular injury); granular casts (renal tubule damage); bilirubinuria consistent with jaundice.

OTHER LABORATORY TESTS

- Coagulation tests—reflect severity of liver injury and DIC.
- Serology for antibodies to CAV-1—fourfold rise in IgM and IgG; recent vaccine-induced antibodies confuse interpretation.
- Viral isolation—anterior segment of eye, kidney, tonsil, and urine; difficult in parenchymal organs (especially liver) unless first week of infection.

IMAGING

- Abdominal radiography—normal or large liver; poor detail due to effusion.
- Abdominal ultrasonography—may observe hepatomegaly, hypoechoic parenchyma (multifocal or diffuse pattern), and effusion.

DIAGNOSTIC PROCEDURES

- Liver biopsy, cytologically evident intranuclear hepatocyte inclusions—aspirates
- Viral culture
- Acute and convalescent serology

PATHOLOGIC FINDINGS

- Acute—edema and hemorrhage of lymph nodes; serosal visceral hemorrhages; liver large, dark-mottled; edematous gallbladder; fibrinous exudate on liver, gallbladder, and other viscera; splenomegaly; renal infarcts; abdominal effusion. Perivasculär necrosis in liver and other organs; widespread centrilobular to panlobular necrosis. Liver is discolored; abdominal effusion also observed in canine herpesvirus in neonates.
- Chronic—small, fibrotic or cirrhotic liver.

TREATMENT

- Usually inpatient.
- Fluid therapy—balanced polyionic fluids; avoid lactate if fulminant hepatic failure; carefully monitor fluids to avoid overhydration in context of increased vascular permeability.
- Judicious potassium (and other electrolyte) supplementation since electrolyte depletion may augment HE.

- Avoid neuroglycopenia—supplement fluids with dextrose (2.5–5.0%) as necessary.
- Blood component therapy for coagulopathy; blood component preferred to synthetic colloids for support of colloidal osmotic pressure; widespread vasculitis and DIC allow rapid systemic third space colloid dispersal.
- Overt DIC—fresh blood products and low molecular weight heparin (e.g., enoxaparin 100 U/kg [1 mg/kg] q24h). See Coagulopathy of Liver Disease.
- Nutritional support—frequent small meals as tolerated; optimize nitrogen intake; inappropriate protein restriction may impair tissue repair and regeneration; nitrogen restriction advised only if overt signs of HE.
- If oral feeding not tolerated, provide partial parenteral nutrition (maximum of 5 days) or, preferably, total parenteral nutrition.

MEDICATIONS

DRUG(S)

- Prophylactic antimicrobials—transmural passage of enteric bacteria/and endotoxemia with hepatic failure; e.g., ticarcillin (33–50 mg/kg q6–8h) combined with metronidazole (reduce conventional dose to 7.5 mg/kg IV q8–12h) and fluoroquinolone.
- Antiemetics—metoclopramide (0.2–0.5 mg/kg PO or SC q6–8h or CRI); ondansetron (0.5–1.0 mg/kg PO q12h); maropitant (1 mg/kg/day SC).
- Gastroprotection—H₂-receptor antagonists (e.g., famotidine 0.5 mg/kg PO, IV, SC q12–24h) and sucralfate (0.25–1.0 g PO q8–12h).
- Manage HE (see Hepatic Encephalopathy).
- Ursodeoxycholic acid—choleretic and hepatoprotectant (10–15 mg/kg daily in two divided doses, with food); give indefinitely if chronic hepatitis.
- Antioxidants—vitamin E (10 IU/kg/day PO), N-acetylcysteine IV (140 mg/kg load, then 70 mg/kg q8h) until PO route possible; transition to S-adenosylmethionine (SAMe, 20 mg/kg/day PO, dose on empty stomach) when patient can tolerate oral medications until liver enzymes normalize or indefinitely if chronic hepatitis.

CONTRAINDICATIONS

Consider severity of liver injury, protein depletion, and age in calculating drug dosages.

FOLLOW-UP

PATIENT MONITORING

- Monitor fluid, electrolyte, acid-base, and coagulation status to adjust supportive measures.
- Monitor for acute renal failure.

(CONTINUED)

HEPATITIS, INFECTIOUS (VIRAL) CANINE**PREVENTION/AVOIDANCE**

MLV vaccination—at 6–8 weeks of age; two boosters 3–4 weeks apart until 16 weeks of age; booster at 1 year; highly effective vaccine; boosters may not be needed.

POSSIBLE COMPLICATIONS

- Fulminant hepatic failure
- Hepatic encephalopathy
- Septicemia
- Acute renal failure
- DIC
- Glaucoma
- Chronic hepatitis

EXPECTED COURSE AND PROGNOSIS

- Peracute—poor prognosis; death within hours.
- Acute—variable: guarded to good prognosis.
- Poor antibody response (titer 1:16–1:50)—chronic hepatitis may develop.

- Good antibody response (titer > 1:500 IgG)—complete recovery in 5–7 days possible.
- Recovered patients—may develop chronic liver or renal disease.

**MISCELLANEOUS****AGE-RELATED FACTORS**

- Maternal antibody—may protect some pups for first 8 weeks; depends on maternal antibody concentration and efficacy of passive transfer.
- Vaccination of pups with high levels of passively acquired antibodies—successful at 14–16 weeks of age.

SEE ALSO

- Herpesvirus Infection—Dogs
- Disseminated Intravascular Coagulation

- Hepatic Encephalopathy
- Hepatic Failure, Acute
- Renal Failure, Acute
- Chronic Hepatitis
- Uveitis

ABBREVIATIONS

- CAV-1 = canine adenovirus-1
- CRI = constant rate infusion
- GSH = glutathione
- HE = hepatic encephalopathy
- MLV = modified live virus

H

HEPATITIS, SUPPURATIVE AND HEPATIC ABSCESS

BASICS

OVERVIEW

- Bacterial infection involving the hepatobiliary system; variable in size and distribution.
- Distribution and lobular involvement—variable; multifocal microabcessation; diffuse suppurative cholangitis/cholangiohepatitis; cholecystitis; choledochitis, or discrete focal necrosuppurative lesions; lesions associate with pyogenic bacteria.
- Large abscesses commonly associate with hepatocellular carcinoma (HCA) in dogs where opportunistic organisms populate necrotic regions.

H

SIGNALMENT

- Dog and cat.
- No breed predilection.
- Hepatic abscesses—most common in old dogs with HCA in necrotic foci, or secondary to immunosuppression or diabetes mellitus; in neonates may develop subsequent to omphalitis.
- Suppurative septic cholangitis/cholangiohepatitis—most common in young-middle-aged male cats secondary to retrograde bile duct infection or hematogenous distribution of translocated enteric bacteria via the portal vein.
- Cholestatic disorders (e.g., EHBO, GB mucocele) predispose to enteric bacterial translocation due to reduced delivery of bile acids and secretory IgA (normally regulate the enteric bacterial population and reduce enteric bacterial translocation); cholestasis also impairs canalicular bacterial egress from the liver.

SIGNS

Historical Findings

- Lethargy
- Gastrointestinal signs: vomiting, diarrhea
- Weight loss
- Polyuria and polydipsia
- Trembling
- Fever
- May become jaundiced

Physical Examination Findings

- Fever
- Abdominal pain: cranial abdomen
- Dehydration
- Hepatomegaly: focal, with large abscess
- Coagulopathy
- Effusion: abdominal distention or fluid wave
- May develop jaundice
- Endotoxemia: tachycardia, tachypnea, hypotension, hypoglycemic collapse

CAUSES & RISK FACTORS

- Hematogenous infection via the portal vein, hepatic artery, or umbilical vein.

- Biliary tree obstruction, preexisting hepatobiliary or pancreatic disease, and inflammatory bowel disease: predispose to enteric bacterial translocation.
- Ascending biliary tract infection.
- Cholecystoenterostomy.
- HCA with necrotic foci.
- Compromised immune responses: diabetes mellitus, glucocorticoid administration, hyperadrenocorticism, hypothyroidism, chemotherapy, immune-mediated disorders managed with immunosuppressives.
- Penetrating wounds.
- Complication of hepatic biopsy or other surgery.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Infectious or necroinflammatory disease—most patients are febrile.
- Hepatic abscess—fever, abdominal pain, and/or hepatomegaly (especially if risk factors).
- Pancreatitis or pancreatic abscess.
- Hepatobiliary neoplasia.
- Gastrointestinal obstruction or perforation.
- Peritonitis or other intra-abdominal abscess.
- Cholecystitis, choledochitis, cholelithiasis.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC—neutrophilic leukocytosis with a left shift and toxic WBC changes; monocytosis; thrombocytopenia; nonregenerative anemia.
- Biochemistry—variably increased ALT > ALP activity; low albumin, hyperglobulinemia, inconsistent hyperbilirubinemia, and hypoglycemia; features reflecting endotoxemia (Gram-negative bacterial infection).
- Urinalysis—usually normal; bilirubinuria; proteinuria; culture may or may not disclose hematogenously dispersed organisms.

OTHER LABORATORY TESTS

- Serum bile acids—may be high; depends on the extent or zonal location of hepatic involvement, cholestasis, or may reflect sepsis-related cholestasis.
- Coagulation tests and RBC morphology (schistocytes)—consistent with DIC.

IMAGING

Abdominal Radiography

- Hepatomegaly; single lobe if isolated abscess, diffuse organomegaly with suppurative cholangiohepatitis or hepatitis.
- Hepatic mass effect if large abscess or abscessed primary hepatic neoplasia.
- Reduced abdominal detail (focal or diffuse) if effusion or peritonitis.
- Gas in hepatic parenchyma or biliary tree (gas-producing bacteria): emphysematous.

Ultrasonography

- Best noninvasive method of abscess detection (> 0.5 cm lesions); solitary, variably echogenic, cavitated lesions hyperechoic rim.
- Dystrophic tissue mineralization or entrapped gas—appear hyperechoic.
- Highly echogenic interface with cavitated mass—may be gas; combination with an abdominal effusion and hyperechoic perilesional effect supports an abscess.
- Multiple masses—some appear complex.
- Miliary abscesses—cannot discern from other parenchymal hepatic disorders.
- Suppurative septic CCHS—image not unique from nonsuppurative CCHS.

DIAGNOSTIC PROCEDURES

Cytology

- Cytologic evaluations are essential; histologic specimens may not reveal bacterial organisms.
- Samples—effusion; aspirate hepatic parenchyma and discrete lesions with ultrasound guidance; cholecystocentesis: transhepatic approach, collect liquid bile and biliary debris (particulates).
- Stains—Wright-Giemsa for cytologic bacterial detection; Gram stain for morphology.
- Look for bacteria within biliary debris, in WBCs, and for signs of a primary or predisposing disease (e.g., neoplasia, VH reflecting adrenal disease or diabetes mellitus).

Culture and Sensitivity Testing

- If suppurative or pyogranulomatous reaction (cytology)—culture for aerobic and anaerobic bacteria and fungal organisms.
- Blood (aerobic and anaerobic cultures)—more likely to be positive if multiple abscesses.
- Polymicrobial infections: ~30%.
- Gram-negative bacteria: common; *E. coli* (most common); *Klebsiella* spp.; *Pseudomonas* spp.; *Enterobacter* spp.; *Proteus* spp.; *Serratia marcescens*; *Citrobacter* spp.
- Gram-positive bacteria: *Enterococcus* spp. (most common); *Staphylococcus* spp.; *Streptococcus* spp.
- Anaerobic organisms: least common; *Clostridium* spp. (most common of these); *Propionibacterium acnes*; *Bacteroides* spp. suggests polymicrobial infection and facilitates growth of other bacteria.

TREATMENT

- Inpatient—if signs of sepsis.
- IV fluids and antibiotics—essential.
- Fluid support—correct dehydration; rectify acid-base and electrolyte disturbances.
- Abscess—drain via hepatic lobectomy during laparotomy or under ultrasound

(CONTINUED)

HEPATITIS, SUPPURATIVE AND HEPATIC ABSCESS

guidance before surgery; in some patients (e.g., endotoxic shock) ultrasound facilitated drainage is best; after drainage, monitor body temperature, liver enzymes, WBC count, and sequentially image with ultrasound (monitor abscess size, focal or diffuse peritonitis); judiciously repeat drainage (may require insertion of an indwelling catheter for short-term continuous drainage).

- In middle age/older dogs—be prepared to liver lobectomy for abscess removal and possible wide-margin resection of an HCA.
- If EHBDO—biliary decompression essential; antimicrobials must be administered IV before surgical manipulations (biliary decompression) to avoid septicemia (see Biliary Obstruction).

MEDICATIONS

DRUG(S)

- Antibiotics—initially based on cytology and Gram stain, then adjusted based on culture and sensitivity results; continue for 2–4 months, perhaps longer.
- Initial treatment—combine antimicrobials to cover possible polymicrobial infection (common aerobic and anaerobic pathogens); common effective empirical combination includes: ticarcillin (25–50 mg/kg over 15 min. CRI) or amoxicillin clavulanate (10–20 mg/kg PO q12h), enrofloxacin (2.5 mg/kg PO or SC q12h dogs or cats; may use 5 mg/kg PO or SC q12h in dogs), and metronidazole (15 mg/kg IV q12h; reduce dose by 50% if hepatic dysfunction or severe

cholestasis) or clindamycin (10–16 mg/kg SC per day; reduce dose if hepatic dysfunction or severe cholestasis to 5 mg/kg SC per day).

- Choleretics advised if biliary tree involved, but if EHBDO *NOT UNTIL* biliary decompression (see Bile Duct Obstruction (Extrahepatic); Cholangitis/Cholangiohepatitis Syndrome).
- Antioxidants advised (see Chronic Hepatitis).

CONTRAINdications

- Aminoglycosides—do not use until normal hydration because of potential for renal injury; also, may not penetrate abscess capsule.
- Avoid drugs metabolized or excreted by the liver or those known to be hepatotoxic if compromised liver function; adjust dosages or frequency of drugs if suspect reduced hepatic elimination, cholestasis, or hepatic dysfunction.

FOLLOW-UP

PATIENT MONITORING

- Assess vital signs and physical condition.
- Sequential ultrasound examinations—monitor for abscess recrudescence or suppurative peritonitis.

POSSIBLE COMPLICATIONS

- DIC
- Septicemia/Endotoxemia
- Fulminant hepatic failure
- Septic peritonitis
- Acute renal failure

EXPECTED COURSE AND PROGNOSIS

- Favorable prognosis—early detection and aggressive antimicrobial treatment, with judicious surgical intervention.
- Guarded prognosis—concurrent disorders, especially unresectable primary hepatic neoplasia.

MISCELLANEOUS

ABBREVIATIONS

- ALP =alkaline phosphatase
- ALT =alanine aminotransferase
- AST =aspartate aminotransferase
- CCHS =cholangitis/cholangiohepatitis syndrome
- CRI =constant rate infusion
- EHBDO =extrahepatic bile duct obstruction
- GB =gallbladder

HEPATOCELLULAR ADENOMA

BASICS

OVERVIEW

- A benign liver tumor of epithelial origin.
- May be more common than primary malignant liver tumors.

SIGNALMENT

- Rare in dog and very rare in cat • Affected dogs commonly > 10 years of age • Breed predispositions unknown

SIGNS

- Usually asymptomatic; however, when clinically signs present, symptoms may be nonspecific. Typically incidental finding.
- Acute tumor rupture may cause hemoperitoneum with resultant weakness and hypovolemic shock-like symptoms.
- Occasionally, large tumors may cause cranial abdominal pain, vomiting, and inappetance.

CAUSES & RISK FACTORS

Definitive cause or risk factors for tumor development are unknown.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hepatocellular carcinoma • Hepatic nodular hyperplasia • Hepatic abscess
- Abdominal mass • Splenomegaly

CBC/BIOCHEMISTRY/URINALYSIS

CBC

- Usually unremarkable.
- Anemia—regenerative anemia if tumor is bleeding, or anemia of chronic disease.
- Leukocytosis with a left shift—large tumors with necrotic centers (rare).

Biochemistry

- Liver enzymes variable. • ALP, ALT, AST—normal or mild to markedly high.
- Serum total bilirubin values—usually normal.

Urinalysis

Unremarkable

OTHER LABORATORY TESTS

- Serum bile acids are usually normal unless tumor growth compromises hepatic perfusion and biliary flow. • Coagulation abnormalities consistent with DIC occur rarely with large necrotic or hemorrhagic tumors.

IMAGING

Radiography

- May demonstrate a single mass lesion or apparent asymmetry of hepatic silhouette.
- Rarely, gas in necrotic center of tumor.

Abdominal Ultrasonography

May identify discrete mass effect with variable echogenicity, ranging from normal liver echogenicity to mixed echogenicity, presence

of multiple nodules, or cystic mass appearance.

Abdominal Computed Tomography

- May allow for improved assessment regarding surgical feasibility, especially for large tumors, or tumors associated with critical structures, such as the gallbladder.
- May detect additional lesions, depending on the contrast enhancement protocol.

DIAGNOSTIC PROCEDURES

• Hepatic aspiration cytology with ultrasonographic guidance may allow the identification of normal hepatocytes or cells with mild atypia. This diagnostic will not be useful to differentiate between benign and low-grade malignant hepatic tumors, but will be useful to exclude other neoplastic diseases, such as lymphoma. • Hepatic biopsy with Trucut needle; several core biopsies are necessary to provide enough tissue for histopathologic characterization. Due to the overlap between the hepatocellular adenoma and the low-grade hepatocellular carcinoma, it may be difficult to obtain a definitive diagnosis. • Abdominal exploratory surgery followed by mass resection (liver lobectomy) and histopathology is the best way to obtain a definitive diagnosis and treat the disease.

PATHOLOGIC FINDINGS

Gross Pathology

- Usually well-circumscribed single nodules < 10 cm in diameter. • May be yellow-brown.
- Often soft, highly vascular, and friable.
- Occasionally multiple. • Occasionally very large (> 20 cm).

Microscopic Findings

- May be difficult to distinguish from nodular hyperplasia, normal liver tissue, or low-grade hepatocellular carcinoma. • Usually well-defined trabecular pattern; not necessarily encapsulated. • Compression of adjacent hepatic parenchyma common.
- Mitotic figures infrequent. • Affected liver cells resemble normal hepatocytes but often are larger and have a clear cytosol.

TREATMENT

• Surgical resection for large tumors, or tumors that cause clinical signs or organ dysfunction. • Bleeding tumor—requires immediate emergency care: hemodynamic stabilization, blood transfusion, and exploratory surgery. • Transarterial embolization or chemo-embolization is an experimental option for large, non-resectable tumors. In such cases, referral to an oncologic surgeon or experienced boarded surgeon is strongly advised, as many large tumors are actually resectable.

SURGICAL CONSIDERATIONS

- Excision recommended for large, single-mass lesions. • Between 60% and 70%

of the liver can be resected if the patient is healthy, and appropriate postoperative supportive care is available. • Biopsy local lymph nodes, normal appearing liver and any abnormal tissue identified during the exploratory surgery is of paramount importance.

MEDICATIONS

None

FOLLOW-UP

PATIENT MONITORING

- Liver enzymes—sequential evaluation, especially if they were elevated at the time of diagnosis. • Abdominal ultrasonography—every 3–4 months for the first year; preferred method of reevaluation.

POSSIBLE COMPLICATIONS

Risk of tumor necrosis and massive abdominal hemorrhage if not resected.

EXPECTED COURSE AND PROGNOSIS

Excellent

MISCELLANEOUS

SYNONYMS

Hepatoma—a confusing term that should be avoided; refers to hepatocellular carcinoma in human medicine and hepatocellular adenoma in veterinary medicine.

SEE ALSO

Hepatocellular Carcinoma

ABBREVIATIONS

- ALP = alkaline phosphatase • ALT = alanine aminotransferase • AST = aspartate aminotransferase • DIC = disseminated intravascular coagulation

Consulting Editor Timothy M. Fan

HEPATOCELLULAR CARCINOMA

BASICS

OVERVIEW

- Malignant epithelial liver tumor.
- Accounts for about 50% of malignant hepatic tumors.
- Metastasis to regional lymph nodes, lungs, and peritoneal cavity in dogs is associated with the nodular and diffuse forms of hepatocellular carcinoma.

SIGNALMENT

- Uncommon in dogs and rare in cats.
- Affected dogs commonly > 10 years of age.
- No breed predispositions, although golden retrievers, miniature schnauzers, and male dogs are overrepresented in some studies.

SIGNS

- Typically absent until disease is advanced, unless it causes biliary obstruction
- Many times incidental finding
- Lethargy
- Weakness
- Anorexia
- Weight loss
- Polydipsia
- Diarrhea
- Vomiting
- Hepatomegaly (asymmetric)—consistent; precedes development of overt clinical signs
- Abdominal hemorrhage

CAUSES & RISK FACTORS

- Unknown
- May be associated with chronic inflammation or hepatotoxicity

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hepatic adenoma
- Nodular hyperplasia
- Biliary cystadenoma
- Bile duct adenoma/carcinoma
- Metastatic neoplasia
- Polycystic liver disease—less common form; fibrous stroma hyperplasia with anaplastic duct cells; few cysts
- Hepatic lymphoma
- Hepatic hemangiosarcoma
- Hepatic carcinoid

CBC/BIOCHEMISTRY/URINALYSIS

CBC

- Usually unremarkable.
- Anemia was detected in > 50% of cases with massive hepatocellular carcinoma in one study.
- Anemia may be regenerative if tumor is bleeding.
- Leukocytosis with a left shift—tumors with necrotic centers.

Biochemistry

- Liver enzymes variable.
- ALT, AST, ALP, and GGT—may be significantly elevated.
- Serum total bilirubin values—usually normal.
- May note hypoalbuminemia, hypoglycemia, and hypcholesterolemia.

OTHER LABORATORY TESTS

- Serum bile acids—normal unless tumor impairs hepatic perfusion and biliary flow.
- Coagulation parameters—may see abnormalities consistent with DIC in patients

with massive or necrotic tumors, or intra-abdominal bleeding.

IMAGING

Radiography

- May demonstrate a single-mass lesion, apparent asymmetry of hepatic silhouette, or hepatomegaly.
- Rarely, gas in necrotic center of tumor.
- Loss of serosal detail in case of hemoabdomen.

Abdominal Ultrasonography

- Discrete mass lesion with variable echogenicity, depending on the presence of intratumoral necrosis, hemorrhage, gas, or cystic cavities.
- Massive enlargement of a single liver lobe is occasionally observed.
- Mixed echogenic pattern—most common.
- Nodular pattern of lesions.

CT/MRI

May be indicated when tumor is suspected to involve critical anatomical structures, (major vessels, bile duct), and do help plan the surgical approach and inform owners on the risk associated with surgery.

DIAGNOSTIC PROCEDURES

- Aspiration cytology—to exclude other types of neoplasia (lymphoma, sarcoma, etc.).
- Aspirate cytology cannot reliably differentiate between hepatocellular carcinoma and benign hepatocellular proliferation (adenoma, hyperplasia).
- Surgical hepatic biopsy for confirmation.
- If tumor is not surgically resectable, ultrasound-guided needle biopsy may be useful in obtaining definitive diagnosis.

PATHOLOGIC FINDINGS

- Three clinical subtypes of this tumor are described—massive, nodular, and diffuse.
- Nodular forms account for 30% and diffuse types account for 10% of all reported hepatocellular carcinomas in dogs, and both types involve multiple liver lobes.
- Massive form that is confined to one lobe accounts for about 60% of canine hepatocellular carcinoma cases.
- Color varies from almost white to normal liver color.
- Presence of necrotic center.
- Diffusely infiltrated tumors may not be grossly apparent other than hepatomegaly.

TREATMENT

SURGICAL CONSIDERATIONS

- Complete excision (liver lobectomy) recommended when possible. Excision with microscopically dirty margins can still afford durable tumor control and long survival times.
- Massive form is often amenable to surgical resection.
- Nodular and diffuse forms are often not amenable to surgery.
- Between 60% and 70% of the liver lobes

can be resected if the patient is healthy and is given appropriate postoperative care.

MEDICATIONS

DRUG(S)

No medical treatment options have been successful in reducing tumor recurrence or risk for metastasis.

FOLLOW-UP

PATIENT MONITORING

- Abdominal ultrasonography: 2 weeks postoperative for baseline and every 3–4 months for the first year.
- Abdominal CT and/or MRI are more sensitive than ultrasonography for detection of small, recurrent lesions.
- Monitor liver enzymes serially.

POSSIBLE COMPLICATIONS

Risk of tumor necrosis and massive abdominal hemorrhage if unresected.

EXPECTED COURSE AND PROGNOSIS

- Prognosis is variable; histologic classification is not prognostic.
- Massive forms treated with surgery have a better prognosis than do the nodular or diffuse forms.
- Median survival of dogs with massive form treated with surgery may be > 1,460 days.
- Local tumor recurrence or de-novo tumor growth is not uncommon.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Polycystic liver disease in cats

ABBREVIATIONS

- ALP = alkaline phosphatase
- ALT = alanine aminotransferase
- AST = aspartate transaminase
- CT = computed tomography
- GGT = gamma-glutamyltransferase

HEPATOMEGLALY

BASICS

DEFINITION

Large liver detected on physical examination, abdominal radiography, ultrasonography, or direct visualization. Liver size—adult dog: ~3.5–5% body weight; neonatal liver: 4.5–5% body weight.

PATHOPHYSIOLOGY

- Liver size: influenced by factors (hepatotrophic) produced by splanchnic viscera (pancreas dominates) delivered in portal blood.
- Enlargement causes: (1) sinusoidal capacitance (blood pooling) or (2) parenchymal or sinusoidal accumulation of cells, substrates, or storage products.

Diffuse or Generalized

- Inflammatory—immune-mediated, infectious, pyogranulomatous hepatitis; classified by infiltrative cell type.
- Lymphoreticular hyperplasia—response to antigens or accelerated erythrocyte destruction.
- Congestion—impaired venous drainage.
- Infiltration—cellular (neoplastic, primary hepatocellular, metastatic) or excessive glycogen, lipid, or rarely, metabolic products (genetic diseases) in hepatocyte cytosol, amyloid in space of Disse.
- Cystic lesions.
- Cholestasis—extrahepatic bile duct obstruction (EHBDO); intrahepatic cholestasis causing bile duct distention.
- Extramedullary hematopoiesis (EMH).

Nodular, Focal, or Asymmetric

- Neoplasia
- Hemorrhage
- Infection or inflammation
- Hepatic nodular hyperplasia
- Nodular regeneration
- Arteriovenous malformation—involved lobe larger than other lobes; other lobes atrophied
- Asymmetric regeneration after large-volume resection or panlobular necrosis
- Cystic lesions
- Liver lobe torsion: acute venous congestion
- Malformations; atretic liver lobes

SYSTEMS AFFECTED

- Gastrointestinal—gastric compression or distension.
- Peritoneal effusion—sinusoidal hypertension.
- Pulmonary—reduced ventilatory space from diaphragmatic compression.
- General/vague pain—stretched liver capsule.

SIGNALMENT

- Dog and cat
- Old animals more commonly affected

SIGNS

Historical Findings

- Abdominal distention or palpable mass
- Abdominal discomfort—vague location
- Depends on underlying cause

Physical Examination Findings

- Dogs—liver palpable beyond costal margin (normal liver palpable in some breeds)
- Cats—liver palpable > 1.5 cm beyond costal margin (normal liver palpable in some cats)
- May remain undetected in obese animals

CAUSES

Inflammation

- Infectious or chronic (early) hepatitis
- Acute toxic hepatopathy—many causes
- Feline CCHS
- EHBDO
- Lymphoreticular/Pyogranulomatous—immune-mediated disease (hemolytic anemia, systemic lupus erythematosus, idiopathic), infectious disorders
- Venous outflow obstruction—sinusoidal occlusion syndrome

Congestive Hepatopathy

- Increased central venous pressure—right-sided congestive heart failure—tricuspid valve disease; cardiomyopathy; congenital anomaly (cor triatriatum dexter); neoplasia; pericardial disease; heartworm disease; pulmonary hypertension; severe arrhythmias.
- Vena caval or hepatic vein occlusion—thrombosis; tumor invasion or extramural caval occlusion; heartworm vena cava syndrome; vena caval stenosis or congenital kink; diaphragmatic hernia; intrahepatic hepatic vein occlusion (Budd-Chiari syndrome).
- Sinusoidal occlusion syndrome: xenobiotics or herbal toxicity (e.g., pyrrolizidine alkaloids).
- Liver lobe torsion (acute).

Infiltration

- Neoplasia
- Metabolic abnormalities—amyloid; lipid (see Hepatic Lipidosis [cats]), glycogen (see Glycogen-Type Vacuolar Hepatopathy [dogs]); cats and dogs: neonatal, diabetes mellitus, hyperlipidemic syndromes; metabolic storage disorders.
- Lymphohistiocytic/Pyogranulomatous—infECTious disease, immune response, antigen stimulation, neoplasia (histiocytic/dendritic).

Extramedullary Hematopoiesis

Regenerative anemias—hemolytic (immune-mediated, congenital, metabolic, infectious); oxidant injury; erythroparasitism; severe blood loss, bone marrow failure; idiopathic.

Neoplasia

- Infiltrative, diffuse, or large focal tumors.

- Primary hepatic—lymphoma; hepatocellular carcinoma; cholangiocarcinoma (bile duct carcinoma).
- Metastatic—lymphosarcoma, hemangiosarcoma, fibrosarcoma, leiomyoma/sarcoma, neuroendocrine, osteosarcoma, others.

Major Bile Duct Obstruction

- Pancreatitis; pancreatic neoplasia
- Neoplasms in porta hepatis: bile duct carcinoma, lymphoma
- Granuloma/Fibrosis of common bile duct
- Inspissated bile syndrome, choledochal cyst, or gallbladder mucocele
- Cholelithiasis
- Proximal duodenitis; duodenal foreign body
- Fluke migration (cats)

Cystic Lesions

- Primary single hepatic or biliary cysts
- Acquired cysts—tumors
- Ductal plate malformations and polycystic diseases—may be associated with renal cysts (common in Persian cats)
- Biliary cystadenoma (cats)
- Hepatic abscesses (cystic cavitation); hepatocellular carcinoma housing abscess

Other

- Drugs—corticosteroids (see Glycogen-Type Vacuolar Hepatopathy), phenobarbital (dogs)
- Hepatic nodular hyperplasia (rare cause)
- Acromegaly—cats

RISK FACTORS

- Cardiac disease
- Heartworm disease
- Neoplasia
- Primary hepatic disease—inflammatory, neoplastic, or cystic
- Corticosteroids—exogenous or endogenous
- Phenobarbital treatment
- Poorly controlled diabetes mellitus
- Anorexia in obese cats—hepatic lipidosis
- EHBDO
- Certain anemias—diffuse hepatic EMH

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Similar Signs

Distinguish from other disorders causing visceromegaly (gastric, splenic), cranial abdominal masses or effusions via radiography and ultrasonography.

Differential Causes

- Cardiac disorders (e.g., heart murmur, weak femoral pulses, hepatojugular reflex, jugular distention and pulses, muffled heart sounds).
- Symptomatic anemia (pallor with or without jaundice); tachycardia; tachypnea; exercise intolerance; bounding pulses.
- Parenchymal liver disease—lethargy,

(CONTINUED)

HEPATOMEGLALY**H**

- anorexia, vomiting, diarrhea, weight loss, variable liver enzymes, jaundice, coagulopathies, HE, PU/PD, ascites.
- VH (dog)—signs of hyperadrenocorticism or adrenal hyperplasia or other chronic disease imposing stress.
 - Hepatic lipidosis—jaundice in obese hyporexic cat, poorly controlled diabetes mellitus (dog or cat); puppies or kittens.

CBC/BIOCHEMISTRY/URINALYSIS**CBC**

- Identify anemia and cause; spherocytes (immune-mediated hemolytic anemia, microangiopathic anemia); schistocytes (vascular shearing-microangiopathic, vena cava syndrome, hemangiosarcoma, DIC), Heinz bodies (oxidant injury); erythroparasitism (*Mycoplasma haemofelis*, *Babesia*).
- Circulating blast cells—myeloproliferative or lymphoproliferative disease.
- Nucleated red cells—EMH, splenic disease.
- Macrocytosis and non-regenerative anemia—FIV, FeLV.
- Thrombocytopenia—increased consumption or destruction; reduced production.
- Thrombocytosis—neoplasia; inflammation; hyperadrenocorticism; splenic disease.

Biochemistry

- Inflammatory hepatic disorders—usually high liver enzyme activity; variable hyperglobulinemia, bilirubin and albumin values.
- Reticuloendothelial hyperplasia—variable liver enzyme activity.
- Primary hepatic neoplasia—moderate to markedly increased liver enzyme activity (ALP, GGT, ALT).
- Metastatic neoplasia—variable liver enzymes; occasionally high calcium or globulin.
- Infiltrative disorders—minor liver enzyme changes; variable hyperbilirubinemia.
- VH (dogs)—markedly high ALP; high cholesterol with increased glucocorticoids or sex steroids.
- Hepatic lipidosis (cats)—high ALP, AST, and ALT; minor increase in GGT unless concurrent pancreatitis, CCHS, or EHBDO.
- Storage diseases—few abnormalities.
- EHBDO—markedly high ALP, GGT, other enzymes; high bilirubin and cholesterol.
- Cystic lesions—normal, except with hepatic abscess (markedly high ALT and AST) or cholangitis/cholangiohepatitis (high ALP, ALT, GGT).
- Phenobarbital-associated—high liver enzymes (especially ALP in dog).
- Nodular hyperplasia—normal or moderately high ALP, elderly dogs.

OTHER LABORATORY TESTS

- FeLV and FIV testing—cats.
- Buffy coat—circulating blasts (neoplasia).

- Coagulation panel—DIC common with hemangiosarcoma or diffuse lymphoma; prolonged coagulation times common with EHBDO > 5 days; (especially PIVKA test).
- TSBA—high in diffuse disorders or EHBDO; *redundant test if nonhemolytic* jaundice.
- Pituitary-adrenal axis testing (dogs)—see Glycogen-Type Vacuolar Hepatopathy; Hyperadrenocorticism (Cushing's Syndrome)—Cats; Hyperadrenocorticism (Cushing's Syndrome)—Dogs.
- Heartworm testing—in endemic areas.
- Fungal serology—in endemic areas.
- Other serology—e.g., Rickettsial, *Bartonella*, *Leishmania*, *Toxoplasmosis*.

IMAGING**Abdominal Radiography**

- Hepatomegaly—rounded margins extend beyond costal arch; caudal-dorsal gastric displacement; caudal displacement: cranial duodenal flexure, right kidney, transverse colon.
- May suggest cause.

Thoracic Radiography

- Three views (lateral [right, left], dorsal-ventral)—metastasis, other disorders, cranial displacement of diaphragm.
- Cardiac, pulmonary, pericardial, and vena caval disorders usually need US imaging.
- Sternal lymphadenopathy—reflects abdominal inflammation or neoplasia.
- Puppies, kittens, and deep inspirations—spurious hepatomegaly.

Abdominal Ultrasonography

- Liver size and surface contour.
- Diffuse enlargement with normal echogenicity—congestion; cellular infiltration (lymphoma); inflammation; EMH; reticuloendothelial hyperplasia.
- Diffuse enlargement with hypoechoic parenchyma—normal variation; congestion, lymphoma, diffuse sarcoma; amyloidosis.
- Diffuse enlargement with hyperechoic parenchymal (minor nodularity)—lipid or glycogen; inflammation; fibrosis; lymphoma.
- Diffuse enlargement with hypoechoic nodules—neoplasia; abscesses; VH (dog); cystic lesions (ductal plate malformations, polycystic liver disease).
- Identify EHBDO.
- Identify concurrent abdominal diseases—kidneys; intestines; lymph nodes; effusion; interrogation of porta hepatis for obstructions and lymphadenopathy.
- Cannot distinguish benign from malignant disease.
- Identify abdominal effusion—distribution and echogenic patterns.

OTHER DIAGNOSTIC PROCEDURES

- Electrocardiography/Echocardiography**
Characterize cardiac conduction, structure, function, pulmonary pressure gradient.

Fine-Needle Aspiration

- Procedure—22-gauge, 2.5–3.75 cm (1–1.5 in) needle; diffusely large liver directly aspirated without US; focal lesions aspirated under US guidance.
- Cytology—may disclose infectious agents, vacuolar change, neoplasia, inflammation, or EMH; definitive diagnosis seldom confidently confirmed (false-positive and -negative results).
- Hepatic biopsy—if US rules out EHBDO, cytology does not indicate septic inflammation or neoplasia, and no obvious diagnoses; percutaneous ultrasound-guided Tru-Cut needle biopsy for suspected neoplasia or amyloid (avoid if abscess or EHBDO possible); otherwise, best sampling with laparoscopic or surgical exploratory approaches.
- Microbial culture—aerobic and anaerobic bacterial; fungal as appropriate.
- Staining—hematoxylin & eosin (routine); reticulin (architectural substructural remodeling, infiltration, compression), Masson's trichrome (collagen deposition); rhodanine (copper); PAS (glycogen, with and without amylase pre-digestion); acid-fast stain (mycobacteria if granulomatous inflammation); Congo red (amyloid); Oil Red O (lipid, requires frozen section); infectious disease stains (see Hepatitis, Granulomatous).
- Coagulation testing—before liver sampling, consider measurement of PT, aPTT, fibrinogen, and buccal mucosal bleeding time (BMBT); lack of dependable prediction of iatrogenic hemorrhage with bench tests is recognized; BMBT may be more relevant.
- Abdominal effusion—cytology; protein content; culture; evaluate before tissue sampling.
- Pericardiocentesis—if pericardial tamponade.

**TREATMENT****APPROPRIATE HEALTH CARE**

- Outpatient—except cardiac or hepatic failure.
- General supportive goals—eliminate or manage inciting cause; prevent complications; palliate derangements due to hepatic failure.
- Important derangements—dehydration and hypovolemia; HE; hypoglycemia; acid-base and electrolyte abnormalities; coagulopathies; enteric hemorrhage; sepsis; endotoxemia.

NURSING CARE

- Heart failure or ascites—impose sodium restriction: fluids and food (< 100 mg/100 kcal, < 0.2% dry matter basis food).
- Supplement potassium chloride if IV fluids—sliding scale (maintenance = 20 mEq/L fluid).
- Supplement B-soluble vitamins.

HEPATOMEGLALY

(CONTINUED)

- If Jaundiced—parenteral vitamin K before invasive procedures.

ACTIVITY

Restricted; initial cage rest in some disorders.

DIET

- Dietary protein—restrict only if HE.
- Well-balanced, adequate energy, positive nitrogen balance is essential; adequate vitamins and micronutrients.
- Sodium—restrict if cardiac failure or ascites.

CLIENT EDUCATION

- Treatment depends on underlying cause.
- Many causes are life-threatening, some less serious and amenable to treatment.
- Thorough diagnostic evaluations are essential for determining definitive diagnosis.

SURGICAL CONSIDERATIONS

- Resection of primary or focal hepatic mass lesions (neoplasia, abscess, compromising cyst)—biliary decompression if EHBDO.
- Pericardiectomy (thoracoscopic procedure)—if effusion recurs after initial pericardiocentesis.

MEDICATIONS

DRUG(S)

Varies with underlying cause.

CONTRAINDICATIONS

- Avoid hepatotoxic drugs.

- Vacuolar hepatopathy (dogs)—avoid glucocorticoids.
- Hepatic lipidosis (cats)—avoid catabolism or drugs that promote catabolism; avoid fasting.

FOLLOW-UP

PATIENT MONITORING

- Physical assessment and hepatic imaging—reassess liver size.
- CBC, biochemistry, TSBA—serial assessment of abnormalities and liver function; reticulocyte count with anemia.
- Thoracic radiography, electrocardiography, and echocardiography—reassess status.
- Pituitary-adrenal axis—adrenal disorders.
- Adjust drug dosages according to status of liver function, body condition, and weight.

POSSIBLE COMPLICATIONS

Many causes are life-threatening.

HEPATOPORTAL MICROVASCULAR DYSPLASIA

BASICS

DEFINITION

- MVD describes intrahepatic microscopic vascular malformations diminishing hepatic perfusion in tertiary branches of the portal vein; this is accommodated by the compensatory increase in hepatic arterial perfusion; MVD lacks macroscopic portosystemic shunting but genetically associates with congenital portosystemic vascular anomalies (PSVA, shunts) as a component of a complex polygenic autosomal syndrome.
- Occurs as an isolated malformation or in association with PSVA.
- Clinically distinct from intrahepatic portal vein atresia that associates with numerous acquired portosystemic shunts (APSS).
- Histologic features—overlap with any condition impairing hepatopetal portal circulation (forward flow of splanchnic blood toward the liver).
- Clinicopathologic hallmark—increased total serum bile acid (TSBA) concentrations.
- Coexistence of MVD with PSVA explains: (1) failure of TSBA to normalize after complete PSVA occlusion (some dogs); and (2) inability to fully attenuate PSVA (some dogs).
- MVD diagnosis is confused by inappropriate terminology where “portal hypoplasia” has been proposed to describe features of portal venous hypoperfusion. “Hypoplasia” defines lack of development—impossible to ascertain from liver biopsy without clinical features and vascular imaging details; MVD is one of many causes of portal venous hypoperfusion.

PATOPHYSIOLOGY

- Malformations impairing intrahepatic portal venous perfusion deprive hepatocytes of splanchnic hepatotrophic factors—causing lobular atrophy and impairing rapid extraction of bile acids from the enterohepatic circulation.
- Compensatory increase in hepatic arterial perfusion (hepatic arterial buffer response) maintains liver viability.
- Absence of macroscopic portosystemic shunting directly into the systemic circulation explains the lack of clinical signs and hepatic encephalopathy (HE) in dogs with MVD.
- Finding signs consistent with HE in a dog thought to have MVD strongly indicates PSVA or APSS; in a young dog APSS develop with portal venous atresia, ductal plate malformation (DPM, with congenital hepatic fibrosis [CHF] phenotype), NCPH, or splanchnic portal venous thromboembolism (TE).

SYSTEMS AFFECTED

- Usually asymptomatic.
- May observe slow recovery from injectable anesthetics and apparent adverse drug reactions with

medications undergoing first-pass hepatic extraction or hepatic metabolism.

- If concurrent IBD—vomiting, diarrhea, inappetence, increased liver enzymes; may lead to centrilobular and/or portal tract inflammation; most severe in eosinophilic IBD.
- No HE in MVD—if HE identified, suspect PSVA or disorders causing APSS.
- Renal/Urologic—MVD dogs *DO NOT* develop ammonium biurate crystalluria/urolithiasis; if such is discovered, consider mistaken MVD diagnosis in a dog with PSVA, APSS, rare inborn errors of ammonia detoxification, or uric acid membrane transporter mutations (bulldogs, Black Russian terriers, Dalmatians, some cats).

GENETICS

- Compelling evidence supports inheritance of PSVA/MVD as a complex polygenic autosomal trait in many small pure-breed dogs.
- TSBA > 25 $\mu\text{M/L}$ designates phenotype (affected/not affected) PSVA/MVD trait, Cornell University.
- Unaffected parents may produce affected progeny due to suspected polygenic inheritance.

INCIDENCE/PREVALENCE

- Prevalence PSVA/MVD trait in small pure-breed dogs: 30–80%, varies with breed.
- Genetic association of MVD and PSVA in kindreds of certain breeds confirms that MVD is most common: 10–30:1 MVD:PSVA.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

Dog

Breed Predilections

- Small breeds.
- Commonly affected breeds: Yorkshire terriers, Maltese, Cairn terriers, Tibetan spaniels, Shih Tzu, Havanese, miniature schnauzers, pugs, Papillon, Norfolk terriers, Bichon Frise, West Highland white terriers.
- Not identified in large-breed dogs.
- Not identified in cats.

Age and Range

MVD usually tested at 4–6 months of age using paired TSBA tests (collected before and 2 h after a meal); neonatal testing not advised; more reliable results at 4 months age.

SIGNS

Historical Findings

- Asymptomatic—unremarkable history; occasionally delayed anesthetic recovery or drug intolerance reported.
- Symptomatic dogs represent misclassified diagnosis (see “Pathophysiology”); PSVA (see Portosystemic Vascular Anomaly, Congenital) or disorders causing APSS.
- MVD dogs are not hyperbilirubinemic.
- MVD dogs do not

develop ascites.

- MVD is often recognized serendipitously during routine screening tests or diagnostic evaluations for unrelated health problems, or during TSBA testing in breeds with high PSVA/MVD prevalence.

- Important to consider and rule out other causes of increased TSBA; concurrent illnesses may complicate TSBA interpretation (e.g., GI malabsorption causes low TSBA values).

Physical Examination Findings

- Unremarkable
- HE, jaundice, or ascites: do not occur

CAUSES

Congenital inherited disorder

RISK FACTORS

Pure-bred small dog breeds and mixes of these breeds.

H

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- PSVA—suspected in symptomatic young dog with increased TSBA or HE; however, 20% of PSVA dogs are asymptomatic.
- Symptomatic dogs > 2 years of age—may have APSS caused by inflammatory, infiltrative, neoplastic, or toxic hepatopathies; DPM with CHF phenotype; rare PSVA dogs show late-onset signs (e.g., miniature schnauzers; dogs with portoazygous shunts) reflecting small relative shunt fraction; portal vein atresia (true intrahepatic portal hypoplasia) and NCPH (acquired loss of tertiary branches of the intrahepatic portal vein) associate with portal hypertension, ascites, and APSS.
- Histopathologic features of all disorders causing portal hypoperfusion are similar.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC—normal.
- Biochemistry—generally unremarkable; hepatic enzyme activities normal (expect high ALP in young patients due to bone growth) or cyclically increased (ALT) if coexistent IBD or degenerative/inflammatory centrilobular lesions; mild hypoglobulinemia or hypoalbuminemia noted in ~50% of young dogs.
- Urinalysis—specific gravity within normal range, no ammonium biurate crystalluria.
- Hyperammonemia is not documented dogs with MVD, without portal atresia or PSVA.

OTHER LABORATORY TESTS

TSBA

- Paired pre- and postprandial TSBA—recommended diagnostic test; values > 25 $\mu\text{mol/L}$ confirm abnormal liver function or perfusion; “shunting pattern” common.
- Shunting pattern—postprandial TSBA concentrations 0.5- to 3-fold > preprandial

HEPATOPORTAL MICROVASCULAR DYSPLASIA

(CONTINUED)

TSBA occurs with MVD, PSVA, APSS. ~15–20% of dogs and ~10% of cats have fasting > postprandial TSBA; thus, random single TSBA in the “normal range” must be followed up by paired TSBA testing.

- $> 25 \mu\text{M/L}$ —cutoff for TSBA in dogs.
- No need to fast patient before meal-provoked enterohepatic bile acid challenge because of physiologic variables influencing fasting values; do not use “fasting” value ranges.
- Important TSBA testing strategy: food-initiated enterohepatic bile acid challenge is essential; verify meal consumption; feed typical size and meal type for that patient.
- Magnitude of TSBA increase: typically lower for MVD vs. PSVA; but wide overlap in values impairs utility of TSBA as a stand-alone test to distinguish MVD.
- Quantitative abnormal TSBA values cannot discriminate “severity” of MVD between dogs; sequential testing show vacillating abnormal values (reflect physiologic variables).

Clearance Studies

Cairn terriers with MVD had reduced clearance of an organic anion indicator dye (ICG), confirming reduced liver perfusion; this test has low clinical utility.

Protein C

- Protein C reflects severity of portosystemic shunting in dogs; is not validated in cats.
- Generalities: ° MVD: protein C usually $\geq 70\%$. ° Symptomatic PSVA: protein C $< 70\%$. ° Asymptomatic PSVA protein C may be $\geq 70\%$ more common in portoazygous PSVA.

IMAGING

- *Abdominal Radiography*—lack microhepatia and renomegaly observed in PSVA.
- *Abdominal Ultrasonography*—no macroscopic shunting vessel; liver size subjectively normal or “slightly” small; experienced operator may suspect portal hypoperfusion that may vary among lobes.
- *Mesenteric Portovenography*—subtle abnormalities of blunted small portal vein branches, protracted contrast “blush” due to truncation of tertiary portal branches that trap contrast. **Caution:** PSVA may be overlooked if radiographic portography only completed in a single recumbent posture.
- *Colorectal or Splenoportal Scintigraphy*—normal or slightly increased shunt fraction in MVD; rules out macroscopic shunt (PSVA, APSS); CRS may demonstrate irregular liver lobe perfusion in MVD.

DIAGNOSTIC PROCEDURES

- Liver biopsy—sample several liver lobes as MVD does not uniformly affect all liver lobes; **AVOID SAMPLING** caudate lobe as this receives perfusion from the first portal vein branch; is often the best perfused liver lobe.
- *Histologic Evaluation*—required for

definitive diagnosis of portal hypoperfusion but must be considered in context of clinical, clinicopathologic, and imaging details; rules out most acquired hepatobiliary disorders causing increased TSBA except portal TE and NCPH. • *US-Guided Needle Biopsies*—may not sample enough tissue for definitive diagnosis; limits sampling to 1 or 2 left-sided liver lobes. • *Surgical Wedge or Laparoscopic Liver Biopsies*—reliably diagnostic if biopsies of several lobes obtained.

PATHOLOGIC FINDINGS

Gross

- Normal appearance and liver size.
- Some liver lobes may appear small.

Microscopic

- Cannot discriminate MVD, PSVA, NCPH or extrahepatic portal venous TE/occlusion: without history, clinical findings, and imaging details.
- *Hepatic Histopathology Reflects Portal Venous Hypoperfusion:* (1) lobular atrophy—small hepatocytes, closely approximated portal tracts and centrilobular regions, miniaturized portal tracts; (2) increased arteriolar profiles in portal tracts and orphaned arterioles without other portal tract elements in parenchyma—physiologic compensatory increase in arteriolar perfusion likely involves the biliary arterial plexus, arteries are coiled in response to increased pressure and flow with formation of new arterial twigs; (3) lymphatic distention—in portal tracts, adjacent to hepatic veins, and variably, beneath the liver capsule; reflects increased ultralymph formation from arterialized sinusoidal perfusion.
- *Unique MVD Features:* (1) maldevelopment of tertiary portal vein branches—inconsistent perfused portal veins in portal tracts, portal veins may demonstrate dilated, thin-walled unusual appearance; (2) malposition of hepatic venules adjacent to portal triads sharing borders = “fusion complexes”; (3) prominent smooth “throttling musculature” of hepatic venules (influence transhepatic perfusion) suggests physiologic hypertrophy or constriction, perhaps reflecting increased pressure; (4) increased numbers of binucleated hepatocytes (esp. near portal tracts); (5) randomly distributed but mildly disorganized hepatic cords with occasional widened sinusoids (random distribution); (6) inconsistent involvement of hepatic lobes: normal, mild to severe.
- **Note:** liver biopsy in any dog ≤ 4 months of age demonstrates juvenile portal triads (small).

TREATMENT

APPROPRIATE HEALTH CARE

- Asymptomatic—requires no medical interventions except avoidance of drugs

dependent on hepatic first-pass extraction, conjugation, metabolism. • **DO NOT**

- **NEED:** ursodeoxycholic acid, S-adenosylmethionine (SAMe, unless chronically increased liver enzymes), silybin (milk thistle) or dietary protein restriction.
- Suspected HE and/or protracted vomiting or diarrhea—hospitalize for supportive care and diagnostic evaluations; these dogs have other disorders that may complicate MVD (see Hepatic Encephalopathy, Portosystemic Vascular Anomaly, Congenital, Inflammatory Bowel Disease, “Pathophysiology”). • Rarely, dogs with zone 3 degenerative changes develop a chronic progressive hepatopathy: leads to hepatic dysfunction, portal hypertension, and ascites; diagnosis requires hepatic imaging and liver biopsy; may require management for hepatic insufficiency and ascites; more common in Maltese, Shih Tzu, Bichon Frise, Yorkshire terriers.
- Confirmed MVD associated with nonsuppurative zone 3 inflammation (especially involving eosinophils) and IBD: usually managed with low-dose dexamethasone (0.05 mg/kg PO q48–72h, rather than prednisone to avoid mineralocorticoid supplementation which may provoke ascites), hypoallergenic diet (protein restriction if HE) or a hydrolyzed protein diet, and low dose metronidazole: 7.5 mg/kg PO q12h; if low protein C: add mini-dose aspirin 0.5 mg/kg PO q12–24h or clopidogrel. **Must have liver biopsy** to confirm need for glucocorticoid and anticoagulants.

NURSING CARE

N/A

ACTIVITY

N/A

DIET

- Dogs with MVD do not require a protein-restricted diet.
- Dogs with HE do not have simple MVD; these have complicated illnesses or PSVA—see Hepatic Encephalopathy and Portosystemic Vascular Anomaly, Congenital, and “Pathophysiology”.

CLIENT EDUCATION

- MVD cannot be culled from a kindred based on TSBA testing; parents with normal TSBA may produce progeny with MVD or PSVA; examination of TSBA in F1 and F2 progeny is the only method of defining optimal breeding strategy, at present.
- Counsel clients that TSBA values cannot be used to grade severity of MVD.
- TSBA testing should be used to identify MVD in juvenile dogs to avoid future diagnostic confusion: e.g., adult with non-hepatic illnesses.
- Protein C—**should not be used** as a screening test without TSBA. Asymptomatic PSVA may have normal protein C. TSBA are **ALWAYS** abnormal in PSVA unless testing is

(CONTINUED)

HEPATOPORTAL MICROVASCULAR DYSPLASIA

inadequate (lack of provocative tolerance test, or compromised enteric fat absorption).

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUG(S) OF CHOICE

For HE—see Hepatic Encephalopathy

CONTRAINDICATIONS

N/A

PRECAUTIONS

Beware of rare adverse reactions to drugs reliant on hepatic first-pass extraction or metabolism.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

N/A

FOLLOW-UP

PATIENT MONITORING

- Asymptomatic dogs—no specific treatment/long-term follow-up has confirmed normal lifespan, no chronic illness, no progressive hepatic degeneration.
- Repeated TSBA tests are not advised as values remain abnormal and fluctuate due to physiologic variables that clients find difficult to understand.

PREVENTION/AVOIDANCE

Specific recommendations to eliminate MVD from a particular genetic line or breed are not possible at present. Based on information derived from large pedigrees of multiple dog breeds, simply breeding unaffected parents does not eliminate MVD from a kindred. In high-incidence kindreds remain vigilant for vaguely ill dogs that may have PSVA; surgical

exploration can miss PSVA as can portovenography if only a single recumbency is evaluated); CRS can definitively detect hepatofugal blood flow (portosystemic shunting) providing a quick YES/NO test for portosystemic shunting; protein C activity assists in differentiating dogs with PSVA from MVD to advise further expensive imaging but is not definitive as a stand-alone test.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Most dogs with MVD remain asymptomatic and have a normal lifespan.
- Progressive increase in magnitude of TSBA values with age (juvenile to adult) has been documented in MVD.
- Generally, TSBA tests in MVD dogs are not quantitatively related to histologic severity.
- Dogs with zone 3 degenerative lesions (described above) may develop progressive hepatopathy leading to HE, portal hypertension, APSS, ascites, and rarely portal venous thromboembolism; this is a *rare* syndrome.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Small-breed dogs with high incidence of PSVA affected.

AGE-RELATED FACTORS

TSBA can be used to screen young dogs (16 weeks of age) in breeds known to have high prevalence of PSVA/MVD.

ZOONOTIC POTENTIAL

N/A

PREGNANCY/FERTILITY/BREEDING

Bitches with MVD carry litters to term.

SYNONYMS

- Congenital portal hypoperfusion
- Hepatic microvascular dysplasia
- Microscopic portovascular dysplasia

CONFUSED TERMINOLOGY

- Intrahepatic portal venous atresia is not a synonym for MVD
- Portal venous hypoplasia is not a synonym for MVD

SEE ALSO

- Ductal Plate Malformation (Congenital Hepatic Fibrosis)
- Hepatic Encephalopathy
- Portosystemic Vascular Anomaly, Congenital
- Portosystemic Shunting, Acquired

ABBREVIATIONS

- ALP = alkaline phosphatase
- ALT = alanine aminotransferase
- AST = aspartate aminotransferase
- APSS = acquired portosystemic shunt
- CRS = colorectal scintigraphy
- ICG = indocyanine green
- MVD = microvascular dysplasia
- NCPH = non-cirrhotic portal hypertension
- PSS = portosystemic shunting
- PSVA = portosystemic vascular anomaly
- SPS = splenoportal scintigraphy
- TE = thromboembolism
- TSBA = total serum bile acids

HEPATOTOXINS

BASICS

DEFINITION

- Endogenous or exogenous substances (drugs, xenobiotics, toxins) that cause hepatic injury.
- Direct—("Dose dependent") causes predictable injury.
- Idiosyncratic—("Dose independent" or "Type II") unpredictable.

PATOPHYSIOLOGY

- Liver highly susceptible because of location and central role in metabolic and detoxification pathways. Liver is most commonly reported organ associated with true adverse drug reactions.
- Mechanisms of damage are direct (active metabolic byproducts) or indirect (oxidative processes from free radical metabolites).
- May cause hepatocellular or cytolytic injury (necrosis and apoptosis), cholestasis, immunologic (innocent bystander or hapten-mediated), or mixed histopathologic patterns of injury.
- Susceptibility and severity of injury—affected by age, species, nutritional status, concurrent drug administration, antecedent disease, antioxidant status; level of hepatic copper accumulation; hereditary factors, and current or prior exposure to the same or similar compounds.

SYSTEMS AFFECTED

- Hepatobiliary
- Nervous—hepatic encephalopathy
- Renal—proximal tubular necrosis or renal tubular acidosis/Fanconi syndrome; hepatorenal syndrome (rare)

GENETICS

Some dog breeds seem predisposed to certain drug-associated hepatotoxicities.

SIGNALMENT

Species

- Dog and cat.
- Cats have lower endogenous detoxification abilities; are susceptible to GSH depletion; dogs have higher risk for hepatotoxicity to some agents due to comparatively lower hepatic GSH (e.g., acetaminophen, aflatoxins).

Breed Predilections

- Siamese cats—some kindreds have high risk (reduced glucuronide formation).
- Some dog breeds have high risk for selected drug toxicity—Dobermanns, Dalmatians, Samoyeds: trimethoprim sulfamethoxazole; Dobermanns: oxibendazole; Labrador retrievers: NSAIDs, Cocker spaniels and German shepherd: phenobarbital; herding breeds: MDR1-polymorphisms (deranged P-glycoprotein production) affecting various drugs or other pharmacogenetic factors.

Mean Age and Range

- Any age.
- Young animals (<16 weeks of age)—immature hepatic metabolic and excretory pathways; less discriminating toxin ingestion.

SIGNS

General Comments

- Signs may reflect chronic long-term or single acute exposure.
- Detailed history essential—environmental, drug, and past medical history.

Historical Findings

- Malaise to moribund state
- Hyporexia, vomiting, diarrhea, jaundice

Physical Examination Findings

- Variable body temperature (hypothermic to febrile), vomiting, diarrhea, weakness
- Icterus—overt or progressive (48–96 hours post-exposure)
- Ascites—rare (grave sign)
- HE or coma
- DIC secondary to liver necrosis—hemorrhage; petechia; ecchymosis

CAUSES

Any drug, toxin, or xenobiotic may cause hepatotoxicity, variable severity, any individual.

Commonly Reported Drugs (dogs and cats unless otherwise noted)

- Acetaminophen
- Anabolic steroids
- Azole antifungals
- Amiodarone
- Amoxicillin
- Azathioprine
- NSAID (dogs)
- CCNU (dogs)
- Cyclosporine
- Diazepam (cats)
- Doxycycline
- Glucocorticoids (dogs)
- Glucosamine-based joint supplements (dogs)
- Griseofulvin (cats)
- Ketoconazole
- Mebendazole (dogs)
- Methimazole (cats)
- Mitotane (Lysodren, op/DDD) (dogs)
- Oxibendazole (dogs)
- Phenytoin (dogs)
- Primidone (dogs)
- Phenobarbital (dogs)
- Stanozolol (cats)
- Sulfa antibiotics (dogs)
- Tetracycline
- Thiacetarsamide (dogs, cats)
- Trimethoprim-sulfadiazine (dogs)

Common Environmental Toxins

- Amanita mushrooms (amanitin-containing mushrooms)
- Aflatoxins/mycotoxins
- Blue-green algae (Cyanobacteria)
- Chlorinated compounds
- Cycad (sago palm nuts)
- Heavy metals (Pb, Zn, Mn, Ar, Fe, Cu)
- Phenolic chemicals (especially cats)
- Gossypol from cottonseed

Endotoxins

- Enteric organisms—*Clostridium perfringens*; Gram-negative organisms
- Food poisoning—*Staphylococcus*; *E. coli*; *Salmonella*

Nutritional/Herbal

- Atractylis gummifera
- Black cohosh
- Callilepis laureola
- Chaparral
- Comfrey extracts (pyrrolizidine alkaloids)
- Chinese herbal medicines (certain constituents, contents difficult to characterize)
- Germander
- Greater celandine
- Green tea extract
- Lipoic acid (cats)
- Kava kava (dogs)
- Licorice
- Lipoic acid (cats)
- Mistletoe
- Pennyroyal
- Senna
- Usnic acid
- Valerian
- Xylitol (sugar substitute; dogs)

RISK FACTORS

- Medications influencing hepatic metabolism (enzyme inducers and P450 inhibitors).
- Antecedent hepatic disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Infectious disorders affecting liver/biliary tract: leptospirosis, cholecystitis, FIP, toxoplasmosis, rickettsial diseases (RMSF, ehrlichiosis).
- Acute necrotizing pancreatitis.
- Traumatic or hypoxic liver injury.
- Hepatic neoplasia
- Diagnosis of hepatotoxicity requires integration of history, environment, food, medications, and temporal relationship(s).

CBC/BIOCHEMISTRY/URINALYSIS

- PCV and total solids—often normal or high in acute hepatotoxicosis (shock or dehydration).
- ALT reflects cellular membrane damage and leakage of this cytosolic enzyme; may be 10- to 100-fold normal; monitor for subsequent decline over 3–28 days; prognosis not correlated with magnitude of increase. Increased ALT may precede increases in bilirubin and ALP.
- AST—may reflect more severe injury (mitochondrial) than ALT; also increased in myonecrosis.
- ALP—usually continues to rise for days/weeks while ALT falls.
- CK—high activity associated with myonecrosis; some hepatotoxins also damage muscle (e.g., feline diazepam toxicity); high AST with normal CK confirms hepatic damage.
- Bilirubin, Albumin, BUN, and glucose—variable.
- Glucosuria and granular casts if proximal renal tubular injury (e.g., carprofen, copper). Some toxins suppress hepatic enzyme synthesis impairing clinical recognition of hepatic injury (e.g., blue-green algae, aflatoxin).

OTHER LABORATORY TESTS

- Coagulation profile—PT, APTT, FDP, platelets, and AT variable; monitor for DIC. Buccal mucosal bleeding time if others unavailable.
- Low protein C activity: biomarker for blocked protein transcription in aflatoxicosis.
- Non-icteric—paired TSBA (pre- and post-meal) assess hepatic function.

IMAGING

- Abdominal radiography—acute toxicity: normal to large liver; chronic injury: variable liver size.
- Abdominal ultrasonography—variable echogenicity, hepatic size, and margins.

DIAGNOSTIC PROCEDURES

- Hepatic biopsy—seldom indicated in acute toxicity (excessive risk/unnecessary for diagnosis/treatment); more helpful in confusing chronic hepatic injury; laparoscopic sampling more dependable; if desire core needle biopsies, need multiple samples using 14- to 16-gauge biopsy needle.
- Fine needle aspiration helpful if find neoplasia or etiologic agents; many toxins induce hepatocyte lipid vacuolation; variable dysplastic cell morphology in aflatoxin and cycad toxicity.

(CONTINUED)

HEPATOTOXINS**PATHOLOGIC FINDINGS**

Variable, depends on toxin, mechanism of cell injury, acinar zone of metabolism or product accumulation, or vascular injury and chronicity.

**TREATMENT****APPROPRIATE HEALTH CARE**

Inpatient—critical care setting

NURSING CARE

- Prevention/correction of shock imperative.
- Fluid therapy—maintain hepatic perfusion to improve oxygenation and toxin removal; administer maintenance requirements—monitor oncotic pressure and ongoing losses/hydration status; administer colloid or plasma if albumin < 2.0 g/dL; fluid therapy—avoid lactate-containing fluids in fulminant hepatic failure.
- Colloid administration—plasma initially preferred for delivery of clotting and anticoagulant precursor proteins followed by cautious use of synthetic colloid, if warranted.
- Bleeding tendencies—provide vitamin K₁ (0.5–1.5 mg/kg SC or IM q12–24h); administer fresh whole blood or fresh frozen plasma as needed. (**Caution:** stored blood products may have high ammonia concentration, causing HE.)
- Nasal oxygen—if compromised peripheral perfusion (hypotension) or pulmonary edema; may improve oxygen delivery to hepatic tissue.
- Oxidant damage likely involved in most hepatotoxic events—administer thiol or GSH donors (see below); GSH important for direct conjugation of certain toxins, may facilitate detoxification of some metabolites, enhances antioxidant protection, helps correct cell redox status conferring resistance to apoptosis, promoting cell membrane repair, and cell regeneration.
- Monitor urine output—diuretics as appropriate; see Renal Failure, Acute.
- Hypoglycemia—administer dextrose (2.5–5%) to maintain euglycemia as needed.

DIET

- Protein—normal, unless overt HE.
- Nutritional support—Antiemetics (maropitant or ondansetron) and antidyspepsics (pantoprazole) lessen nausea/promote appetite. If normal body condition score and acute disease, can wait up to 48 h for patient to voluntarily ingest food. If not eating within 48 h, first preference is NE tube enteral nutrition.
- Energy—strict calculation cumbersome. Initial starting points are: bodyweight kg × 50 (dogs) and bodyweight kg × 45 (cats); modified based upon size, body condition and monitoring—begin with 10–20% of calculated requirement; gradually increase to full requirement over 3–5 days. PPN only if unable to feed enterally. PPN/TPN can cause

severe complications—only use if familiar with techniques/complications.

CLIENT EDUCATION

- Potential for 3–10 days of ICU.
- Many recover, but post-necrotic cirrhosis, acquired shunting, and chronic hepatitis can develop later.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Electrolyte supplementation—KCl (must monitor serum potassium).
- Short-acting glucocorticoids—for endotoxic shock (prednisolone sodium succinate)—controversial.
- Ampicillin or metronidazole theoretically protect against transmural migration of enteric flora.
- Antioxidant therapy—crisis intervention: *N*-acetylcysteine for acute or fulminant hepatic necrosis (140 mg/kg IV load, followed by 70 mg/kg IV q6–8h; give over 20 minutes not by CRI, dilute in saline, administer with non-pyrogenic 0.25 µm filter); when patient can accept oral medications and condition stabilizes, change to oral S-adenosylmethionine (SAMe; 20 mg/kg enteric-coated tablet PO q24h, on an empty stomach); vitamin E as d-α-tocopherol acetate (10 IU/kg q24h PO, although currently no evidence of clinically important benefit from vitamin E).
- B-complex vitamins—parenteral; co-factors for hepatic metabolism.
- Silybin (active component of silymarin [milk thistle extract]); prefer form complexed with phosphatidylcholine (2–5 mg/kg q24h PO); may augment liver regeneration and provide antioxidant, hepatoprotective, and antifibrotic effects.
- Ursodeoxycholic acid—primarily for chronic hepatopathies (15 mg/kg/day PO), give with food. Provide taurine supplementation in anorectic cats (obligate taurine bile acid conjugation).

CONTRAINdicATIONS

Avoid known hepatotoxic drugs and those that require or inhibit hepatic metabolism.

PRECAUTIONS

- Use drugs listed as hepatotoxins with caution.
- Use caution when catheterizing large vessels or doing diagnostic needle aspirates/biopsies if coagulopathy.

**FOLLOW-UP****PATIENT MONITORING**

- Prevent hypothermia.
- Monitor blood glucose, electrolytes, PCV—frequently; fluctuations occur rapidly in critically ill patients.
- CBC/platelet, serum biochemical analyses, coagulation tests—typically monitor q48h or as warranted.
- Monitor urine output.

PREVENTION/AVOIDANCE

Close scrutiny of environment and future medications

POSSIBLE COMPLICATIONS

- DIC or hemorrhage
- Hepatic encephalopathy
- Progressive hepatic failure
- Post-necrotic cirrhosis with acquired shunting/ascites

EXPECTED COURSE AND PROGNOSIS

- Usually need 2–5 days to estimate prognosis.
- Negative indicators: intractable emesis, hematemesis, intolerance to supportive treatments, oliguria, DIC, HE; decline of ALT with increasing bilirubin and/or lowering of serum albumin; lowering cholesterol.
- Positive indicator: ALT declining by 20–30% or more every 48–72 hours, with other evidence of improvement, is positive indicator.
- Post-necrotic cirrhosis—possible in 2–6 months.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- Hepatitis
- Fibrosis
- Hepatic encephalopathy
- Hepatic lipidosis (cats)
- Icterus
- Ascites
- Hypoglycemia
- Sepsis

AGE-RELATED FACTORS

- Young animals may have greater exposure and risk for toxin ingestion.
- Older animals—may have diseases requiring drug therapies increasing their risk (e.g., cimetidine, phenobarbital, NSAIDs).

SEE ALSO

- Acetaminophen (APAP) Toxicosis
- Cirrhosis and Fibrosis of the Liver

HEPATOZOOONOSIS

BASICS

OVERVIEW

- Disease caused by infection with the protozoan *Hepatozoon americanum* or *Hepatozoon canis*. This chapter focuses on systemic infection with *Hepatozoon americanum*—the primary cause of American canine hepatozoonosis.
- Hepatozoon canis* is less prevalent in the United States than *Hepatozoon americanum*. It is also less virulent and infections are typically subclinical.
- Infection typically involves muscle and bone.
- Dogs—more common in the southern and southeastern United States.
- Cats—uncommon in the United States; one reported case from Hawaii.

H

SIGNALMENT

- Dogs and rarely cats
- No age, breed, or sex predilections

SIGNS

- Lameness and stiff gait
- Waxing and waning fever
- Mucopurulent ocular discharge
- Hyperesthesia
- Weight loss and cachexia
- Polyuria and polydipsia in some cases if glomerulonephritis is present

CAUSES & RISK FACTORS

- Amblyomma maculatum*—tick ingestion.
- Ingestion of infected paratenic hosts (predation or scavenging).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Neoplasia
- Endocarditis
- Immune-mediated polyarthritis or polymyositis
- Chagas disease
- Leishmaniasis
- Meningitis/meningoencephalitis
- Hypertrophic osteopathy
- Ehrlichiosis
- Discospondylitis
- Hepatic failure

CBC/BIOCHEMISTRY/URINALYSIS

- Neutrophilic leukocytosis, usually profound (20,000–200,000 WBC/ μ L) sometimes with a left shift.
- Anemia—mild to moderate, usually non-regenerative.
- Usually have a normal platelet count unless there is a co-infection.

- High serum ALP activity.
- Decreased urea nitrogen.
- Despite severe myositis, creatinine kinase concentrations are often within reference range.
- Hyperglobulinemia.
- Hypoalbuminemia.

OTHER LABORATORY TESTS

Blood films—in rare cases identify organisms in circulating neutrophils and monocytes.

IMAGING

Radiographs—pelvis, lumbar vertebrae, and long bones; reveal periosteal proliferation.

DIAGNOSTIC PROCEDURES

- Muscle biopsy
- Polymerase chain reaction on blood or muscle

PATHOLOGIC FINDINGS

- Cachexia.
- Muscle atrophy: “onion-skin” meronts and pyogranulomatous myositis.
- Enlarged liver and spleen—may contain meront stages on histopathology.
- Periosteal proliferation of bone.

TREATMENT

- Inpatient—for severe pain; provide symptomatic relief.
- Pain management—as for any musculoskeletal disease.
- General activity level and appetite—on pain level.
- Most dogs will require life-long treatment to maintain clinical remission.

MEDICATIONS

DRUG(S)

- Mostly palliative as no treatments have been shown to clear infection.
- Combination therapy (TCP) initially:
 - Trimethoprim = sulfadiazine—15 mg/kg PO q12h for 14 days.
 - Clindamycin—10 mg/kg PO q8h for 14 days.
 - Pyrimethamine—0.25 mg/kg PO q24h for 14 days.
- Followed with long-term therapy:
 - Decoquinate 10–20 mg/kg PO q12h for up to 33 months (possibly indefinite).
 - Ponazuril 10 mg/kg PO q12h for 28 days has shown promise as an alternative initial treatment. Long-term therapy with decoquinate is still necessary.
 - Glucocorticoids—may give temporary relief but are not routinely recommended.
 - NSAIDs.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

None

FOLLOW-UP

PATIENT MONITORING

- Difficult to monitor organisms in chronically infected dogs.
- Best to monitor for clinical improvement.

PREVENTION/AVOIDANCE

- Control ticks within the household or kennel.
- Avoid predation and scavenging.

POSSIBLE COMPLICATIONS

- Glucocorticoids—may exacerbate clinical disease.
- Radiographic changes may never occur.

EXPECTED COURSE AND PROGNOSIS

- Treatment typically results in improvement of clinical signs and quality of life but does not cure the infection.
- Treatment is likely to be needed for the remainder of the patient's life.
- If clinical relapse occurs, repeat of both initial and long-term treatments are recommended.

MISCELLANEOUS

ZOONOTIC POTENTIAL

No reported risk to humans

ABBREVIATIONS

- ALP = alkaline phosphatase
- NSAIDS = nonsteroidal anti-inflammatory drug
- TCP (trimethoprim-sulfa, clindamycin, and pyrimethamine)

HERPESVIRUS INFECTION—DOGS

BASICS

OVERVIEW

CHV causes a systemic infection in immunologically naïve animals; systemic disease in pups <2–3 weeks of age is usually fatal; systemic infection in naïve pregnant dams causes fetal death, mummification, and abortion. Pups born to immune dams develop life-long infection. After primary infection, CHV becomes latent in neurons of sensory ganglia, but can reactivate when animals are stressed or are receiving immunosuppressive treatments leading to excretion in nasal secretions; reactivation associated with mild respiratory illness or mild to severe ocular disease. Prevalence of latent infection is high; CHV ocular disease in adult animals is common, but underdiagnosed.

- Mature non-pregnant animals usually have inapparent, localized infections in the nasopharynx or external genitalia.
- Localized genital infections reported in both sexes.

SIGNALMENT

• All members of the canine family are susceptible.

- Death usually occurs between 9 and 14 days after birth; range is from 1 day (prenatal infection) to about 1 month (neonatal infection).
- Most commonly reported in purebred dogs, although there is no breed predilection. Ocular signs associated with CHV are common, but underdiagnosed.

SIGNS

- Dyspnea.
- Serous to mucopurulent nasal discharge.
- Anorexia.
- Grayish yellow or green, soft, odorless stool.
- Persistent, agonizing crying.
- Encephalitic signs.
- Severe gasping before death.
- Petechial hemorrhages on the mucous membranes occasionally seen.
- Incubation period in neonatal pups is 4–6 days.
- Onset sudden; death occurs 12–36 hours later.
- Some pups are found dead without premonitory signs.
- Occasionally, pups with mild signs survive but often later develop ataxia, persistent vestibular signs, or blindness.
- Mature females may have lymphofollicular or hemorrhagic lesions in the vagina.
- Infertility—evidence of increased seroprevalence in kennels with reproductive problems.
- Conjunctivitis—CHV is a common cause of acquired idiopathic conjunctivitis.
- CHV ulcerative keratitis—common sequelae of recrudescent infections.

CAUSES & RISK FACTORS

- CHV—typical herpesvirus; only one serotype described; latent infection is endemic in domestic dogs; young, naïve females and their newborn pups at greatest risk.
- Closed breeding kennels—CHV endemic; infection is less common and most adults are immune; newly introduced breeding bitches at high

risk.

- Abortion storms with massive pup losses can occur when pregnant bitches maintained in private homes are assembled for whelping.
- Immunosuppressive drugs may provoke reactivation of latent CHV with associated transient ocular disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Bacteria (brucellosis, coliform bacteria, or streptococci), toxoplasmosis, toxic substances—no typical gross lesions of CHV.
- MVC (canine parvovirus type 1)—causes enteric or respiratory disease; no characteristic CHV lesions.
- Distemper and canine adenovirus type 1 (canine hepatitis)—uncommon; no characteristic CHV renal lesions.

CBC/BIOCHEMISTRY/URINALYSIS

Thrombocytopenia may occur

DIAGNOSTIC PROCEDURES

- Immunofluorescence or immunoperoxidase staining; reveal viral antigen in most organs, especially in the lesion areas.
- Cell cultures—viral isolation accomplished from several tissues, especially lung and kidney; refrigerate (don't freeze) samples.
- PCR from samples of suspected tissues; e.g., conjunctival swabs; PCR can be used to screen for naïve animals prior to breeding.

PATHOLOGIC FINDINGS

Gross

- Characteristic lesions—disseminated focal necrosis; hemorrhage in several organs.
- Kidneys—diffuse hemorrhagic areas, necrotic foci, and hemorrhagic infarcts pathognomonic.
- Lungs, liver, adrenal glands—diffuse foci of hemorrhage and necrosis.
- Small intestine variably affected.
- Lymph nodes and spleen—generalized enlargement; consistent finding.
- Panuveitis.

Histopathologic

- Foci of perivasculär necrosis—with mild cellular infiltration; kidney, lung, liver, spleen, small intestine, and brain.
- Lesions in the CNS of recovered pups—non-suppurative ganglionitis; meningoencephalitis; necrosis in the cerebellum and retina; acidophilic intranuclear inclusions may be observed but are not abundant.
- Necrotizing lesions—may be seen in fetal placentas.

TREATMENT

- Not recommended.
- Antiviral drug therapy—unsuccessful for systemic infection.
- Immune sera from recovered bitches—beneficial in reducing pup deaths when antiserum is given before onset of illness.

Topical cidofovir ophthalmic solution may be effective for ocular disease in adult animals—no controlled clinical trials as yet.

MEDICATIONS

DRUG(S)

N/A

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Use of systemic immunosuppressive drugs in adult animals may induce reactivation of latent CHV possibly leading to ocular disease (conjunctivitis and/or keratitis).

H

FOLLOW-UP

- Normal litters can be expected from bitches that have suffered pup losses or abortions.
- An inactivated subunit vaccine for pregnant bitches is available in Europe but benefit unknown.
- Isolate pregnant dams, especially young bitches, when introduced into a kennel; adults commonly shed latent CHV in nasal secretions for 1–2 weeks after encountering newly introduced dogs.
- Surviving pups may suffer deafness, blindness, encephalopathy, or renal damage.

MISCELLANEOUS

AGE-RELATED FACTORS

- Dogs of all ages susceptible.
- Fatal illness occurs only in pups infected during the neonatal period (1–10 days after birth).

PREGNANCY/FERTILITY/BREEDING

Infection of dams during last 3 weeks of gestation—fetal infections with death and mummification, or ill pups that die shortly after birth.

ABBREVIATIONS

- CHV = canine herpesvirus
- CNS = central nervous system
- MVC = minute virus of canines
- PCR = polymerase chain reaction

HIATAL HERNIA

BASICS

OVERVIEW

• Hiatal herniation – when abdominal contents (most commonly the stomach), herniate cranial to the diaphragm into the thorax through the esophageal hiatus. Four types of hernia have been described:
◦ Type I (sliding hiatal hernia; most common)
◦ Type II (paraesophageal hiatal hernia)
◦ Type III (includes elements of both type I and II)
◦ Type IV (herniation of organs other than the stomach)
• Congenital and acquired hiatal hernias have been reported. Acquired most commonly associated with severe upper respiratory disease (brachycephalic syndrome, laryngeal paralysis).

H

SIGNALMENT

- Dogs and less commonly cats
- Prevalence—higher in English bulldogs, Shar-Peis and other brachycephalic breeds. Type I more commonly congenital and therefore seen in younger animals.

SIGNS

Typically recognized in young animals 2–6 months of age. Signs can coincide with weaning. Most signs secondary to GER and esophagitis.
• Regurgitation
• Dysphagia
• Hypersalivation
• Lip smacking
• Inability to gain weight
• Vomiting
• Respiratory distress
• Anorexia
• Weight loss

CAUSES & RISK FACTORS

Congenital. Acquired—traumatic event ± severe upper respiratory disease; brachycephalic airway syndrome.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Physical examination findings are generally unremarkable unless aspiration pneumonia or chronic weight loss are present.
- Distinguish from other causes of weight loss or regurgitation.

CBC/BIOCHEMISTRY/URINALYSIS

No specific abnormalities. May find inflammatory leukogram secondary to associated pneumonia.

OTHER LABORATORY TESTS

N/A

IMAGING

Thoracic Radiographic Findings—Cranial displacement of stomach. Soft tissue mass in the caudal thorax adjacent to diaphragm. Gas-filled viscera in thorax. Hiatal hernia is infrequently diagnosed on survey thoracic radiographs alone.

Positive Contrast Esophagram—Preferably performed using videofluoroscopy. Helps to confirm the diagnosis and differentiate

between types I and II hiatal hernias. Can also diagnose associated gastroesophageal reflux and esophageal dysmotility. False-negative studies are common due to the highly intermittent and dynamic nature of hiatal herniation.

DIAGNOSTIC PROCEDURES

Upper gastrointestinal endoscopy—can document gastroesophageal reflux, esophageal strictures, esophagitis and hiatal hernia in some cases. Secondary evidence may only be detectable if herniation does not occur during the study.

TREATMENT

Not all dogs that have radiographic evidence require treatment. Conservative therapy can be successful in controlling clinical signs in dogs with mild hiatal herniation.

MEDICAL MANAGEMENT

- Can often be managed as an outpatient unless animal has severe aspiration pneumonia.
- Reduce gastric acid secretion (proton pump inhibitors are superior to H₂ receptor antagonists).
- Increase rate of gastric emptying and increase LES sphincter tone (prokinetic agents such as cisapride).
- Provide esophageal mucosal protection (sucralfate).
- Feed a low-fat diet in an elevated position.
- 30-day trial of medical management before surgery often recommended; not all patients require surgery.

SURGICAL MANAGEMENT

- Patients nonresponsive to medical therapy
- Treat with antacids and prokinetics prior to surgery
- Surgical procedures (used alone or in combination)
 - Phrenoplasty
 - Esophagopexy
 - Left-sided gastropexy

MEDICATIONS

DRUG(S)

- H₂ receptor antagonists/antacids—help to neutralize gastric pH and therefore reduce esophagitis secondary to GER
 - Famotidine 0.5–1 mg/kg PO, IV q12h
 - Ranitidine 1–2 mg/kg PO, IV, IM q8–12h
 - Proton pump inhibitors—are more potent than H₂ receptor antagonists
 - Omeprazole 0.7–1.5 mg/kg q24h PO
 - Pantoprazole 0.7–1.5 mg/kg q24h IV
 - Prokinetics—increase gastric emptying
 - Metoclopramide 0.2–0.5 mg/kg q6–8h PO or 1–2 mg/kg/24h as a CRI
 - Cisapride 0.5 mg/kg q8–12h PO
 - Mucosal protectants
 - Misoprostol 2–5 µg/kg q8h PO 1 h before or 2 h after food or other medications.

FOLLOW-UP

PATIENT MONITORING

- Long-term medical therapy may be indicated in both surgically and conservatively managed patients.
- Postoperative—monitor for dyspnea, worsening regurgitation (may require second surgery), abdominal distension that could result from overtightening of the hiatus resulting in an inability to eructate.

POSSIBLE COMPLICATIONS

Continuation of clinical signs, bloat episodes

EXPECTED COURSE AND PROGNOSIS

- Overall prognosis is good.
- Not all patients will necessarily need surgical intervention.
- When medical management fails, surgical intervention leads to a positive outcome in the majority of cases.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Often found in dogs with brachycephalic airway disease or other forms of upper airway obstructive diseases. Hypothesized that profound decreases in intrathoracic pressures generated in dogs with upper airway obstruction may act to pull the stomach into the thorax through the hiatus. Some evidence that gastroesophageal reflux can also worsen clinical signs of upper respiratory disease due to irritation of upper respiratory area with irritant gastric contents or associated bronchospasm of the lower airway.

ABBREVIATIONS

- GER = Gastroesophageal reflux
- LES = Lower esophageal sphincter

HIP DYSPLASIA

BASICS

DEFINITION

A developmental syndrome resulting in osteoarthritis of the coxofemoral joints

PATHOPHYSIOLOGY

- Developmental defect initiated by a genetic predisposition to subluxation of the immature hip joint.
- Poor congruence between the femoral head and acetabulum; creates abnormal forces across the joint; interferes with normal development (leading to irregularly shaped acetabula and femoral heads); overloads the articular cartilage (causing microfractures and osteoarthritis).

SYSTEMS AFFECTED

Musculoskeletal

GENETICS

- Complicated, polygenic transmission.
- Expression is determined by an interaction of genetic and environmental factors.
- Heritability index—depends on breed.

INCIDENCE/PREVALENCE

- One of the most common skeletal diseases encountered clinically in dogs.
- Actual incidence—unknown; depends on breed.
- Incidence in cats is significantly lower than in dogs.

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Dog, rarely cat

Breed Predilections

- Large-breed dogs—Saint Bernard, German shepherd, Labrador retriever, golden retriever, rottweiler.
- Smaller-breed dogs—may be affected; less likely to demonstrate clinical signs.
- Cats—more commonly affects purebred cats. Reportedly affects approximately 18% of Maine coon cats.

Mean Age and Range

- Begins in the immature dog. Onset of clinical signs varies with the severity of hip laxity in the immature dog and with worsening secondary OA in the mature dog.
- Clinical signs—may develop after 4 months of age in dogs with severe laxity; may also develop at any age after onset of secondary OA.

Predominant Sex

- Dogs—none
- Cats—more common in female cats

SIGNS

General Comments

- Severity of signs depends on the degree of joint laxity, degree of OA, and chronicity of the disease.

- Early—related to joint laxity.
- Later—related to OA.

Historical Findings

- Decreased activity.
- Difficulty rising.
- Reluctance to run, jump, or climb stairs.
- Intermittent or persistent hind limb lameness—often worse after exercise.
- Bunny-hopping or swaying gait.
- Narrow stance in the hind limbs.

Physical Examination Findings

- Pain on palpation or manipulation of the hip joint(s).
- Increased joint laxity (positive Ortolani sign)—characteristic of early disease; may not be a finding in chronic cases owing to periarthritis fibrosis.
- Crepitus.
- Decreased range of motion in the hip joints.
- Atrophy of thigh muscles.

CAUSES

- Genetic predisposition for hip laxity.
- Rapid weight gain, nutrition level, and pelvic muscle mass—fluence expression and progression.

RISK FACTORS

N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cranial cruciate ligament rupture: up to 1/3 of dogs referred for treatment of hip dysplasia are suffering from concurrent cranial cruciate rupture.
- Degenerative myelopathy.
- Lumbosacral instability.
- Unilateral or bilateral stifle disease.
- Panosteitis.
- Polyarthropathies.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

- Ventrodorsal hip-extended radiographs—commonly used for diagnosis; may need sedation or general anesthesia for accurate positioning.
- Early radiographic signs—subluxation of the hip joint with poor congruence between the femoral head and acetabulum; initially normally shaped acetabulum and femoral head; with disease progression, shallow acetabulum and flattened femoral head.
- Radiographic evidence of OA—flattening of the femoral head; shallow acetabulum; periarthritis osteophyte production; thickening of the femoral neck; sclerosis of the subchondral bone; periarthritis soft tissue fibrosis. Remodeling of the femoral neck is uncommon in cats.

- Distraction radiographs—quantify joint laxity; may accentuate the laxity for more accurate diagnosis.

- Dorsal acetabular rim view radiographs—evaluate acetabular rim; assess dorsal coverage of the femoral head.

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Early—normal femoral head and acetabulum; may note joint laxity and excess synovial fluid.
- With progression—malformed acetabulum and femoral head; synovitis; articular cartilage degeneration.
- Chronic—may note full-thickness cartilage erosion.

H

TREATMENT

APPROPRIATE HEALTH CARE

- May treat with conservative medical therapy or surgery.
- Depends on the patient's size, age, and intended function; severity of joint laxity; degree of OA; clinician's preference; and financial considerations of the owner.

NURSING CARE

- Physical therapy (passive joint motion)—decreases joint stiffness; helps maintain muscle integrity.
- Swimming (hydrotherapy)—excellent non-concussive form of physical therapy; encourages joint and muscle activity without exacerbating joint injury.

ACTIVITY

- As tolerated.
- Swimming—recommended to maintain joint mobility while minimizing weight-bearing activities.

DIET

- Weight control—important; decrease the load applied to the painful joint; minimize weight gain associated with reduced exercise.
- Supplementation with omega-3 fatty acids (in commercial diets or as a food additive) is beneficial to decrease pain and inflammation and improve function.

CLIENT EDUCATION

- Discuss the heritability of the disease.
- Explain that medical therapy is palliative, because the joint instability is not corrected.
- Warn the client that joint degeneration often progresses unless a corrective osteotomy procedure is performed early in the disease.
- Explain that surgical procedures can salvage joint function once severe joint degeneration occurs.

SURGICAL CONSIDERATIONS

Triple or Double Pelvic Osteotomy

- Corrective procedure; designed to reestablish congruity between the femoral head and the acetabulum.

HIP DYSPLASIA

(CONTINUED)

- Immature patient (6–12 months of age).
- Rotate acetabulum—improve dorsal coverage of the femoral head; correct the forces acting on the joint; minimize the progression of OA, but OA frequently progresses on radiographs even though progression is not clinically apparent in the dog.

Juvenile Pubic Symphysiodesis

- Pubic symphysis is fused at an early age (8–16 weeks) using electrocautery.
- Causes ventroversion of the acetabulum to better cover the femoral head.
- Improves joint congruence and stability—similar effects as TPO without surgical implants.
- Minimal morbidity; easy to perform—must be performed very early (ideally 3–4 months of age) to achieve effect; minimal effect achieved if performed after 5 months of age.

Total Hip Replacement

- Indicated to salvage function in mature dogs with severe degenerative disease that is unresponsive to medical therapy.
- Pain-free joint function—reported in > 90% of cases.
- Unilateral joint replacement—provides acceptable function in ~80% of cases.
- Staged bilateral joint replacement now chosen by 50% of owners.
- Complications—luxation; sciatic neuroparaxia; infection.

Excision Arthroplasty

- Removal of the femoral head and neck to eliminate joint pain.
- Extremely important to achieve a smooth osteotomy close to femoral shaft.
- Primarily a salvage procedure—for significant OA; when pain cannot be controlled medically; when total hip replacement is cost-prohibitive.
- Best results—small, light dogs (< 20 kg); patients with good hip musculature.
- Can provide good results in larger dogs.
- A slightly abnormal gait often persists.
- Postoperative muscle atrophy—common, particularly in large dogs.

Denervation Procedure

- Surgical procedure described in anecdotal literature to reduce pain associated with HD.
- Does not improve joint conformation or OA.
- Little objective scientific evidence exists for this procedure's effectiveness.
- Most recent studies suggest that the treatment does not improve the treated hip, but may slow the development of further clinical signs.

MEDICATIONS

DRUG(S) OF CHOICE

- Analgesics and anti-inflammatory drugs—minimize joint pain (and thus

stiffness and muscle atrophy caused by limited usage); decrease synovitis.

- Medical therapy—does not correct biomechanical abnormality; degenerative process likely to progress; often provides only temporary relief of signs.
- Agents—carprofen (2.2 mg/kg PO q12h or 4.4 mg/kg PO q24h); etodolac (10–15 mg/kg PO q24h); deracoxib (3–4 mg/kg PO q12h for 1 week, then 2 mg/kg PO q12h); firocoxib (4 mg/kg PO q24h).
- Diet supplementation with omega-3 fatty acids (fish oils) decreases joint inflammation and provides pain relief.

CONTRAINdications

Avoid corticosteroids—potential side effects; articular cartilage damage associated with long-term use.

PRECAUTIONS

- NSAIDs—gastrointestinal upset may preclude use in some patients.
- Carprofen—reported to cause acute hepatotoxicity in some dogs.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

Polysulfated glycosaminoglycans, glucosamine, and chondroitin sulfate—may have a chondroprotective effect in OA, but recent evidence suggests they are not or are only minimally efficacious.

FOLLOW-UP

PATIENT MONITORING

- Clinical and radiographic monitoring—assess progression.
- Medical treatment—clinical deterioration suggests an alternative dosage or medication or surgical intervention.
- Triple pelvic osteotomy—monitored radiographically; assess healing, implant stability, joint congruence, and progression of OA.
- Hip replacement—monitored radiographically on an annual basis; assess implant stability.

PREVENTION/AVOIDANCE

- Best prevented by not breeding affected dogs.
- Pelvic radiographs—may help identify phenotypically abnormal dogs; may not identify all dogs carrying the disease.
- Do not repeat dam-sire breedings that result in affected offspring.
- Special diets designed for rapidly growing large-breed dogs—may decrease the severity.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

Joint degeneration usually progresses—most patients lead normal lives with proper medical or surgical management.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

N/A

PREGNANCY/FERTILITY/BREEDING

Do not breed affected dogs; added weight owing to pregnancy may exacerbate clinical signs.

ABBREVIATIONS

- HD = hip dysplasia
- OA = osteoarthritis
- NSAID = nonsteroidal anti-inflammatory drug
- TPO = triple pelvic osteotomy

BASICS

OVERVIEW

The histiocytic diseases encompass a wide spectrum of diseases characterized by a variety of biologic behaviors and include: canine cutaneous histiocytoma, cutaneous histiocytosis (CH), systemic histiocytosis (SH), histiocytic sarcoma (HS) and hemophagocytic histiocytic sarcoma (HHS). Subtypes are classified by the cell of origin (i.e., Langerhans dendritic cell, interstitial dendritic cell, monocyte/macrophage).

SIGNALMENT

Cutaneous Histiocytoma

- Common in dog, extremely rare in cat.
- More than 50% of affected dogs are < 2 years old.
- Commonly affected breeds include boxer, dachshund, cocker spaniel, American Staffordshire terrier, Great Dane, Boston terrier, Doberman pinscher, miniature schnauzer, Shetland sheepdog, Labrador retriever, West Highland white terrier, and bull terrier.
- No breed predilection in cats.
- No sex predilection in cats or dogs.

Cutaneous Histiocytosis (CH)

- Uncommon in dog and cat
- Younger dogs more commonly affected (range 2–11 years)
- No breed predilection
- Male predilection

Systemic Histiocytosis (SH)

- Uncommon in dog and cat
- Commonly affected breeds include Bernese mountain dog (BMD), rottweiler, golden retrievers, and Irish wolfhound
- Male predilection in the BMD
- Younger dogs more commonly affected (range 3–9 years)

Histiocytic Sarcoma (HS)

- Common in dogs, rare in cats
- Commonly affected breeds include BMD, flat-coated retrievers, rottweiler, golden retriever, Labrador retriever, and Pembroke Welsh corgi
- Middle-aged or older dogs
- Possible male predisposition

Hemophagocytic Histiocytic Sarcoma (HHS)

Similar signalment to HS

SIGNS

Cutaneous Histiocytoma

- Solitary “button-like,” raised, well-circumscribed, hairless dermal lesion that may be ulcerated.
- Often fast growing in first 1–4 weeks.
- Considered nonpainful.
- Common sites—head, ear pinna, and limbs.

Cutaneous Histiocytosis

- Cutaneous/subcutaneous nodules that may wax and wane, disappear with new lesions appearing at different sites.
- Limited to the skin, subcutis, and local draining lymph node(s); lack of systemic extension beyond peripheral lymph nodes is a distinguishing factor from SH.
- The head, pinna,

extremities (including footpad) and scrotum are commonly affected.

Systemic Histiocytosis

- Cutaneous/subcutaneous lesions may be similar to CH.
- Other common sites include lymph nodes, bone marrow, scrotum, spleen, liver, lung, and mucous membranes (nasal and ocular tissue).
- Clinical signs include depression, anorexia, weight loss, conjunctivitis and respiratory difficulty.

Histiocytic Sarcoma

- Lameness and a palpable mass (periarticular location) or lymphadenopathy often reported.
- Clinical signs vary depending on site(s) of involvement by the tumor, however, lethargy, anorexia, weight loss, respiratory signs, fever, vomiting, diarrhea, and lymphadenopathy are reported.
- Reported anatomic sites include lung, lymph node, liver, spleen, stomach, pancreas, mediastinum, skin, skeletal muscle, central nervous system, bone and bone marrow; the author has also seen cases with intranasal and ocular involvement.

Hemophagocytic Histiocytic Sarcoma

- Similar clinical signs to HS, however patients tend to be symptomatic (secondary to widespread disease).
- Rather than presenting as solid tumors, this subtype tends to present in a more infiltrative manner, causing hepatosplenomegaly and myelophthisis.

CAUSES & RISK FACTORS

- Histiocytoma is hypothesized to represent an atypical proliferation or reactive hyperplasia rather than a true cancer.
- SH has a possible familial causation in BMD.
- HS and HHS likely have a genetic origin due to breed predilections (specifically in the BMD).
- History of joint disease may be a predisposing factor in periarticular HS.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Differentiate from focal granulomatous inflammation, other sarcomas, other round cell tumors (transmissible venereal tumor, lymphoma, plasma cell tumor, mast cell tumor) and each distinctive subtype of the histiocytic disease.
- Differentiate HHS from immune-mediated anemia/thrombocytopenia and tick-borne diseases.

CBC/BIOCHEMISTRY/URINALYSIS

- *Histiocytoma/CH, SH:* Usually normal.
- *HS/HHS:* Anemia (regenerative), thrombocytopenia, leukocytosis, increased liver enzymes, hypoalbuminemia, hypcholesterolemia are commonly reported.

OTHER LABORATORY TESTS

- *Immunohistochemistry:* Differentiate HS from other sarcomas and round cell tumors.
- *Serum ferritin:* Hyperferritinemia has been

documented in dogs with HS and has potential as a biomarker for early screening.

IMAGING

SH

Thoracic radiographs: perihilar lymphadenopathy, focal pulmonary lesions.

HS, HHS

- Thoracic radiographs: diffuse interstitial infiltrate, patchy consolidated areas, focal or multifocal mass lesions. Sternal, cranial mediastinal or tracheobronchial lymphadenopathy may also be noted.
- Limb radiographs: periarticular soft tissue mass ± lytic lesions may be noted for periarticular HS.
- Ultrasonography: hepatosplenomegaly, splenic or hepatic mottling, masses in these organs and lymphadenopathy are the most commonly noted.

DIAGNOSTIC PROCEDURES

Cytology of Lesions

- *Cutaneous histiocytoma:* Characterized by sheets of pleomorphic round cells with abundant pale gray/blue cytoplasm, centrally located round to slightly indented nuclei, and inconspicuous nucleoli are noted. An inflammatory cell infiltrate (lymphocytes) may be present and often will precede spontaneous lesion regression.
- *CH/SH:* Characterized by mainly benign appearing histiocytes with occasional multinucleated giant cells. Lymphocytes, eosinophils and neutrophils can be interspersed.
- *HS/HHS:* Characterized by large, discrete, mononuclear cells often with marked anisocytosis and anisokaryosis. Nuclei are round, oval, or reniform with prominent nucleoli and cytoplasm is moderate to abundant, lightly basophilic, and vacuolated. Mitotic figures are common and erythrophagocytosis and/or multinucleated giant cells may be present.

Bone Marrow Cytology

In patients with cytopenias, tumor infiltrate and hemophagocytosis may be noted.

PATHOLOGIC FINDINGS

Cutaneous Histiocytoma

- Characterized by sheets of histiocytes infiltrating the dermis and subcutis, tracking hair follicles, and elevating the overlying hyperplastic and often ulcerated epithelium.
- Presence of lymphocyte infiltration and necrosis is often recognized in regressing lesions.
- A high mitotic index consistent with the rapid growth rate is a common feature of this tumor.

CH/SH

- Multicentric, nodular, perivascular histiocytic infiltrates within the deep dermis and subcutaneous tissue with variable lymphocyte, plasma cell, eosinophil and neutrophil infiltration.
- Blood and lymphatic vessel invasion is commonly noted, often accompanied by vascular wall degeneration, thrombosis and ischemic necrosis.
- **Note:** In CH the lesions are limited to the skin and

HISTIOCYTIC DISEASES

(CONTINUED)

draining lymph nodes while in SH, lesions are more widespread.

HS/HHS

- Lesions are composed of sheets of large, pleomorphic, mononuclear cells and multi-nucleated giant cells with numerous bizarre mitotic figures.
- Phagocytosis of red cells and leukocytes may be present in HS but is more typical of HHS where it is present to a high degree (spleen and liver).

TREATMENT

Cutaneous Histiocytoma

- Surgical excision or cryosurgery is generally curative.
- Cutaneous histiocytomas may spontaneously regress within 2–3 months, thus treatment is often not necessary. It is important to differentiate histiocytoma from a malignant tumor if client elects to monitor the lesion.

CH/SH

- Cutaneous lesions may wax and wane or spontaneously regress, but both diseases are usually progressive and require treatment.
- Rarely, dogs can present with localized lesions that can be surgically excised; however, most times disease is multifocal to widespread.
- Long-term aggressive immunosuppression is indicated for SH.

HS/HHS

- Localized (i.e., periarticular) HS can be successfully treated with surgical excision, usually requiring amputation. Radiation therapy can also be used as a palliative option for localized disease.
- Chemotherapy is indicated for multifocal and widespread systemic disease. Multiple agents have been evaluated, but lomustine (CCNU) has been the only drug with documented efficacy.

MEDICATIONS

DRUG(S)

- Lomustine (CCNU): 60–90 mg/m² q3 weeks
- Prednisone: 1–2 mg/kg/day continuously

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Lomustine can lead to severe myelosuppression and hepatotoxicity; prophylactic antibiotics and liver protectants

(Denamarin) are recommended with this drug.

ALTERNATIVE DRUG(S)

- Doxorubicin, vincristine, Doxil, paclitaxel, cyclophosphamide, mitoxantrone, dacarbazine and vinblastine have all been used with limited success.
- Immunomodulators such as leflunomide and cyclosporine have also been used and are most indicated for the reactive diseases (CH/SH).
- Bisphosphonates (pamidronate, zoledronate, liposomal clodronate) have been shown to have in vitro activity and synergy with certain chemotherapeutics in HS cell lines.

FOLLOW-UP

PATIENT MONITORING

Cutaneous Histiocytoma

Ensure the lesion is resolving within 2–3 months; if not, surgical excision is recommended.

CH/SH/HS/HHS

- Intensive scheduled monitoring occurs during treatment.
- Physical examination, complete blood count, serum chemistry panel, abdominal ultrasonography, and thoracic radiography every 2–3 months after completion of treatment.

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

Bleeding due to thrombocytopenia

EXPECTED COURSE AND PROGNOSIS

Cutaneous Histiocytoma

- Prognosis is considered excellent with surgical removal.
- Spontaneous regression is likely within 2–3 months.
- Cases with multiple histiocytomas may have a more lengthened clinical course, but spontaneous resolution is still possible.
- Metastatic histiocytomas (rare) have been reported.

CH/SH

- Both diseases are rarely fatal, but can negatively impact quality of life.
- Cutaneous lesions may wax and wane or spontaneously regress but are usually progressive and require treatment with immunomodulatory drugs or surgical excision (if localized).
- SH is associated with a poorer prognosis than CH because dogs are often ill from the disease and relapses are common, often prompting euthanasia.

HS/HHS

- Localized (periarticular) HS: Long-term (> 12 months) survival has been documented for dogs that undergo aggressive local and systemic therapy (surgery + CCNU).
- Disseminated HS: Reported response rates to CCNU are 40–50% for a median remission duration of 3–6 months.
- HHS is associated with rapid progression and a grave prognosis (median 7 weeks) even with treatment.

HISTOPLASMOSIS

BASICS

DEFINITION

A systemic fungal infection caused by *Histoplasma capsulatum*.

PATHOPHYSIOLOGY

- Soil-borne dimorphic fungus with the mycelial form growing best in bird manure or organically enriched soil. • Mycelium in the soil—produces infectious spores (microconidia); inhaled into the terminal airways.
- Spores—germinate in the lungs; develop into yeast form that reproduce by budding.
- Yeast are phagocytized by mononuclear phagocytes.
- Mononuclear phagocytes—distribute the organisms throughout the body.
- Ingested organisms may directly infect the intestinal tract.
- Immune response—determines whether disease develops; affected animals often develop transient, asymptomatic infection.

SYSTEMS AFFECTED

- Cats—respiratory tract main site of infection; bone, bone marrow, liver, spleen, skin, and lymph nodes also affected; intestinal tract, eyes, kidneys, adrenals, and brain less frequently involved.
- Dogs—intestinal tract most frequently involved site; liver, lung, spleen, and lymph nodes often involved; bones, bone marrow, kidneys, adrenals, oral cavity, tongue, eyes, and testes less frequently affected.

GENETICS

N/A

INCIDENCE/PREVALENCE

Prevalence of clinically relevant histoplasmosis relatively low in cats and dogs; an active practice, even in endemic areas, would see three to four cases a year.

GEOGRAPHIC DISTRIBUTION

- Endemic areas—Ohio, Missouri, Mississippi, Tennessee, and St. Lawrence river basins.
- Also seen in Texas, the southeastern United States, the Great Lakes region, and California.
- Has been isolated from the soil of 31 continental US states.

SIGNALMENT

Species

Dog and cat

Breed Predilections

N/A

Mean Age and Range

- Cats—predominantly young; many < 1 year of age; all ages can be infected.
- Dogs—most often young to middle-aged; all ages can be infected.

Predominant Sex

- Cats—females may be overrepresented.
- Dogs—none reported.

SIGNS

Historical Findings

Cat

- Insidious onset over days to weeks.
- Anorexia, weight loss, and dyspnea—most common.
- Coughing occasionally.
- Lameness.
- Ocular discharge.
- Diarrhea.

Dogs

- Weight loss, depression, and diarrhea with straining—most common.
- Coughing.
- Dyspnea.
- Exercise intolerance.
- Lymphadenopathy.
- Lameness and eye and skin changes—less common.

Physical Examination Findings

Cats

- Fever to 40°C (104°F).
- Increased respiratory effort and harsh lung sounds.
- Mucous membranes pale.
- Enlarged lymph nodes.
- Lameness, ocular changes, and skin lesions may be found.

Dogs

- Thin to emaciated.
- Fever to 40°C (104°F).
- Hepatosplenomegaly.
- Mucous membranes often pale.
- Icterus and ascites occasionally seen.
- Coughing and dyspnea associated with harsh lung sounds.
- Ocular and skin lesions less commonly noted.

CAUSE

H. capsulatum

RISK FACTORS

- Bird roosts where the soil is enriched with bird or bat droppings are high-risk environments; old chicken coops and caves have been implicated.
- Exposure to airborne dust contaminated with fungal spores coming from sites of fungal growth (especially indoor cats).
- Tissue samples from nearly half of stray dogs and cats from an endemic area were positive for *Histoplasma*, supporting the theory that many people and animals are infected but few develop clinically significant disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Cats

- Dyspnea from fungal pneumonia—differentiate from heart failure, feline asthma, lymphoma, pneumonia, pleural effusion, and other fungal pneumonias.
- Lameness—differentiate from trauma.
- Ocular changes—differentiate from lymphoma, toxoplasmosis, and feline infectious peritonitis.

Dogs

- Severe chronic diarrhea and weight loss—consider lymphocytic plasmacytic enteritis, eosinophilic enteritis, lymphoma, chronic parasitism, and pancreatic exocrine insufficiency.
- Diarrhea and anemia—consider severe inflammatory bowel disease, lymphoma or other intestinal neoplasia, and

parasitism (hookworm infection).

- Hepatosplenomegaly and peripheral lymphadenopathy—consistent with lymphoma.
- Respiratory signs—differentiate from infectious causes (distemper, bacterial, or other fungal pneumonia), chronic bronchitis, pleural effusion, heart failure, and pulmonary hypertension.

CBC/BIOCHEMISTRY/URINALYSIS

- Moderate to severe nonregenerative anemia common.
- Leukocyte counts—usually normal; some patients have a leukocytosis; patients with bone marrow involvement may be leukopenic.
- *Histoplasma* organisms—may be found in circulating neutrophils and monocytes; 2–4 µm round body with a basophilic center and lighter halo.
- Severe liver involvement—may see hyperbilirubinemia and high ALT activity.
- Dogs with severe intestinal histoplasmosis often have low total protein and exhibit panhypoproteinemia.

H

OTHER LABORATORY TESTS

- AGID test—for antibodies; supports diagnosis; positive results indicate active disease; previous infections may produce false-positive results; many animals with active disease are negative on serology.
- Antigen testing—antigen excretion in urine may provide a more accurate assay for identifying infected animals, although little data available; has been found to be a sensitive assay in cats; resource: www.miravistalabs.com.
- Coombs' test—may be positive because antibodies to *Histoplasma* may cross-react with RBCs; steroid therapy contraindicated.

IMAGING

Thoracic Radiography

- Dogs—diffuse interstitial to nodular pneumonia; enlarged tracheobronchial lymph nodes compressing the tracheal bifurcation; old lung lesions may be calcified, coin-like opacities that suggest metastatic tumors.
- Cats—usually a diffuse interstitial pattern of lung involvement; calcification and tracheobronchial lymphadenopathy uncommon.

Abdominal and Bone Radiography

- Dogs—hepatosplenomegaly, mesenteric lymphadenopathy, and potentially ascites..
- Cats and less often dogs—bone lesions predominantly osteolytic and usually occur distal to the elbows and stifles.

DIAGNOSTIC PROCEDURES

- Identification of organisms on cytology, histopathology, or culture—definitive.
- Tissue samples—enlarged lymph nodes, liver, and spleen are higher yield sites; rectal scrapings may be rich in organisms; bone marrow; lung aspirates (when less invasive procedures are not diagnostic); tracheal washes inconsistent.
- Urine antigen assay has high sensitivity in initial report.

HISTOPLASMOSIS

(CONTINUED)

PATHOLOGIC FINDINGS

- Multifocal, granulomatous lesions in organs rich in reticuloendothelial cells (e.g., spleen, liver, lymph nodes, lungs, and bone marrow).
- Dogs—gut prime site of involvement; tracheobronchial lymph node enlargement common.
- Cats—predominantly respiratory involvement.

TREATMENT

APPROPRIATE HEALTH CARE

- Usually outpatient with oral itraconazole.
- Inpatient with intravenous amphotericin B—dogs with severe intestinal disease and malabsorption.

H

NURSING CARE

- Dogs on amphotericin B therapy—keep well hydrated to decrease potential for nephrotoxicity.
- Emaciated animals with malabsorption—consider total parenteral nutrition until the intestinal disease is resolved enough for adequate food absorption.
- Animals with severe dyspnea—oxygen supplementation.

ACTIVITY

Dogs with dyspnea—reduce.

DIET

Good-quality, easily absorbed, palatable food.

CLIENT EDUCATION

- Discuss possible areas of exposure in the home environment.
- Inform client that both pets and family members may have been exposed to the same source but that the animal is not a hazard to the family.

MEDICATIONS

DRUG(S) OF CHOICE

Itraconazole

- Drug of choice if adequate intestinal function for drug absorption exists.
- Dogs and cats—5 mg/kg PO q12h; give with a high-fat meal.
- Be cautious about compounded itraconazole because absorption may not be acceptable.
- Duration depends on the clinical response; minimum treatment is 90 days.

Intravenous Amphotericin B

Dogs

- With severe inflammatory bowel disease and malabsorption—use until patient begins to gain weight; then start on itraconazole.
- Patient must be well hydrated before starting treatment; do not give amphotericin B in electrolyte solutions that may precipitate the drug.
- Usual dose—0.5–1.0 mg/kg IV q48h.
- Reconstitute in 5% dextrose and dilute for administration.
- Normal renal function—dilute in 60–120 mL 5% dextrose

and give over 2 hours.

- Some renal compromise—dilute in 0.5–1 L 5% dextrose and give over 3–4 hours to reduce renal toxicity.

Cats

- Use cautiously.
- Usual dose—0.25 mg/kg IV in 5% dextrose over 3–4 hours q48h.
- More sensitive to the drug than are dogs.

Fluconazole

- Eye and CNS involvement may best be treated with fluconazole that penetrates the blood-brain barrier.
- Use for dogs that cannot be given amphotericin B.
- Usual dose (intravenous form)—5 mg/kg IV q12h until intestinal absorption allows oral itraconazole treatment.

CONTRAINdications

Amphotericin B—caution with azotemic patients (in life-threatening situation, may still consider its use); monitor creatinine throughout therapy—elevation above normal or 20% greater than baseline is considered significant.

PRECAUTIONS

- Steroids—use with caution; allows proliferation of *Histoplasma*; life-threatening respiratory distress due to infiltrative lung disease or hilar lymphadenopathy justifies use of dexamethasone 0.1–0.2 mg/kg IV daily for 2–3 days.
- Itraconazole and fluconazole—hepatotoxicity; temporarily discontinue if patient becomes anorexic or if serum ALT activity > 300 U/L; restart at half-dose after appetite improves.

POSSIBLE INTERACTIONS

Itraconazole—inhibits cytochrome P450 system (CYP3A) and can increase concentrations of cyclosporine, digoxin, and midazolam in humans.

ALTERNATIVE DRUG(S)

None

FOLLOW-UP

PATIENT MONITORING

- Serum ALT—with itraconazole treatment; check monthly or if the patient becomes anorexic.
- Chest radiographs—with pulmonary involvement; check after 60 days of treatment to assess improvement; repeat at 30-day intervals and stop treatment when infiltrates are clear or remaining lung lesions fail to improve, indicating residual scarring; may be difficult to differentiate between residual fibrotic lesions and active disease; continue treatment for at least 1 month after all signs of active disease have resolved.
- Monitoring urinary antigen levels may be helpful.

PREVENTION/AVOIDANCE

- Avoid suspected areas of exposure (e.g., bird roosts).
- Recovered dogs are potentially immune.

POSSIBLE COMPLICATIONS

Recurrence possible; requires a second course of treatment.

EXPECTED COURSE AND PROGNOSIS

- Treatment—duration is usually about 4 months; drugs are expensive, especially for large dogs.
- Prognosis—good for stable patients without severe dyspnea; influenced by severity of lung involvement and debility of patient.

MISCELLANEOUS

ASSOCIATED CONDITIONS

No apparent predisposing conditions.

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

- Yeast form is not spread from animals to humans.
- Care must be taken to avoid needlestick injury when collecting aspirates.
- Infection can occur from cuts when doing necropsies on infected animals.

PREGNANCY/FERTILITY/BREEDING

Itraconazole—no teratogenic effects in rats and mice at therapeutic doses; embryotoxicity found at high doses; no dog or cat studies; however, azole drugs can be teratogenic, use with caution in pregnant animals.

ABBREVIATIONS

- AGID = agar gel immunodiffusion
- ALT = alanine transaminase • RBC = red blood cell

HOOKWORMS (ANCYLOSTOMIASIS)

BASICS

OVERVIEW

- Nematode parasites of small intestine; *Ancylostoma caninum*, dogs; *A. tubaeforme*, cats; *A. braziliense* and *Uncinaria stenocephala*, dogs and cats. • *A. braziliense* in southern states; others also in temperate zone.
- Voracious blood-sucking adults and fourth-stage larvae of *A. caninum* and *A. tubaeforme* cause blood-loss anemia, enteritis; active worms leave bite sites with ongoing hemorrhage. • Disease can occur in peracute to chronic forms; peracute form in neonates results from transmammary infection; acute disease in older pups; in adults infection can be acute, chronic compensatory, or chronic non-compensatory in immunosuppressed or debilitated dog.
- *Uncinaria* is of little clinical concern.
- *A. braziliense* is major cause of CLM in humans. • Respiratory disease may result from larval migration in lungs. • *A. caninum* is transmitted via colostrum/milk to pups; all species are transmitted by ingestion of infective larvae in food, water, or transport hosts and by larval skin penetration.

SIGNALMENT

- Peracute to acute disease in young animals; asymptomatic or chronic in mature dogs and cats. • Clinical severity greater in dogs than cats.

SIGNS

Historical Findings

- Pale mucous membranes; dark, tarry stools (melena); diarrhea; constipation; loss of condition; poor appetite; dry cough.
- Sudden death.

Physical Examination Findings

- Poor body condition; ill-thrift, poor hair coat. • Pale mucous membranes.
- Erythematous, pruritic lesions, papules on feet, especially between toes.

CAUSES & RISK FACTORS

- Neonatal animals are at highest risk for clinical disease. • Infected bitch or queen.
- Environment contaminated with feces of hookworm-infected dog/cat. • Concurrent enteric infections. • Compromising conditions (e.g., pregnancy, malnutrition).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of erythrocyte destruction or blood loss resulting in anemia. • Ascariasis (large roundworm infection), coccidiosis, and strongyloidosis can cause similar signs without significant anemia. • Melena and mild anemia can also occur with physalopterosis.

CBC/BIOCHEMISTRY/URINALYSIS

- Eosinophilia. • Anemia usually acute normochromic, normocytic, and regenerative; can become microcytic, hypochromic due to chronic iron deficiency.

DIAGNOSTIC PROCEDURES

- Note that disease/death may occur prior to egg shedding by adult worms. • Fecal flotation to detect typical morulated strongylid eggs; minor size differences among species; eggs of *Uncinaria* slightly longer than *Ancylostoma* spp. • Necropsy of littermates that died with similar clinical signs.

PATHOLOGIC FINDINGS

- Gross: hookworms attached to small intestinal mucosa; multifocal hemorrhagic ulcerations ("bite sites") on mucosa; blood in intestinal lumen. • Microscopic: eosinophilic enteritis.

TREATMENT

- Peracute and severe acute cases treated as inpatients; anthelmintic plus fluid therapy, blood transfusion, supplemental oxygen as indicated by severity of anemia and clinical signs. • Peracute and severe acute cases: alert owner to possible sudden death in spite of treatment. • Chronic compensatory cases: anthelmintic; if non-compensatory, provide nutritional support (iron supplement).

MEDICATIONS

DRUG(S)

Adulcicide/Larvicide Anthelmintics

- Fenbendazole 50 mg/kg PO q24h for 3 consecutive days in dogs. • Milbemycin oxime 0.5 mg/kg (dogs) or 2 mg/kg (cats) PO q30 days. • Emodepside (3 mg/kg)/praziquantel (12 mg/kg) topically once in cats. • Moxidectin 0.17 mg/kg SC q6 months in dogs. • Moxidectin 2.5 mg/kg (dogs) or 1.0 mg/kg (cats)/imidoclopramide 10 mg/kg, topically q30 days. • Ivermectin 24 µg/kg PO q30 days in cats.

Adulcicide Activity

- Pyrantel pamoate, label dose in dogs; 10–20 mg/kg PO in cats (extra-label).
- Praziquantel/pyrantel pamoate/febantel, label dose for dogs. • Praziquantel/pyrantel pamoate, label dose for cats. • Ivermectin/pyrantel pamoate or ivermectin/pyrantel pamoate/praziquantel, label dose for dogs.
- Selamectin 6 mg/kg topically q30 days in cats.

FOLLOW-UP

Monitor fecal egg counts after treatment and hematocrit in anemic patients.

PREVENTION/AVOIDANCE

- Eliminate intestinal stages and activated dormant larvae in breeding bitch; fenbendazole at 50 mg/kg/day from day 40 of gestation to day 14 of lactation or ivermectin at 0.5 mg/kg 4–9 days prior to whelping and again 10 days later. • Begin biweekly anthelmintic treatment of pups at 2 weeks of age; continue until weaned, especially pups at high risk of infection from bitch or environment; treat monthly after weaned.
- Treat queen with adulticide/larvicide anthelmintic prior to breeding and after littering. • Begin anthelmintic treatment of kittens at 3–4 weeks of age; treat monthly thereafter. • Promptly remove and dispose of feces to prevent contamination of environment with larvae. • Prevent hunting and scavenging to prevent ingestion of potential transport hosts.

H

EXPECTED COURSE AND PROGNOSIS

- Puppies with peracute or acute *A. caninum* infection may die in spite of treatment.
- Expect full recovery in cases with anthelmintic treatment and nutritional support. • Anthelmintic treatment of adult dogs with dormant larvae in their tissues can result in larval activation and repopulation of small intestine.

MISCELLANEOUS

AGE-RELATED FACTORS

- Disease more acute in young animals and chronic in adults. • Transmission of *A. caninum* larvae from bitch to offspring in colostrum/milk results in high rate of infection in pups.

ZOONOTIC POTENTIAL

- All hookworms, especially *A. braziliense*, cause CLM when infective larvae penetrate human skin. • *A. caninum* larvae can cause VLM or migrate to GI tract, causing abdominal pain and eosinophilia without becoming patent.

ABBREVIATIONS

- CLM = cutaneous larva migrans • GI = gastrointestinal • VLM= visceral larva migrans

HORNER'S SYNDROME

BASICS

OVERVIEW

- Sympathetic denervation to the eye.
- Anatomic pathway very important. • Affects the ophthalmic and nervous systems.

SIGNALMENT

- Idiopathic—one study suggests male golden retrievers 4–13 years of age at increased risk. Most of these localize to a postganglionic

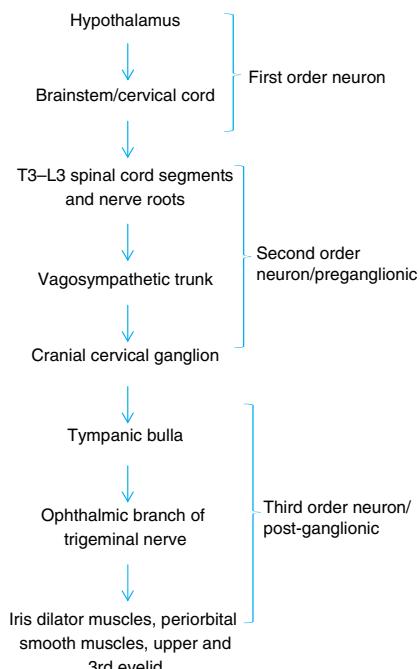

Figure 1.

lesion. • Idiopathic—dogs, 50–93%; cats, 45%. • Other causes—N/A.

SIGNS

- Miosis. • Protruding third eyelid. • Ptosis (drooping) of upper eyelid. • Enophthalmia.
- Other neurologic and non-neurologic signs dependent on the underlying cause.

CAUSES & RISK FACTORS

See Table 1.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Anterior uveitis—IOP usually low; aqueous flare.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

- See Table 1. • Thoracic radiographs—may reveal cause of injury to the sympathetic trunk (e.g., trauma and mediastinal tumor). • Skull radiographs—may reveal middle ear problem.
- MRI—may help identify brainstem lesion, retrobulbar mass, cervical spinal cord problem. • CT may help identify middle ear problem. • Ultrasonography—orbit; may reveal retrobulbar mass.

DIAGNOSTIC PROCEDURES

- See Table 1. • CSF tap—investigate brain and spinal cord disease. • Electromyography—look for brachial plexus avulsion.
- Pharmacologic testing—see Anisocoria.

TREATMENT

Treat underlying disease.

MEDICATIONS

DRUG(S)

- Depends on underlying disease
- Idiopathic—none

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Do not use drugs which alter the autonomic nervous system prior to referral for lesion localization.

FOLLOW-UP

- Depends on severity of underlying disease.
- Idiopathic—may take up to 4 months for a partial or complete recovery.

MISCELLANEOUS

ABBREVIATIONS

- CN = cranial nerve • CSF = cerebrospinal fluid • CT = computed tomography
- FCE = fibrocartilagenous embolism
- IVDH = intervertebral disc herniation
- MRI = magnetic resonance imaging

Table 1

Summary of lesions resulting in Horner's syndrome.

Lesion location	Causes	Common concurrent neurologic abnormalities	Diagnostic plan
Brainstem	Neoplasia, encephalitis, vascular, trauma	Altered mental status, ipsilateral hemiparesis, ipsilateral postural reaction deficits	MRI; CSF analysis
C1–T3 spinal cord	IVDH, trauma, neoplasia, FCE	Ipsilateral or bilateral hemiparesis/plegia, ± reduced reflexes to thoracic limbs, normal mentation	MRI preferred, myelogram also may show lesion. CSF analysis
T1–T3 nerve roots	Brachial plexus avulsion, peripheral nerve tumor (lymphoma, nerve sheath tumor most common)	Ipsilateral loss of thoracil imb reflexes, ipsilateral loss of cutaneous trunci, ipsilateral monoparesis/plegia, absent postural reactions in affected thoracic limb only	MRI, electrodiagnostic testing
Sympathetic trunk, cranial cervical ganglion*	Trauma, iatrogenic following jugular venipuncture, mediastinal or thyroid neoplasia	Possibly laryngeal dysfunction	Neck ultrasound, MRI, thoracic radiographs
Tympanic bulla	Otitis media, polyp (cat), neoplasia, trauma	Ipsilateral vestibular disease, ipsilateral facial nerve paralysis	MRI, CT, bulla radiographs, myringotomy
Retrobulbar	Neoplasia, abscess, trauma	None, or dysfunction of CN II, III, IV, and VI.	MRI, orbital ultrasound

BASICS

DEFINITION

- Deposition of urine or feces outside the litter box.
- Urine housesoiling (also called periuria) includes inappropriate urination, a toileting behavior in which urine is typically found on horizontal surfaces outside the litter box, and urine marking, in which urine is sprayed on vertical surfaces as part of a ritualistic tail-up display.
- Fecal housesoiling includes both inappropriate defecation, a toileting behavior characterized by feces deposited outside the litter box, and fecal marking, called middening, characterized by feces deposited in prominent locations.
- Marking behavior serves a normal communicative function in cats.
- Housesoiling will negatively impact the human-animal bond and can lead to relegation outside, rehoming, relinquishment, or euthanasia.

PATOPHYSIOLOGY

- Inappropriate urination/defecation—may be a response to dissatisfaction with the litter box environment or preference for an alternative location or substrate, or may reflect an underlying pathophysiologic state such as a negative (pain) association with the litter box secondary to uroliths, constipation, or orthopedic pain.
- Urine marking—a normal behavior observed in free-ranging and confined cats; significant individual differences in the propensity to urine mark in a given environment. Cat density is correlated to probability of urine marking. Cats that urine mark also commonly use a litter box for toileting.
- Fecal marking (middening) is rarely observed; it should be a diagnosis of exclusion.
- Social or environmental stressors may contribute to housesoiling, primarily marking.

SYSTEMS AFFECTED

- Behavioral
- Endocrine
- Gastrointestinal
- Renal/Urologic

GENETICS

- Not specifically identified.
- Persians and Himalayans that exhibit inappropriate urination should be DNA tested for the genetic disorder polycystic kidney disease.

INCIDENCE/PREVALENCE

- Housesoiling is the most common behavioral problem for which cat owners seek veterinary advice and the second most common reason for relinquishment of cats to animal shelters.

- Inappropriate urination/defecation: in one survey, 11% of indoor cat owners reported inappropriate elimination as a problem.
- Urine marking: exhibited by approximately 10% of castrated male and 5% of ovarioectomized female house cats.

GEOGRAPHIC DISTRIBUTION

Housesoiling may be more problematic where cats are commonly restricted indoors.

SIGNALMENT

Species

Cat

Breed Predilections

Housesoiling may occur in any breed, although Persians, Himalayans, and relatives are overrepresented in some studies.

Mean Age and Range

Inappropriate urination/defecation can occur at any age. Marking behaviors are typically seen in cats > 6 months.

Predominant Sex

- Housesoiling can occur in either sex, intact or altered.
- Urine marking is more common in males (intact and neutered) than females (intact and neutered).

SIGNS

General Comments

Identify the Affected Cat in a Multi-Cat Household

- Direct observation, although if punished, cats may become secretive.
- Videotaping or video monitoring.
- Separate the cats to identify the culprit. Note that this protocol may alter the social milieu sufficiently to inhibit inappropriate elimination.
- Add a urine indicator. If urine is alkaline, administer the dye fluorescein (6 fluorescein test strips in a gel capsule PO or 10 mg/cat) sequentially to each cat. Urine outside the litter box will fluoresce under a Wood's light for approximately 24 hours; if negative after 36 hours, the test can be repeated on another cat. Negative results are common in households in which the frequency of urine housesoiling is low. Fluorescein may stain fabrics.

Identify the Locations of Housesoiling within the House

The owner should generate a map of the home, indicating the locations of urine and fecal housesoiling and locations of litter boxes. Location of the housesoiling can provide insight into the type of housesoiling and etiology.

Historical Findings

Inappropriate Urination/Defecation

- Abnormal pattern of urination (incontinence, polyuria, hematuria, dysuria) suggests an underlying congenital or medical problem.
- History of straining to defecate; vocalizing or running away when defecating; hard, dry,

or bulky feces suggest painful defecations that may lead to conditioned avoidance of the litter box for defecation.

- History of polydipsia, anorexia, vomiting, or diarrhea suggest an underlying medical etiology.

Urine Marking

- History of displacement, aggression, or avoidance behavior between cats in a multi-cat household.
- Observation of the posture of spraying urine: the cat orients caudally to a vertical surface, stiffens its posture, raises and quivers its tail, and directs a small burst of urine caudally.
- Observation of urine marks on vertical surfaces or puddled at the bottom of a wall.
- Urine marks can be found on prominent furniture or other objects, or urine sprayed on new objects brought into the house.
- Horizontal urine marks may be found on clothing or bedding associated with a particular person or in response to visitors or novel objects.

Fecal Marking

Feces deposited on prominent, conspicuous locations.

Physical Examination Findings

- Presence of abnormal physical findings depends on whether problem is pathophysiologic or behavioral.
- If strictly behavioral, physical examination will be normal.
- Apparently-neutered males that urine mark should be examined for the presence of penile spines, indicating the presence of endogenous testosterone, or quantify serum testosterone.

CAUSES

Medical Causes

- Any metabolic or GI condition that causes polyuria, diarrhea, or constipation
- Lower urinary tract disease, including idiopathic interstitial cystitis (may be associated with environmental stressors)
- Urolithiasis
- Diabetes mellitus
- Hyperthyroidism
- FeLV
- FIV
- Liver disease
- CNS disease/cognitive dysfunction (senility)
- Iatrogenic—administration of fluids, corticosteroids, diuretics
- Musculoskeletal pain that make entry/exit from the litter box or elimination postures difficult, can contribute to litterbox aversion
- Hormonal influences may contribute to urine marking

Behavioral Causes

Inappropriate Urination/Defecation

- Soiled litter box.
- Inadequate number of boxes or locations (one box per cat plus one is recommended).

HOUSESOILING—CATS

(CONTINUED)

- Box located in remote or unpleasant surroundings or subject to interference by dogs or children.
- Inappropriate type of box—a covered litter box, box too small to allow large cats to move around comfortably; or allows other cats, pet dogs, and young children to target the cat as it exits.
- Time factors—daily or weekly temporal patterns of inappropriate urination suggest an environmental cause; acute onset in a cat that has previously used the litter box suggests a medical or social problem.
- Substrate—unacceptable litter type; preference tests indicate that most cats prefer unscented, fine-grained (clumping) litter but individual variability; coincident change in litter box habits with new litter type suggests an association; a sudden shift from one substrate (e.g., litter) to an unusual substrate (e.g., porcelain sink) suggests a lower urinary tract disorder.
- Location—urination outside the litter box may suggest a location preference or influential social factors. Urination in the vicinity of the litter box may suggest dissatisfaction with qualities of the litter box, including litter box hygiene.
- Social dynamics—consider social conflicts between cats at the time the problem started (e.g., addition of a new cat).

Marking

- Marking is associated with arousal, anxiety, or territorial behavior.
- The probability of urine marking is directly proportional to the number of cats in the household.
- Marking can be a response to household disruption or another cat(s) in or outside the home. Urine marks around windows and doors to the outside suggest a response to the presence of an outdoor cat.
- Urine marking grocery bags or new furniture suggests arousal in response to new stimuli.

RISK FACTORS

Inappropriate Urination/Defecation

- Inadequate litter box hygiene
- Litter box features (litter type or scent, box size or style)

Urine Marking

- Male
- Sexually intact
- Multiple-cat household
- History of urine marking by a parent

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Must identify if a medical problem underlies the behavioral problem.

- If behavioral, must differentiate inappropriate urination from urine marking.

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal when urine marking and inappropriate urination are strictly behavioral; urinalysis via cystocentesis is the minimum database in any cat examined because of inappropriate urination; collect serial samples from cats whose behavioral signs wax and wane; CBC and biochemistry are recommended prior to administration of medication and to evaluate medical status.

OTHER LABORATORY TESTS

Cats with refractory inappropriate urination or progressive signs should be tested for hyperthyroidism, FeLV, and FIV.

IMAGING

Abdominal ultrasonography, abdominal radiographs, and contrast studies if indicated to rule out urolithiasis as an underlying cause for inappropriate urination.

DIAGNOSTIC PROCEDURES

Helpful historical information: map of the house, with litter boxes and urine/fecal housesoiling identified; behavioral diary with daily frequency of urinations/defecations inside each litter box and outside the litter boxes. Requires daily household monitoring.

PATHOLOGIC FINDINGS

None, unless an underlying medical etiology.

TREATMENT

APPROPRIATE HEALTH CARE

- Treat any underlying medical condition.
- Use environmental and behavioral therapies before or concomitant with pharmacologic treatment.
- The environment for indoor cats should include safe resting places, separated resources, and positive and predictable human-cat interactions.
- Restrict the cat from rooms in which urine housesoiling occurs.
- For immediate management and in cases of agonistic relationships between cats in a multi-cat household, it may be necessary to confine the cat to one room in the owner's absence. Provide a litter box (see specifications below), water, food, and resting sites. The cat can be let out of the room when the owner returns and is available for strict supervision of the cat. Initiate other, more permanent treatments.
- Clean urine "accidents" with an enzymatic cleaner specific for this purpose.

Inappropriate Urination

- Scoop out the litter boxes daily. Clean out and wash litter box and refill regularly.
- Avoid deodorizers, scented litters, or other strong odors in the vicinity of the litter box.

- Move food bowls away from litter boxes.

- Provide one litter box per cat, plus one, distributed in more than one location; positioned away from high traffic or noisy areas.

- If the litter box is covered, provide an additional large, plain, uncovered litter box filled with unscented, fine-grained, clumping litter, with no liner and quantify cat use on a behavioral diary. Additional boxes may be provided ("litter box buffet") to reveal cat preference for litter box type and substrate.
- If one site in the home is preferred for inappropriate urination, place another litter box over this site. After it is in regular use, move it 2.5 cm per day to a site more acceptable to the owner.

Urine Marking

- If there are signs that the cat is marking in response to cats outside the home, use mechanical or olfactory products to deter outside animals, or trap and remove.
- Reduce cat numbers to reduce conflicts if possible.
- Synthesized feline facial pheromone (Feliway, Ceva Animal Health) is commercially available as a treatment for urine marking. The product is sprayed regularly or diffused in the environment and may reduce urine marking up to 75%.
- Litter box management, as described above, has been shown to decrease urine marking.
- Pharmacotherapy plays an important role in the control of urine marking.

NURSING CARE

N/A

ACTIVITY

Opportunities for active play that incorporate behavioral patterns of predatory stalking and pouncing should be provided daily.

DIET

No specific diet unless suggested by an underlying medical etiology, such as urolithiasis or constipation.

CLIENT EDUCATION

- Cats do not housesoil to be spiteful.
- Scolding and punishment are contraindicated, they may increase cat anxiety and will cause the cat to avoid the owner.
- Understanding the underlying motivation for housesoiling behavior is critical for treatment success.
- Creating a predictable environment will decrease anxiety and arousal that may contribute to housesoiling.
- Work to resolve cat conflicts within the home (see Aggression, Intercat Aggression).
- Meet cat needs for exercise, play, and safe elevated resting sites.

SURGICAL CONSIDERATIONS

Castration reduces urine marking in up to 90% of males and 95% of females.

(CONTINUED)

HOUSESOILING—CATS**Table 1**

Drugs and dosages used to manage feline urine marking.

<i>Drug</i>	<i>Drug Class</i>	<i>Oral Dosage in Cats</i>	<i>Frequency</i>	<i>Side Effects (Usually Transient)</i>
Fluoxetine	SSRI	0.5–1.0 mg/kg	q24h	Decreased appetite, sleepiness
Paroxetine	SSRI	0.25–0.50 mg/kg	q24h	Constipation
Clomipramine	TCA	0.2–0.50 mg/kg	q24h	Sleepiness
Amitriptyline	TCA	0.25–1.0 mg/kg	q24h	Sleepiness
Buspirone	Azaprione	0.5–1.0 mg/kg	q12h	GIT side effects (rare)

**MEDICATIONS****DRUG(S) OF CHOICE****Inappropriate Urination**

Psychotropic medication not usually indicated, except in treatment-resistant cases or when associated with generalized anxiety or heightened arousal.

Urine Marking

- Medication to decrease arousal is often needed for treatment success.
- Drugs from a number of drug classes may be used. All have the general effect of decreasing arousal and anxiety. Side effects can be sedation and/or altered social behavior (see Table 1). Drugs commonly used include fluoxetine, paroxetine, clomipramine, amitriptyline, buspirone.

Fecal Marking

Medication may be needed to decrease the arousal that drives this behavior.

CONTRAINDICATIONS

- Benzodiazepines—use cautiously or avoid because of rare reported cases of fatal idiopathic hepatic necrosis in cats receiving diazepam.
- Tricyclic antidepressants—cats with a history of cardiac conduction disturbances, urinary or fecal retention, megacolon, lower urinary tract blockages, seizures, and glaucoma.
- Transdermal route does not appear to consistently produce satisfactory drug levels.

PRECAUTIONS

All drugs listed are extra-label. Inform the client of extra-label use and potential side effects; document the discussion in the medical record or use a release form. Start psychotropic drugs when the owner is present to monitor the patient.

POSSIBLE INTERACTIONS

Do not use monoamine oxidase inhibitors (e.g. selegiline) concurrently with TCAs or SSRIs.

ALTERNATIVE DRUG(S)

- Synthetic progestins—the risk of serious side effects, including blood dyscrasias, pyometra, mammary hyperplasia, mammary carcinoma, diabetes mellitus, and obesity, has diminished their once-common use.
- Pheromone therapy (Feliway, Ceva Animal Health) may reduce urine spraying.
- L-theanine (Anxitane, Virbac Animal Health) or alpha-casozepine may reduce cat anxiety.

**FOLLOW-UP****PATIENT MONITORING**

- Regular follow-up is essential.
- The owner should keep a daily log of elimination patterns so that treatment success can be evaluated and appropriate adjustments in therapy can be made. Number the litter boxes and request that client count and record the number of urinations/defecations in each box and outside the litter boxes each day.
- For marking behavior, after 2 months of successful medication management, medication might be withdrawn gradually over 2 weeks. However, if the social features that underlie the behavior are still present, medication may need to be continued for treatment success.
- For medication monitoring, an annual CBC, chemistry profile, urinalysis, and physical examination are recommended at a minimum.

PREVENTION/AVOIDANCE

- Neuter cats.
- Restrict cat numbers to decrease the probability of urine marking.
- Counsel clients on appropriate litter box selection, location, and hygiene.
- Veterinary practitioners should inquire about housesoiling at each veterinary visit. Early identification and treatment optimize treatment success.

POSSIBLE COMPLICATIONS

Client expectations must be realistic. Immediate control of a long-standing

problem of housesoiling is unlikely; the goal is gradual improvement over time.

EXPECTED COURSE AND PROGNOSIS

- Prognosis for improvement is good if underlying etiology is identified and managed.
- Housesoiling is destructive to household belongings and erosive to the human-animal bond, which if not successfully controlled can lead to abandonment, relegation outside, relinquishment to an animal shelter, and euthanasia.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Aggression between cats may be associated with urine marking.

AGE-RELATED FACTORS

- Older cats might find litter box access difficult and seek alternative locations. Low-rise litter boxes can provide better access for these cats.
- Failure to use the litter box could be associated with age-related cognitive decline.

ZOONOTIC POTENTIAL

Pregnant women should avoid or take appropriate precautions when cleaning cat feces because of the risk of toxoplasmosis.

PREGNANCY/FERTILITY/BREEDING

Tricyclic antidepressants are contraindicated in animals used for breeding.

SYNOMYS

- General: feline housesoiling.
- Urine: feline inappropriate elimination, squat urination outside the litter box, urine marking, urine spraying, peruria.
- Feces: feline inappropriate defecation, defecation outside the litter box, fecal marking, middening.

HOUSESOLING—DOGS

BASICS

DEFINITION

Urination and/or defecation, for the means of eliminating or marking territory, in a location that owners consider inappropriate.

PATHOPHYSIOLOGY

- Improper or incomplete housetraining
- Submissive or excitement urination
- Testosterone, leading to marking behavior
- Marking behavior, due to territoriality, anxiety
- Anxiety (separation anxiety, noise phobia)
- Cognitive dysfunction

SYSTEMS AFFECTED

Behavioral—shelter relinquishment, leading to euthanasia or rehoming.

GENETICS

Some dog breeds appear to be more easily housetrained than others.

INCIDENCE/PREVALENCE

- Almost 20% of owners relinquishing a dog to a shelter did so because it soiled in the house.
- 37% of owners who reported talking to their veterinarian about a behavior problem reported that their dog was housesoiling.
- Housesoiling also represents a common reason that dogs are referred to a veterinary behaviorist.
- The incidence of inappropriate elimination, including marking behavior, in intact male dogs is almost 60%, higher than that seen in castrated male dogs and intact or spayed female dogs.

GEOGRAPHIC DISTRIBUTION

None described

SIGNALMENT

Species
Dogs

Breed Predilections

Potential genetic breed predisposition for ease of housetraining and submissive or excitement urination is anecdotally described. Dogs obtained from a commercial breeding establishment are more likely to urinate against household objects or display submissive urination than those obtained from a non-commercial breeder.

Mean Age and Range

- Inappropriate elimination due to improper or incomplete housetraining primarily seen in younger dogs.
- Submissive and excitement urination seen primarily in younger dogs.
- Urine marking begins to be displayed as the dog reaches sexual maturity.
- Housesoiling is a common complaint from owners of elderly dogs.

Predominant Sex

Intact male dogs are more likely to urine mark than female dogs and castrated male dogs.

SIGNS

General Comments

- Inappropriate elimination is the most common individual reason for relinquishment of a pet to a shelter.
- Proper housetraining must be discussed with clients from the very beginning.
- Housesoiling can be associated with medical problems such as endocrine disorders, urinary tract disorders, orthopedic disease, and metabolic disease.

Historical Findings

- History of urination and/or defecation in inappropriate areas.
- May be associated with signs of other behavioral disorders (such as separation anxiety).
- May be associated with lack of time spent by owner to properly teach housetraining.
- May be associated with punishment of a dog that has submissive urination.
- A complete medical and behavioral history will help determine potential triggers, including when, where, and how often the elimination occurs, and reliability of outdoor elimination.

Physical Examination Findings

- If examination findings and laboratory results are normal, housesoiling is probably due to a behavioral cause.
- There may have been an inciting medical cause that has since resolved but the animal has learned to eliminate indoors.

CAUSES

Canine inappropriate elimination can be primarily due to a behavioral problem or secondary to/concurrent with a medical disorder.

Behavioral

- Lack of, improper, or incomplete housetraining
- Marking behavior
- Submissive urination
- Excitement urination
- Separation anxiety
- Cognitive dysfunction syndrome
- Noise phobia
- Fear-induced
- Psychogenic polydipsia/polyuria

Medical Causes

Degenerative

- Osteoarthritis
- Renal failure

Anatomic

Ectopic ureters

Metabolic

- Incontinence
- Diabetes mellitus
- Diabetes insipidus
- Hepatic insufficiency
- Hyperadrenocorticism
- Hypoadrenocorticism
- Seizures

Neoplastic

- Genitourinary neoplasia
- Neurologic
- Other neoplastic diseases causing weakness

Infectious/Inflammatory

- Urinary tract infection or inflammation
- Crystalluria with cystitis
- Inflammatory bowel disorder
- Pancreatic disease
- Intestinal parasites

RISK FACTORS

- Intact male.
- Concurrent behavioral problem, such as separation anxiety.
- Owners

poorly informed or motivated to properly housetrain the dog.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Differentiate behavioral causes of inappropriate elimination from medical causes with a proper medical workup.

CBC/BIOCHEMISTRY/URINALYSIS

- Indicated to rule out medical causes.
- Normal if inappropriate elimination is solely due to a behavioral cause.

IMAGING

Not indicated, other than to rule out medical causes, primarily urolithiasis or ectopic ureters.

H

DIAGNOSTIC PROCEDURES

- Video recording when the owner is present to view household interactions with the dog.
- Journal to monitor potential causal factors, as well as to monitor improvement of the problem.
- Video recording the dog when the owner is gone from the home to rule in/out separation anxiety or other anxiety disorders.

PATHOLOGIC FINDINGS

None for behavioral causes

TREATMENT

APPROPRIATE HEALTH CARE

Appropriate measures to assure continued good health of the dog.

ACTIVITY

- Take dog outside often to ensure enough access to eliminate outside, or provide acceptable access to the outside, for example, via a dog door if the dog is trained properly.
- Increase activity level to help in the treatment of other problem behaviors, as well as to improve the dog's health.

DIET

- If the dog is inappropriately eliminating stool, feeding scheduled meals may help to maintain the dog on a schedule of elimination.
- Feeding a diet of higher caloric density may help decrease the urge to defecate as frequently.
- In general, water should not be withheld from the dog.

CLIENT EDUCATION

General Comments

- Counsel the owner as to the cause(s) of the inappropriate elimination, as well as the potential long-term management of the problem.
- Treat underlying/contributing medical problems.
- Treat other underlying/contributing behavioral problems.
- Counsel owners on proper housetraining techniques.
- Clean the soiled areas with an enzymatic cleaner to help eliminate any odor that may attract the dog to eliminate there again.
- If the

HOUSESOILING—DOGS

(CONTINUED)

soiled object is a piece of clothing or other smaller cloth object, such as a throw rug, wash it. • Punishment is inappropriate, as it may create anxiety, fear, and defensive aggression. • Do not use punishment to housetrain a dog, such as rub its nose in the soiled area, nor should they be verbally or physically reprimanded.

Incomplete Housetraining

- Keep the dog supervised at all times. If it is not supervised, keep confined unless confinement causes panic, destruction, and/or injury to the dog. • In some cases, tethering the dog to owners or nearby allows better supervision. Dogs should never be tethered without supervision. • Take the dog outside frequently to eliminate. • Accompany the pet to the appropriate elimination site and reward elimination as soon as it occurs. • Thoroughly clean soiled areas. • Use a consistent “key phrase” to help associate the act with the location and timing of elimination. • Feed on a set schedule, with water always available.

Submissive or Excitement Urination

- Do not punish the behavior, since this may make problem worse. • Owners should ignore the dog when they come into the house (no verbal or physical interactions or eye contact). • The dog should go outside to eliminate before it is greeted. • The dog should be greeted in a non-confrontational and quiet manner; do not lean over the dog or institute interactive play at the time of greeting. • Alternating activities at homecoming, such as asking for a toy or requesting a “Sit,” may help in mild cases.

Urine Marking Behavior

- Educate owners on effectiveness of neutering to decrease urine marking. • Determine any possible triggers to the behavior, including anxiety-provoking stimuli. • Address those triggers with desensitization and counter-conditioning and/or avoidance of the trigger as appropriate. • Prevent access to the preferred marking locations. • Make the areas that have been urine marked aversive to the dog by use of “booby traps” such as upside-down plastic carpet runners or foil. • Alternatively, the owner can change the significance of the area to a positive place, such as by feeding the dog in the marked area.

SURGICAL CONSIDERATIONS

Neutering intact male dogs decreases urine marking rapidly in 30% of dogs, with a gradual decline in 20% of dogs, and no change in 50% of them. The results are the same regardless of age of neutering.

MEDICATIONS

DRUG(S) OF CHOICE

- Behavioral modification used in conjunction with psychotropic medications.

- Negligible effect in animals not housetrained or if displaying submissive or excitement urination. Rarely effective when anxiety is not part of the problem behavior.
- If urine marking or inappropriate elimination is anxiety induced, medications may be helpful, in conjunction with behavior modification. • Selective serotonin reuptake inhibitors or tricyclic antidepressants/antianxiety medications may be helpful.
- SSRI: fluoxetine at 1–2 mg/kg PO q24h.
- TCA: clomipramine at 3 mg/kg PO q12h.
- The full onset of action of these medications can be 4–6 weeks after initiation of treatment; inform owners of time required for response to be noted. • Side effects of the SSRIs and TCAs can include nausea, vomiting, diarrhea, and lethargy. • Additional side effects of the TCAs can include potentiation of seizure activity.

CONTRAINDICATIONS

- Medication without concurrent behavior modification. • Tricyclic antianxiety medications are contraindicated in seizures and cardiac disease, and may interfere with thyroid medications.

PRECAUTIONS

Based on drug chosen

POSSIBLE INTERACTIONS

Do not use an SSRI and TCA together or in conjunction with an MAOI.

ALTERNATIVE DRUG(S)

- Pheromone products can potentially help decrease anxiety. • Some neutraceuticals such as alpha-casozepine and L-theanine may decrease anxiety.

FOLLOW-UP

PATIENT MONITORING

Monitor with owner by follow-up visits or telephone calls. The owner should keep a journal of incidents, inciting factors, and treatments instituted to have an objective view of improvement.

PREVENTION/AVOIDANCE

- Properly housetrain the dog. • Neuter male and female dogs. • Treat any underlying medical condition. • Treat any underlying behavioral condition.

POSSIBLE COMPLICATIONS

Recurrence if owner relapses in treatment, perhaps pet relinquishment.

EXPECTED COURSE AND PROGNOSIS

- Prognosis for any behavioral problem is highly dependent on the owner's ability to follow instructions. The following estimations of prognosis are based on the owner following your instructions for behavior modification.
- Prognosis for decreasing submissive and excitement urination is good. • Prognosis for managing incomplete housetraining is good.

- Prognosis for marking in previously intact male: 50% improve (30% quickly, 20% more slowly) with neutering, even without complementary behavior modification.
- Prognosis for managing urine marking in spayed or neutered dogs is good if the triggers are identified and managed with avoidance or other forms of behavior modification. • Some animals with a history of a medical cause of inappropriate elimination can still eliminate inappropriately after the medical cause has been treated.

MISCELLANEOUS

AGE-RELATED FACTORS

- Puppies are more likely to present for lack of or incomplete housetraining, as well as for submissive and excitement urination.
- Cognitive dysfunction becomes more likely as the dog ages.

ZOONOTIC POTENTIAL

Low unless potentially zoonotic organisms in the urine or feces.

SYNOMYMS

- Inappropriate defecation • Inappropriate elimination • Inappropriate urination • Urine marking

SEE ALSO

- Cognitive Dysfunction Syndrome
- Separation Distress Syndrome • Submissive and Excitement Urination—Dogs

HYDROCEPHALUS

BASICS

DEFINITION

- Abnormal dilation of the ventricular system due to an increased volume of cerebrospinal fluid.
- May be symmetrical or asymmetrical.
- May involve the entire ventricular system or only elements proximal to a site of ventricular system obstruction.

PATHOPHYSIOLOGY

- Hydrocephalus is an active distension of the ventricular system—most commonly obstructive, rarely due to CSF overproduction.
- Obstructive—CSF accumulates in front of an obstruction along the normal CSF circulatory pattern (non-communicating) or at its resorption site by the meningeal arachnoid villi (communicating); depending on the balance between production of CSF (which is constant and independent of intracranial pressure) and the capacity for absorption of CSF, ICP may be high or normal; clinical signs may be noted in either case.
- Congenital obstruction—primary obstructive hydrocephalus; most common site is at the level of the mesencephalic aqueduct due to fusion of the rostral colliculi; prenatal infections (especially parainfluenza virus) may cause aqueductal stenosis with subsequent hydrocephalus; may result in considerable disruption of the architecture of the brain.
- Acquired obstruction—secondary obstructive hydrocephalus; sites include the interventricular foramina, mesencephalic aqueduct, or lateral apertures of the fourth ventricle.
- Overproduction of CSF (communicating)—rare; caused, for example, by a choroid plexus tumor.
- “Compensatory hydrocephalus”—condition wherein CSF fills the space where the neural parenchyma was destroyed; not true hydrocephalus; terminology obsolete.
- Clinical signs of neurologic dysfunction result from damage to neural parenchyma, which has a multifactorial etiology.

SYSTEMS AFFECTED

Nervous

GENETICS

Siamese cats—autosomal recessive

INCIDENCE/PREVALENCE

Unknown

SIGNALMENT

Species

Dog and cat

Breed Predilections

- Congenital—small and brachycephalic dogs: bulldogs, Chihuahuas, Maltese, Pomeranians, toy poodles, Yorkshire terriers, Lhasa apsos, Cairn terriers, Boston terriers, Pug dogs, and Pekingese.
- Inherited—Siamese cats and Yorkshire terriers. High incidence of clinically asymptomatic

ventriculomegaly in normal adult beagles.

- Acquired—any breed of cat or dog.

Mean Age and Range

- Congenital—usually becomes apparent at a few weeks up to 1 year of age. Acute onset of signs can occur in dogs with previously undiagnosed congenital hydrocephalus. The exact cause of this decompensation is uncertain.
- Acquired—any age.

Predominant Sex

None

SIGNS

General Comments

- Congenital—may occur without clinical signs, especially in dogs of toy breeds; other malformations or anomalies of the CNS may be noted (e.g., malformations of the cerebellum or syringomyelia), which may further contribute to the constellation of signs.
- Acquired—signs attributable to the underlying disease may be as or more prominent than the signs attributable to the hydrocephalus.
- Severity of the clinical signs may not correspond to the degree of ventricular enlargement.

Historical Findings

- Behavioral—decreased awareness; lack of or loss of training ability (including house-training); excessive sleepiness; vocalization; sometimes hyperexcitability.
- Visual deficits including blindness.
- Seizures—may be noted.

Physical Examination Findings

- Head—may appear large and dome-shaped with an exaggerated “stop”; open sutures and/or persistent fontanelles often present, but these may be present without hydrocephalus and vice versa. Bilaterally divergent strabismus in some dogs with severe congenital hydrocephalus—due to malformation of the orbit or to brainstem dysfunction.

Neurologic Examination Findings

- Signs may be acute or gradual in onset, and may be static or progressive.
- A wide variety of signs of brain dysfunction can occur.
- Cerebral disease—abnormal behavior (dullness and sleepiness), cortical blindness (loss of vision with normal eyes and pupillary light reflexes), inappropriate vocalization, sometimes hyperexcitable, circling may be present in lateralized disease.
- Gait abnormalities—incoordination, ataxia, and decreased postural reactions.
- Seizures—may occur.
- Congenital form—malformation of the orbit during growth may result in a ventrolateral strabismus with normal oculocephalic movements; oculocephalic movements may be abnormal if brainstem dysfunction is the cause of strabismus.
- Severely increased ICP—stupor or coma, pinpoint or dilated fixed pupils, loss of normal oculocephalic movements (physiologic nystagmus), abnormal respiratory patterns,

decerebrate posture; may lead to fatal tentorial herniation.

- Severity of clinical signs may not correlate with ventricular size, although there is a tendency for worse clinical signs with greater enlargement of the ventricles.

CAUSES

- Congenital—numerous congenital malformations cause obstruction of the ventricular system and result in hydrocephalus; heritable malformation, prenatal infection (e.g., dogs: parainfluenza virus, cats: coronavirus), exposure to teratogens, brain hemorrhage secondary to dystocia, nutritional deficiency (vitamin A), other.
- Acquired—tumors, abscesses, and inflammatory diseases (including inflammation resulting from hemorrhage caused by traumatic injuries or other causes of bleeding).

RISK FACTORS

Animals with compensated hydrocephalus may decompensate in the face of an insult such as infection or trauma, resulting in development of clinical signs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other congenital brain anomalies.
- Metabolic or toxic diseases resulting in cerebral dysfunction.
- Brain mass lesions or infectious diseases resulting in high intracranial pressure (hydrocephalus may coexist).
- Traumatic injury to the brain (hydrocephalus may coexist).

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal

IMAGING

- Skull radiography (congenital)—enlarged domed cranium with open sutures and persistent fontanelles; cranial vault may have a ground-glass appearance; also may reveal calvarial thinning.
- CT and MRI—provide definite diagnosis.
- Ultrasonography through fontanelles may reveal enlarged ventricles.

DIAGNOSTIC PROCEDURES

- CSF—use caution when collecting sample if patient has high ICP (may lead to fatal brain herniation through the foramen magnum and/or beneath the tentorium cerebelli); composition normal if no other intracranial disease (e.g., neoplasia, inflammation), but frequently abnormal when acquired underlying disease is present.
- EEG—congenital: usually characteristic, including hypersynchrony, high amplitude (25–300 µV), and low frequency (1–7 Hz); acquired: varies.

PATHOLOGIC FINDINGS

- Brain—may be large with loss of the normal pattern of sulci and gyri; may see distortion of the parenchyma, including thinning of the

H

H HYDROCEPHALUS

(CONTINUED)

cerebral cortex, rupture of the septum pellucidum, and atrophy of other adjacent structures; with severe disease, brain herniation may occur, either of the cerebrum and midbrain under the tentorium cerebelli or of the cerebellum and caudal medulla oblongata through the foramen magnum.

- Ventricular system—mildly to severely distended (either entirely or only the part rostral to the obstructive lesion); with non-communicating form, narrowing or blockage of the ventricular system due to inflammation or mass lesions.

TREATMENT

APPROPRIATE HEALTH CARE

- Inpatient—intensive care for patients with severe signs or when undergoing surgical therapy.
- Outpatient—patients with mild-to-moderate signs that can be treated medically.

NURSING CARE

Prevent secondary complications of recumbency for stuporous or comatose patients—avoid pressure sores; drying eyes; hypostatic lung congestion.

CLIENT EDUCATION

Advise client to observe for deterioration in mental alertness, vision, and behavior, which may signal worsening of the problem.

SURGICAL CONSIDERATIONS

- Surgical shunting of the CSF from the ventricles to the peritoneal cavity or right atrium—definitive treatment.
- Surgery should be considered only when medical management is ineffective or results in adverse side effects.
- Complications—shunt blockage occurs in up to 50% of patients; infection is less common; shunt revision commonly needed; over-shunting may result in severe and potentially fatal complications (collapse of the cerebral mantle).
- Clinical signs may not resolve completely; residual signs usually indicate irreversible brain damage.
- Surgery for a brain tumor or other mass lesion—consider if it is the underlying cause.

MEDICATIONS

DRUG(S) OF CHOICE

- Reduce CSF production. Data on the efficacy of corticosteroids in reducing CSF

production are conflicting, but beneficial clinical effects usually are seen (prednisone 0.25–0.5 mg/kg PO q12h or dexamethasone 0.1 mg/kg PO q12h); should be tapered to an alternate-day regimen and the dose lowered as far as possible. Carbonic anhydrase inhibitors: acetazolamide (10 mg/kg PO q8h) with or without furosemide (1 mg/kg q24h); electrolytes must be monitored frequently; long term use is unlikely to be beneficial and may lead to adverse consequences. Omeprazole has been reported to reduce CSF production in normal dogs in an experimental model, but no data is available on the usefulness of this drug in the clinical setting; anecdotal reports have been disappointing.

- Reduce ICP—osmotic diuretics: mannitol (1 g/kg slow IV infusion over 20 minutes; may repeat twice at 6-hour intervals); and/or loop diuretics: furosemide (dogs, 2–8 mg/kg IV, IM, SC q12h; cats, 1–2 mg/kg IV, IM, SC q12h). These are short-term treatments only, helpful for acute treatment of severe cases.
- Treat underlying cause—administer specific drugs when possible (e.g., antibiotics for bacterial infection, irradiation or surgery for neoplasia).

CONTRAINDICATIONS

Fluid therapy—use with caution with severe disease; do not overhydrate.

PRECAUTIONS

- Corticosteroids—long-term treatment may cause iatrogenic hyperadrenocorticism or hypoadrenocorticism if drug is suddenly withdrawn.
- Diuretics—may cause shock or electrolyte imbalances, especially hypokalemia with furosemide administration.

FOLLOW-UP

PATIENT MONITORING

Monitor for exacerbation of the hydrocephalus and for signs attributable to an underlying cause (e.g., intracranial neoplasia).

POSSIBLE COMPLICATIONS

- Brain herniation and death.
- Infection and blockage when ventriculo-peritoneal shunting is carried out; shunt revision and specific treatment for bacterial infection are then indicated.

EXPECTED COURSE AND PROGNOSIS

- Good to poor—depends on cause and severity.
- Mild congenital form—good prognosis; may require only occasional medical treatment.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Cerebellar hypoplasia in kittens congenitally infected with feline panleukopenia virus.

AGE-RELATED FACTORS

Congenital—usually seen in animals < 1 year old

SEE ALSO

Stupor and Coma

ABBREVIATIONS

- CNS = central nervous system
- CSF = cerebrospinal fluid
- CT = computed tomography
- EEG = electroencephalogram
- ICP = intracranial pressure

BASICS

OVERVIEW

• Hydronephrosis causes progressive distention of the renal pelvis resulting in compression and atrophy of the renal parenchyma secondary to ureteral outflow tract obstruction and associated increased hydrostatic pressure. • Most often hydronephrosis is unilateral (~80–85%) and occurs secondary to complete or partial obstruction of the ureter by uroliths, ureteral strictures, ureteral or trigonal neoplasia, retroperitoneal disease causing extraluminal compression, spay stump granuloma, trauma, radiotherapy, and accidental ligation of the ureter during ovariohysterectomy, cryptorchectomy, or after ectopic ureter surgery. • Bilateral hydronephrosis is less common, resulting from ureteral stone disease, congenital ureteral strictures, trigonal neoplasia, or a urethral outflow obstruction. Severe hydronephrosis can also be seen in dogs with ectopic ureters (commonly males) associated with a ureterovesical junction (UVJ) stenosis.

SIGNALMENT

Dog and cat

SIGNS

Historical Findings

- Subclinical in some dogs/cats.
- Inappetence.
- Weight loss.
- Polydipsia and/or polyuria.
- Hematuria.
- Depression, diarrhea, vomiting associated with uremia in patients with bilateral hydronephrosis or with compromised function in the contralateral kidney.
- May be referable to the cause of the obstruction (e.g., abdominal pain).
- It is important to realize that most dogs and cats with a ureteral obstruction will continue to produce urine due to the unilateral nature of the condition or the presence of a partial, rather than complete, ureteral obstruction.

Physical Examination Findings

- Normal in some patients.
- Renomegaly.
- Big kidney–little kidney syndrome associated with a previous ureteral obstruction.
- Renal, abdominal, or lumbar pain.
- Abdominal mass—bladder or prostate.
- Trigonal, prostatic, vaginal, or urethral mass (including ureteroliths) palpable on rectal examination.

CAUSES & RISK FACTORS

Ureteral Diseases

- Ureteroliths
- Ureretal stricture ± circumcaecal ureter
- Neoplasia
- Ureteral fibrosis
- Ureteral ligation during ovariohysterectomy
- Secondary to congenital ectopic ureter
- Complication from previous ectopic ureter surgery

Lower Urogenital Tract Diseases

- Urinary bladder masses (e.g., transitional cell carcinoma)
- Prostatic disease (e.g., neoplasia)
- Vaginal mass
- Cryptorchectomy resulting in inadvertent prostatectomy

Retroperitoneal Disease

- Masses—granuloma, neoplasm, cyst, abscess, hematoma
- Perineal hernia
- Post-radiotherapy-induced fibrosis

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes for renal pelvic dilation—e.g., ureteral obstruction (stone, stricture, tumor), pyelonephritis, pyelonephrosis, IV fluid therapy, chronic kidney disease, PU/PD
- Other causes of renomegaly—e.g., neoplasia, cysts, and perinephric pseudocysts (cats)
- Other causes of abdominal pain—e.g., pancreatitis and peritonitis
- Intervertebral disc disease leading to lumbar pain.
- Other causes for azotemia—e.g., chronic kidney disease, dehydration, urethral obstruction

CBC/BIOCHEMISTRY/URINALYSIS

- Normal in some patients
- Loss of urine-concentrating ability (first abnormality detected), hematuria, pyuria
- Azotemia, hyperphosphatemia, hyperkalemia, and acidemia with either bilateral ureteral obstructions or concurrent renal parenchymal disease

IMAGING

- Abdominal radiographs may be normal or show nephroliths, ureteroliths, urocystoliths, urethroliths, renomegaly, prostatomegaly, reduced retroperitoneal contrast, ureteral distension, or urinary bladder distension.
- Ultrasonography reveals dilation of the renal pelvis and diverticula, with thinning of the renal parenchyma; dilation of one or both ureters is detected in some dogs/cats if the hydronephrosis is associated with a ureteral obstruction (most common cause). If ureteral dilation is present, evaluation for cause (UVJ tumor, stenosis; ureteral stones; ureteral stricture).
- Injection of radiographic contrast material via either excretory urography (not recommended) or by nephropelvocentesis and ureteropyelography may be required to determine the location and cause of obstruction.
- CT can be helpful. Most commonly ultrasound and radiographs will determine cause without the need for further contrast imaging.

DIAGNOSTIC PROCEDURES

Urethrocystoscopy or vaginoscopy may help determine the location and cause of lower urinary tract obstruction or presence of ureteral ectopia, UVJ stenosis.

TREATMENT

- Treat as an inpatient.
- Start supportive care (e.g., fluids, ± antibiotics) while performing diagnostic tests.
- Correct fluid and electrolyte deficits with intravenous fluid therapy over 12–24 hours, followed by maintenance fluids as needed. Patients with extreme polyuria may need higher maintenance fluid rates to maintain hydration.
- Pending reestablishment of urinary patency, relieve lower urinary tract obstruction by catheterization, serial cystocentesis, or tube cystostomy as soon as possible.
- Specific treatment (e.g., interventional or surgical) depends on the cause and whether there is concurrent kidney disease or other disease processes (e.g., bilateral uroliths affecting contralateral kidney and/or ureter, metastatic neoplasia, etc.).
- Emergency surgery often required for a ureteral obstruction; metabolic and electrolyte abnormalities should be corrected prior to surgery.
- Nephrectomy is rarely ever indicated (e.g., neoplasia). If a ureteral obstruction is present, traditional ureteral surgery (ureterotomy, ureteral re-implantation) or more novel interventional therapies such as subcutaneous ureteral bypass (cat) or endoscopic ureteral stent placement (dog) should be considered.
- Referral to an experienced clinician is mandatory for the best ultimate outcome.

H

MEDICATIONS

DRUG(S)

- For a ureteral obstruction caused by uroliths alpha-adrenergic blockade should be considered (prazosin 0.25 mg/cat q12h or 1 mg/15 kg dog q8–12h).
- IV fluid diuresis; being careful to avoid overhydration.
- Diuretics, e.g., mannitol (0.25 g/kg bolus over 30 minutes then 1 mg/kg/min constant rate infusion (CRI) for 24 hours).
- Hyperkalemia (mild to moderate) often resolves with fluid replacement and/or bicarbonate administration unless bilateral obstruction and/or oliguria is present. Severe, symptomatic hyperkalemia requires more aggressive medical or surgical management for emergent decompression (ie. calling for prompt action).

CONTRAINdicATIONS/POSSIBLE INTERACTIONS

- Do not add or mix sodium bicarbonate with calcium-containing fluids.
- Do not give radiographic contrast material intravenously until the patient is rehydrated. Use radiographic contrast material with caution in azotemic patients.

HYDRONEPHROSIS

(CONTINUED)

SPECIAL CONSIDERATIONS

Patients with ureteral obstruction(s) should be considered an emergency and referred to colleagues who are highly experienced in managing this condition.

FOLLOW-UP

PATIENT MONITORING

- Ultrasonography—can repeat at 2- to 4-week intervals after relief of obstruction to assess improvement. Often some signs of resolution appear within days after relief of obstruction but can take up to 3 months.
- Monitor serum chemistries and electrolytes as needed. • After relief of obstruction—polyuria and post-obstructive diuresis may lead to hypokalemia, weight loss, dehydration, and possibly permanent renal injury so care should be taken to monitor these patients carefully.

POSSIBLE COMPLICATIONS

Rupture of the excretory system and irreversible renal damage. Decompression

should be considered when medical management fails to relieve obstruction.

EXPECTED COURSE AND PROGNOSIS

- Variable depending on the cause, duration of obstruction, and presence or absence of concurrent infection.
- Irreversible damage to the kidney usually begins 15–45 days after obstruction.
- If the obstruction is relieved within 2–4 weeks, some renal damage is reversible. If the obstruction is partial (over 80% of cases), the time before irreversible damage is prolonged.
- Concurrent infection accelerates the severity of renal damage. Antimicrobial therapy should be initiated when pyelonephritis is suspected.

HYPERADRENOCORTICISM (CUSHING'S SYNDROME)—CATS

BASICS

OVERVIEW

Feline Cushing's (hyperadrenocorticism or HAC) syndrome is a disorder of excessive cortisol secretion by the adrenal glands.

PATHOPHYSIOLOGY

- Spontaneous FCS—caused by overproduction of cortisol by the adrenal glands.
- Approximately 85% of cats with FCS have bilateral adrenocortical hyperplasia resulting from pituitary hyperplasia or tumor. The remaining 15% have an adrenal tumor, half of which are benign and half malignant. Regardless of the cause, FCS is usually (80%) accompanied by diabetes mellitus.

SIGNALMENT

- Cat
- No known breed or sex predisposition
- Middle-aged to older cats

SIGNS

- Polyuria, polydipsia, polyphagia, fragile (bruising, tearing, thin) skin, weight loss, and muscle weakness are most common.
- Obesity, hepatomegaly, alopecia, diarrhea, vomiting, abdominal enlargement, curled ear tips, and unkempt appearance are also seen.
- Lethargy (dullness) has been reported due to muscle weakness or the effects of a pituitary mass.
- Excess sex hormones can cause signs such as penile barbs and behavioral changes (sexual behavior).

CAUSES & RISK FACTORS

- Pituitary adenoma with subsequent corticotrophic hyperplasia and excess adrenocortical cortisol secretion.
- Autonomously functioning benign adenoma (50%) or malignant adenocarcinoma (50%).
- Iatrogenic due to glucocorticoid administration is rare.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Diabetes mellitus
- Insulin resistance
- Acromegaly
- Hepatopathy
- Renal disease
- Sex hormone-secreting adrenal tumors
- Hypothyroidism

CBC/BIOCHEMISTRY/URINALYSIS

- Stress leukogram.
- Hyperglycemia, hypercholesterolemia, mild increased ALT due to poorly regulated concomitant diabetes mellitus.
- High serum alkaline phosphatase not common because cats do not have corticoid-induced isoenzyme.
- Elevated urine cortisol:creatinine ratio (UC:Cr) is common.
- Less common—azotemia, proteinuria, and hyperglobulinemia.

OTHER LABORATORY TESTS

Screening Tests

- UC:Cr—sensitive (useful for its negative

predictive value, i.e., if a normal UC:Cr is obtained, FCS is unlikely), inexpensive, and easy to perform and interpret. Home collection (non-stressed) of urine is preferred.

- Low-dose dexamethasone-suppression test (LDDST)—extremely sensitive. Requires ten times the dose used in dogs: 0.1 mg/kg IV. Plasma obtained for cortisol before and 4 and 8 hours after dexamethasone administration. Failure to suppress is consistent with FCS.
- ACTH stimulation test, mainly a test of adrenal reserve—requires little time, is easy to interpret, is relatively inexpensive, and is specific for FCS when results are abnormal.

Differentiating Tests

- High-dose dexamethasone-suppression test (HDDST)—1 mg/kg dexamethasone, protocol as with LDDST. An at-home version using multiple UC:Crs and oral dexamethasone is easier to perform and interpret than the in-hospital protocol.
- Plasma endogenous ACTH measurement is high normal or greater with PDH compared to low plasma ACTH levels with AT (< 10 pg/mL). The normal range for cats is 0–60 pg/mL. Blood is collected in EDTA, spun immediately, and the plasma transferred to plastic and frozen.
- “At home” dexamethasone-suppression protocol—have owners collect morning urine samples on days 1, 2, and 3. Give oral doses of dexamethasone (LDDST [0.1 mg/kg] or HDDST [1 mg/kg]) at 6-h intervals for 2 days. Submit all three urine samples for UC:Cr ratio. Days 1 and 2 are basal values. Day 3 suppression less than 50% is not seen in cats with AT but may be seen with PDH.

IMAGING

- Abdominal ultrasound preferred to visualize adrenal glands. Although subjective, ultrasonography can be an excellent tool to discern PDH from AT. Symmetric adrenal glands of normal or enlarged size are suggestive of PDH, whereas unilateral enlargement supports AT.
- CT and MRI allow visualization of pituitary macroadenomas.

DIAGNOSTIC PROCEDURES

Sex hormone panels or insulin-like growth factor-1 (IGF-1) obtained to rule-out differentials.

TREATMENT

- FCS is a debilitating disease. Compared to dogs, options with cats are more limited and not as successful.
- Medical pretreatment prior to surgery is beneficial to prevent complications from fragile skin, infections, and bruising.
- Pituitary cobalt radiation of PDH has the potential to become a part of FCS treatment.
- Unilateral adrenalectomy for AT and bilateral adrenalectomy for PDH (with medical management of

hypoadrenocorticism) appear to be the most successful treatment options.

- Desoxycorticosterone pivalate (DOCP) and depo-medrol may be required.
- Hypophysectomy (microsurgical transsphenoidal) is available at some institutions.

MEDICATIONS

DRUG(S)

- Mitotane (Lysodren; o,p'-DDD) causes selective destruction of cortisol-secreting adrenocortical cells. Doses of 50 mg/kg/day divided have been used, but even when doubled sometimes failed to demonstrate improvement.
- Trilostane reversibly inhibits 3- β -17-hydroxysteroid dehydrogenase, which blocks steroid synthesis. In a majority of cases of FCS with PDH, trilostane reduced clinical signs and improved endocrine test results. Doses up to 60 mg/cat PO q12h have been used.
- Other medications have been used with some limited success (ketoconazole, metyrapone, and aminoglutethimide).

H

FOLLOW-UP

- Clinical improvement with reduced signs of FCS is supportive of beneficial drug therapy.
- Repeated UC:Cr and ACTH stimulation tests can be beneficial.

MISCELLANEOUS

ABBREVIATIONS

- ACTH = adrenocortotropic hormone
- AT = adrenal tumor
- CT = computed tomography
- FCS = feline Cushing's syndrome
- HAC = hyperadrenocorticism
- HDDST = high-dose dexamethasone-suppression test
- LDDST = low-dose dexamethasone-suppression test
- MRI = magnetic resonance imaging
- PDH = pituitary-dependent hyperadrenocorticism
- UC:Cr = urine cortisol:creatinine ratio

HYPERADRENOCORTICISM (CUSHING'S SYNDROME)—DOGS

BASICS

DEFINITION

- Spontaneous hyperadrenocorticism (HAC) is a disorder caused by excessive production of cortisol by the adrenal cortex.
- Iatrogenic HAC results from excessive exogenous administration of glucocorticoids of any form or by any route.
- In either instance, clinical signs are due to deleterious effects of elevated circulating glucocorticoid concentrations on multiple organ systems.

PATOPHYSIOLOGY

- Approximately 80–85% of cases of naturally occurring HAC are due to bilateral adrenocortical hyperplasia resulting from pituitary corticotroph tumors or hyperplasia with oversecretion of ACTH.
- In the remaining 15–20% of cases, cortisol-secreting adrenocortical neoplasia is present; approximately one-half of these are malignant.
- Rarely caused by ectopic ACTH secretion from a non-pituitary tumor.
- Iatrogenic HAC results from excessive administration of exogenous glucocorticoids.

SYSTEMS AFFECTED

- The degree to which each system is involved varies considerably; signs referable to one system may predominate or several systems may be involved to a comparable degree.
- Signs referable to the urinary tract or skin often predominate.
- Endocrine/Metabolic—hyperglycemia; diabetes mellitus occurs in 10%.
- Cardiovascular—hypertension (usually mild).
- Gastrointestinal—polyphagia.
- Hemic/Lymphatic/Immune—stress leukogram; immunosuppression; mild erythrocytosis and thrombocytosis.
- Hepatobiliary—hepatopathy due to glycogen deposition; increased serum ALP activity due to production of corticosteroid-induced isoenzyme.
- Neuromuscular—muscle weakness; CNS signs including anorexia, ataxia, disorientation and, uncommonly, seizures if pituitary macroadenoma present.
- Renal/Urologic—polyuria/polydipsia in 90% of cases; proteinuria; UTI common.
- Reproductive—testicular atrophy and anestrus.
- Respiratory—panting; pulmonary thromboembolism possible due to a hypercoagulable state.
- Skin—bilaterally symmetric alopecia common; comedones; hyperpigmentation; recurrent pyoderma.

GENETICS

No genetic basis known.

INCIDENCE/PREVALENCE

- No exact figures available.
- Considered one of most common endocrine disorders in dogs.

SIGNALMENT

Species

Dog

Breed Predilections

Poodle, dachshund, Boston terrier, German shepherd dog, and beagle.

Mean Age and Range

Generally a disorder of middle-aged to old animals; pituitary-dependent HAC (PDH) can very rarely be seen in dogs as young as 1 year.

Predominant Sex

No predilection for PDH in dogs; possible predilection for female dogs to have an adrenal tumor.

SIGNS

General Comments

- Severity varies greatly, depending on duration and severity of cortisol excess.
- In some cases, the physical presence of the neoplastic process (pituitary or adrenal) contributes.

Historical and Physical Examination Findings

Polyuria and polydipsia, polyphagia, pendulous abdomen, increased panting, hepatomegaly, hair loss, cutaneous hyperpigmentation, thin skin, muscle weakness, obesity, lethargy, muscle atrophy, comedones, bruising, testicular atrophy, anestrus, calcinosis cutis, facial nerve palsy.

CAUSES

- Pituitary-dependent—adenoma most common; adenocarcinomas rare; anterior pituitary involved in approximately 80% of cases, intermediate lobe in remaining cases; exact incidence of pituitary macroadenomas (i.e., > 1 cm diameter) unknown, may be 10–25%.
- Adrenal tumor—adenoma or carcinoma (50/50).
- Ectopic ACTH secretion—rare.
- Iatrogenic—due to glucocorticoid administration.

RISK FACTORS

- None known for spontaneous disease.
- Presence any condition that leads to exogenous glucocorticoid administration is a risk factor for iatrogenic HAC.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Depends on clinical and laboratory abnormalities displayed.
- Includes hypothyroidism, sex hormone dermatoses, Alopecia X, sex hormone-secreting tumors, acromegaly, diabetes mellitus, hepatopathies, renal disease, and other causes of polyuria/polydipsia.

CBC/BIOCHEMISTRY/URINALYSIS

- Hemogram may show eosinopenia, lymphopenia, leukocytosis, neutrophilia, erythrocytosis and/or thrombocytosis.
- Serum chemistry may show high liver enzymes, cholesterol, and total CO₂; alkaline

phosphatase activity high in approximately 90% and ALP elevations are proportionately greater than that for ALT; hyperglycemia common but only about 10% of dogs with HAC have concurrent diabetes mellitus.

- Urinalysis may reveal low specific gravity, proteinuria, hematuria, pyuria and/or bacteriuria.

OTHER LABORATORY TESTS

- Endocrine testing required in dogs with history, clinical signs, and laboratory abnormalities suggestive of HAC.
- Do not perform testing for HAC in sick dogs unless clinical signs consistent with HAC are present.
- Screening tests are designed to determine if HAC is present or not.
- Once a diagnosis of HAC is made, a differentiation test should be performed to determine if PDH or AT is present; differentiation provides information crucial to therapeutic decisions and an accurate prognosis.
- Differentiation tests should never be performed before a diagnosis of HAC is made via screening tests.
- See Appendix II for table of endocrine test protocols.
- To convert cortisol concentration in nmol/L to µg/dL, divide by 27.6.
- All cortisol concentrations below used for illustration purposes; check with your own laboratory for its normal ranges and cut-off values.

Screening Tests

Urine Cortisol:Creatinine Ratio (UC:Cr)

- Urine cortisol excretion increases as a reflection of augmented adrenal secretion of the hormone, whether PDH or AT present.
- An elevated UC:Cr is a sensitive marker of HAC, present in 90–100% of affected dogs.
- Should be measured in a sample collected at home when the pet not stressed.
- False-positive results common; only about 20% of dogs with an elevated UC:Cr have HAC.
- A normal ratio makes the diagnosis of HAC very unlikely ($\leq 10\%$ chance).
- Elevated ratio consistent with a diagnosis of HAC, but since the chance of a false-positive result is great, an ACTH stimulation test or low-dose dexamethasone suppression test must always be done to confirm the presence of HAC.

Low-Dose Dexamethasone Suppression Test

- Lack of suppression 8 hours after an injection of a low dose of dexamethasone consistent with a diagnosis of HAC.
- Sensitivity approximately 95% in dogs.
- In dogs, there is a relatively high chance of a false-positive result, up to 50%, if non-adrenal illness is present.
- Lack of suppression at 4 hours but with full suppression at 8 hours is technically not consistent with HAC but is suspicious for its presence; further testing warranted.
- With certain results, the LDDST may also serve as a differentiation test; if the 8-hour sample is > 30 nmol/L, the result is consistent with HAC; if, in addition,

(CONTINUED) HYPERADRENOCORTICISM (CUSHING'S SYNDROME)—DOGS

there is suppression to < 30 nmol/L at 4 h post-dexamethasone (i.e., an “escape” at 8 hours post-dexamethasone) or the 4- and/or 8-h post-dexamethasone samples are < 50% of baseline, the results are consistent with PDH; if criteria for PDH not met, chances are still approximately 50/50 for PDH versus AT. • If baseline values close to 30 nmol/L or suppression just at 50%, presence of PDH should be confirmed by other means. • A protocol exists in Europe where a minimum of two morning urine samples are collected and then dexamethasone is administered (3 doses over 24 h) for differentiating purposes and another urine sample is collected. The protocol reportedly has high sensitivity and specificity. However, the cortisol assay used is proprietary and not commercially available. The accuracy of the protocol using cortisol assays commercially available in the United States has not been established, and, thus, the method is not recommended for use in the United States and Canada.

ACTH Stimulation Test

- A response greater than normal is consistent with a diagnosis of spontaneous HAC.
- Overall sensitivity of the test approximately 80%; for PDH, sensitivity is approximately 87%, while for HAC due to an AT, sensitivity is approximately 61%. • More specific in dogs than the LDDST (only 15% chance of a false-positive result with non-adrenal illness).
- Can never differentiate between PDH and AT. • Only test that can diagnose iatrogenic HAC; a diagnosis is made with a history of glucocorticoid exposure by any route, presence of consistent clinical signs and a post-ACTH cortisol concentration below the reference range. • Cortrosyn is the recommended form of ACTH to use; if using compounded ACTH, collect samples before and at 1 and 2 hours post-ACTH administration so peak response not missed.

Differentiating Tests**High-Dose Dexamethasone Suppression Test**

- Two responses consistent with PDH; if there is suppression to < 30 nmol/L at 4 and/or 8 hours post-dexamethasone or the 4-and/or 8-h post-dexamethasone samples are < 50% of baseline, PDH is present. • If baseline values close to 30 nmol/L or suppression just at 50%, presence of PDH should be confirmed by other means. • Can never confirm presence of an AT; if criteria for diagnosis of PDH not met, there is a 50/50 chance the patient has PDH or an AT.

Endogenous ACTH Concentration

- Requires only a single blood sample but special handling needed. • In patients with PDH, endogenous ACTH (eACTH) concentration is normal to increased; with AT, eACTH concentration is below normal.
- Can be used to confirm the presence of an AT. • A gray zone exists in the results; if the

patient's eACTH concentration falls into this zone, results not diagnostic. • With repeat testing when the original concentration measured is in the gray zone (about 15% chance), approximately 96% have definitive differentiation. • There is no way to predict when eACTH concentration will be in the gray zone.

IMAGING

- Abdominal radiographs may differentiate PDH from AT; approximately 40–50% of canine ATs are visualized; adrenal mineralization is highly suspicious for the presence of an AT. • Chest radiographs indicated in patients with an AT to check for metastases. • Ultrasonography, CT, and MRI—useful for differentiating PDH from AT and for staging AT; abdominal ultrasonography can never be used as a screening test as bilateral adrenal enlargement may be seen due to chronic non-adrenal illness; AT can be small and may be difficult to see with ultrasonography; vena caval, hepatic or renal invasion is an indicator of malignancy; adrenal atrophy can be difficult to determine with ultrasonography. • CT and MRI—often useful for demonstrating pituitary macroadenomas. • Since radiation therapy, a treatment modality required for a pituitary macroadenoma, is more effective for smaller tumors, some authors advocate routine pituitary imaging in all dogs when PDH diagnosed; follow-up and treatment recommendations vary depending on tumor size.

DIAGNOSTIC PROCEDURES

Adrenal biopsy (usually performed on AT obtained via adrenalectomy) often needed to differentiate benign vs. malignant tumor.

PATHOLOGIC FINDINGS

- PDH—gross examination reveals normal-to-enlarged pituitary and bilateral adrenocortical enlargement. • Microscopically, pituitary adenoma, adenocarcinoma, or corticotroph hyperplasia of pars distalis or pars intermedia and adrenocortical hyperplasia. • AT—gross examination reveals variable-sized adrenal mass, atrophy of contralateral gland (rarely bilateral tumors), and metastasis in some patients with adrenal carcinoma; invasion into vena cava or vena caval thrombosis may be seen with malignant tumors. • Microscopically, see adrenocortical adenoma or carcinoma.
- With any form HAC, general changes of cortisol excess may be seen such as cutaneous atrophy and glomerulopathy.

**TREATMENT****APPROPRIATE HEALTH CARE**

Dictated by severity of clinical signs, patient's overall condition, and any complicating

factors (e.g., diabetes mellitus, pulmonary thromboembolism).

NURSING CARE

Variable as above.

ACTIVITY

No alteration of activity necessary.

DIET

Usually no need to alter; use appropriate diet if diabetes mellitus concurrent.

CLIENT EDUCATION

- If using medical therapy, life-long therapy required. • If adverse reaction to mitotane or trilostane occurs—discontinue drug, give prednisone, and have veterinarian reevaluate next day; if no response to prednisone noted in a few hours, veterinarian should evaluate immediately.

SURGICAL CONSIDERATIONS

- Hypophysectomy—described, but generally not available in the United States. • Bilateral adrenalectomy not used for treatment of PDH in dogs • Surgery is the treatment of choice in dogs with adrenocortical adenomas and small carcinomas unless the patient is a poor surgical risk or the client refuses surgery.
- Appropriate personnel and facilities are required as adrenalectomy is a technically demanding surgery and intensive postoperative management is required.
- Removal of tumor and vena caval thrombi can be performed; surgery not expected to be curative in such cases, but long-term survival can be achieved, e.g., > 1 year. • Depending on patient status, medical control of HAC may be desirable prior to surgery, if possible.

**MEDICATIONS****DRUG(S) OF CHOICE****Mitotane**

- Mitotane (*o,p'*-DDD, Lysodren) is one of two main drugs used for medical management of PDH in dogs; selectively destroys glucocorticoid-secreting cells of the adrenal cortex; may be drug of choice for medical management of AT since it may destroy tumor cells as well as control cortisol secretion.
- PDH—give an initial loading dose of 40–50 mg/kg divided twice daily; evaluate efficacy with ACTH stimulation test after 8 days or sooner if decreased appetite, vomiting, diarrhea, listlessness or decreased water intake (< 60 mL/kg/day) noted; goal is for both basal and post-ACTH cortisol concentration to be in ideal range of 30–150 nmol/L; continue induction with repeat testing as necessary until adequate response seen, then initiate maintenance therapy at 50 mg/kg/week divided into two to three doses; dosage adjustments based on ACTH stimulation testing (maintain basal

HYPERADRENOCORTICISM (CUSHING'S SYNDROME)—DOGS (CONTINUED)

and post-ACTH cortisol levels within ideal range); if serum cortisol concentration pre- or post-ACTH < 30 nmol/L, stop administering mitotane and administer physiologic doses prednisone (0.1 mg/kg q12h); cannot administer prednisone within 12 hours before ACTH stimulation test; perform ACTH stimulation tests every 7–14 days initially; cortisol secretion usually recovers in weeks to a couple months but can take longer; once cortisol concentration is in ideal range, discontinue prednisone and begin maintenance therapy; if had been on maintenance therapy when became cortisol deficient, restart maintenance at 25% lower dose; if relapse occurs at any time while on maintenance therapy, as indicated by cortisol levels above ideal range, dose adjustment required; if post-ACTH serum cortisol concentration 150–300 nmol/L, increase maintenance dose 25% and reevaluate in 4 weeks; if post-ACTH serum cortisol concentration > 300 nmol/L, reload for 5–7 days and do an ACTH stimulation test; continue loading until cortisol concentration is in ideal range, then reinstitute weekly maintenance dose at approximately 50% higher dose.

- AT—goal of mitotane use is low-to-non-detectable (i.e., < 30 nmol/L) basal and post-ACTH cortisol concentrations; starting dose 50–75 mg/kg divided daily; perform ACTH stimulation test after 10–14 days to evaluate efficacy or sooner if decreased appetite, vomiting, diarrhea, listlessness or decreased water intake (< 60 mL/kg/day) noted; induction typically requires higher doses and is of longer duration than for treatment of PDH; dose should be increased by 50 mg/kg/day every 10–14 days if control has not been achieved as judged by an ACTH stimulation test; if adverse effects develop due to mitotane, administration should continue at highest tolerable dose; once control achieved, maintenance therapy should begin at 75–100 mg/kg/wk divided into 2–3 doses; if cortisol levels pre- and post-ACTH rise into normal resting range (i.e., 10–160 nmol/L), increase maintenance dose 50%; if cortisol levels rise above normal resting range pre- and post-ACTH, reload until control achieved and increase weekly maintenance dose approximately 50%; during induction and maintenance, since goal is to create glucocorticoid insufficiency, give prednisone at 0.2 mg/kg/day.
- Aldosterone deficiency possible secondary to mitotane therapy; if occurs, likely patient will have permanent complete adrenocortical insufficiency; treatment for hypoadrenocorticism should be initiated.

Trilostane

- Trilostane (Vetoryl) is approved for use in Europe and the United States; efficacy for treatment of PDH high, comparable to mitotane; survival of dogs with PDH is same

for dogs treated with mitotane or trilostane; inhibits adrenocortical enzyme 11- β -hydroxysteroid dehydrogenase and maybe others, thereby suppressing production of progesterone and its end-products, including cortisol and aldosterone.

- Initial dose is 2.2–6.7 mg/kg PO q24h or divided q12h; if minor side effects are seen (i.e., anorexia, vomiting, diarrhea), stop the drug for 3–5 days and then restart q48h for 1 week before continuing with initial dosing scheme; an ACTH stimulation test should be performed beginning 4–6 hours post-pill at 10–14 days, 30 days, and 90 days after being on a full dose; if at the 10–14 day recheck any improvement is seen, do not increase the dose even if cortisol concentrations above ideal but wait until the 30 day recheck and change the dose then if needed. If post-ACTH cortisol concentration is < 40 nmol/L and the patient feels well, stop the trilostane for 48–72 hours and then either restart at a lower dose, or, ideally, an ACTH stimulation test should be performed and trilostane not reinstated until cortisol secretion has recovered; if the post-ACTH cortisol concentration is 40–150 and clinical signs have resolved, the dose should continue as is; if the post-ACTH cortisol concentration is 150–250 nmol/L, increase the trilostane dose if clinical signs are present or, if the clinical signs have resolved, leave as is but monitor carefully for signs of recurrence; if the post-ACTH serum cortisol concentration is > 250 nmol/L, increase once-daily dose or twice-daily therapy should be used; the same dose given once-daily should be divided and given twice (e.g., if giving 60 mg once daily then give 30 mg q12h); if post-ACTH serum cortisol concentration is 40–150 nmol/L but clinical signs are continuing, use twice-daily therapy; once the dog's clinical condition and dose have stabilized, an ACTH stimulation test should be performed every 3–6 months and serum potassium concentration measured to check for hyperkalemia.
- Since trilostane can suppress aldosterone secretion, an Addisonian crisis can occur; adrenocortical necrosis secondary to trilostane administration may be more common than previously believed; hypocortisolemia secondary to trilostane administration usually resolves within 48–72 hours of discontinuation of drug administration, but temporary suppression of weeks to months and even permanent suppression can occur.
- Can be used to treat AT and will control clinical signs, at least transiently, but not the drug of choice; for AT, mitotane is the drug of choice as it is truly chemotherapeutic and may kill tumor cells.

I-Deprenyl

- I-Deprenyl (selegiline hydrochloride) FDA approved for treatment of PDH; decreases pituitary ACTH secretion by increasing dopaminergic tone in the hypothalamic-

pituitary axis, thus decreasing serum cortisol concentrations; indicated only for treating uncomplicated PDH; not recommended for dogs with concurrent illnesses such as diabetes mellitus; cannot be used to treat AT; initiate therapy with 1 mg/kg daily and increase to 2 mg/kg/day after 2 months if response inadequate; if higher dose also ineffective, give alternative therapy; no objective monitoring; assessment of efficacy based on subjective evaluation of remission of clinical signs.

- Efficacy questionable; one study found 20% efficacy and another judged L-deprenyl ineffective.

- Adverse effects such as anorexia, lethargy, vomiting, and diarrhea uncommon (< 5% of dogs) and usually mild; disadvantages include need for lifelong daily administration and medication expense.

Ketoconazole

Ketoconazole (10 mg/kg PO q12h initially; up to 20 mg/kg PO q12h in some dogs) inhibits enzymes responsible for cortisol synthesis; indicated for dogs unable to tolerate mitotane at doses necessary to control HAC; may be useful for palliation of clinical signs of HAC in dogs with AT; monitoring done by performance of ACTH stimulation tests with same goals as for mitotane; efficacy approximately 50% or less; adverse effects include anorexia, vomiting, diarrhea, lethargy, thrombocytopenia and idiosyncratic hepatopathy.

CONTRAINdications

- Do not use nonsteroidal anti-inflammatory agents in dogs with uncontrolled HAC.
- Drugs that increase blood pressure or coagulation should be used with caution.

PRECAUTIONS

- Side effects of mitotane not uncommon; mild in most dogs; include lethargy, weakness, anorexia, vomiting, diarrhea, ataxia, and iatrogenic hypoadrenocorticism. • Side effects more common in dogs with AT given high doses of mitotane. • For mitotane, use with caution in patients with renal insufficiency and primary hepatic disease. • Side effects of ketoconazole seem to be less common; include anorexia, vomiting, diarrhea, thrombocytopenia, and hepatopathy. • For ketoconazole, use with caution in patients with primary hepatic disease or thrombocytopenia; effect on breeding ability unknown. • Side effects of l-deprenyl uncommon. • Side effects of trilostane include anorexia, lethargy, vomiting and diarrhea; may occur in approximately 60% of patients; Addisonian crisis and adrenocortical necrosis have been reported. • For trilostane, use with caution in patients with renal insufficiency and primary hepatic disease; contraindicated in pregnancy. • For all drugs, if using on a diabetic patient, careful monitoring needed; insulin needs can decrease rapidly with control of HAC.

(CONTINUED) HYPERADRENOCORTICISM (CUSHING'S SYNDROME)—DOGS

ALTERNATIVE DRUG(S)

Radiation therapy required for animals with pituitary macroadenomas; ACTH levels may take several months to decrease; control HAC with above drugs in the interim.

**FOLLOW-UP****PATIENT MONITORING**

Response to therapy—use periodic ACTH stimulation testing to assess mitotane, ketoconazole, or trilostane efficacy (see above for details); once on maintenance mitotane therapy, test at 1, 3, and 6 months and every 3–6 months thereafter or if clinical signs of HAC recur; adequacy of any necessary mitotane reloading period is checked with an ACTH stimulation test before higher maintenance mitotane dose initiated; adequacy of ketoconazole or trilostane dose checked with an ACTH stimulation test after any dose alteration; with trilostane, ACTH stimulation test should be performed starting 4–6 hours post-pill, while with mitotane and ketoconazole, post-pill timing does not matter; clinical signs of HAC resolve several days to months after control achieved; evaluate efficacy of l-deprenyl therapy solely on the basis of resolution of clinical signs of HAC.

PREVENTION/AVOIDANCE

For prevention of recurrence, regular administration of medications with appropriate follow-up required.

POSSIBLE COMPLICATIONS

- Hypertension • Proteinuria • Recurrent infection • Urinary calculi (calcium oxalate)
- Diabetes mellitus • Pulmonary thromboembolism • Neurologic signs secondary to a pituitary macroadenoma

EXPECTED COURSE AND PROGNOSIS

- Untreated HAC—generally a progressive disorder with a poor prognosis. • Treated PDH—usually a good prognosis; median

survival time with mitotane or trilostane treatment approximately 2 years; at least 10% survive 4 years; dogs living longer than 6 months tend to die of causes unrelated to HAC. • Macroadenomas and neurologic signs—poor-to-grave prognosis; macroadenomas with no or mild neurologic signs—fair-to-good prognosis with radiation and medical therapy. • Adrenal adenomas—usually good-to-excellent prognosis; small carcinomas (not metastasized) fair-to-good prognosis overall, good-to-excellent with surgical resection. • Large carcinomas and AT with widespread metastasis—generally poor-to-fair prognosis, but impressive responses to high doses of mitotane occasionally seen.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Neurologic signs in dogs with large pituitary tumors; glucose intolerance or concurrent diabetes mellitus; pulmonary thromboembolism; increased incidence of infections, especially urinary tract and skin; hypertension; proteinuria/glomerulopathy.

H

HYPERCALCEMIA

BASICS

DEFINITION

- Serum total calcium > 11.5 mg/dL (dogs).
- Serum total calcium > 10.5 mg/dL (cats).
- Serum ionized calcium > 1.45 mmol/L (dogs).
- Serum ionized calcium > 1.4 mmol/L (cats).
- Hypercalcemia must be confirmed by demonstration of increased concentrations of ionized calcium.
- Total calcium concentrations and correction formulas do not accurately predict ionized calcium.

H

PATHOPHYSIOLOGY

- Control of calcium is complex and is influenced by the actions of PTH and vitamin D and the interaction of these hormones with the gut, bone, kidneys, and parathyroid glands.
- Derangement in the function of these can lead to hypercalcemia.
- Secretory products of some neoplastic cells can also disturb calcium homeostasis.

SYSTEMS AFFECTED

- Cardiovascular—hypertension and altered cardiac contractility.
- Gastrointestinal—reduces excitability of smooth muscle and can alter gastrointestinal function.
- Neuromuscular—depressed skeletal muscle contractility causes weakness.
- Renal/Urologic—high levels of calcium are toxic to the renal tubules and can cause polyuria and polydipsia (PU/PD) and renal failure; can also lead to urolithiasis and associated lower urinary tract disease.

SIGNALMENT

- Dog and cat
- Primary hyperparathyroidism in the Keeshond and Siamese cat

SIGNS

General Comments

- Depend on the cause of hypercalcemia.
- Patients with underlying neoplasia, renal failure, or hypoadrenocorticism generally appear ill.
- Patients with primary hyperparathyroidism show mild clinical signs, if any, due solely to the effects of hypercalcemia.
- Signs become apparent when hypercalcemia is severe and chronic.

Historical Findings

- Many animals have no clinical signs.
- PU/PD—most common in dogs.
- Anorexia.
- Lethargy—most common in cats.
- Vomiting.
- Constipation.
- Weakness.
- Stupor and coma—severe cases.

- Lower urinary tract signs in animals with secondary calcium-containing uroliths.

Physical Examination Findings

- Lymphadenomegaly or abdominal organomegaly in patients with lymphoma.
- Usually unremarkable in dogs with primary hyperparathyroidism.
- Parathyroid gland adenoma—rarely palpable in dogs; often palpable in cats with primary hyperparathyroidism but can be confused with the thyroid gland.

CAUSES

- Neoplasia—lymphoma (most common in dogs, less common in cats), anal sac apocrine gland adenocarcinoma (dogs), multiple myeloma, lymphocytic leukemia, metastatic bone tumor, fibrosarcoma (cats), various types of carcinoma.
- Primary hyperparathyroidism.
- Renal failure—acute or chronic.
- Granulomatous diseases.
- Hypoadrenocorticism.
- Vitamin D rodenticide intoxication—no longer marketed in the United States.
- Vitamin D intoxication from plant or food sources.
- Osteolytic diseases.
- Aluminum toxicosis.
- Idiopathic hypercalcemia in cats.

RISK FACTORS

- Keeshond breed—hyperparathyroidism
- Renal failure
- Neoplasia
- Use of calcium supplements or calcium-containing intestinal phosphate binders
- Use of calcitriol or other vitamin D preparations

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- History should include exposure to exogenous vitamin D sources and any previous response to steroids.
- History of waxing/waning illness suggests hypoadrenocorticism.
- Complete lymph node, rectal, and abdominal palpation may raise index of suspicion for lymphoma and other neoplasia.
- Assessment of hydration status, renal palpation, and urinary history points toward lower urinary tract disease or renal failure.

LABORATORY FINDINGS

Drugs That May Alter Laboratory Results

- Oxalate, citrate, and EDTA anticoagulants bind calcium and falsely lower calcium measurement.
- Vitamin D preparations and thiazide diuretics can raise serum calcium concentrations.

Disorders That May Alter Laboratory Results

- Hemolysis and lipemia can falsely raise calcium concentrations.
- Hypoalbuminemia can falsely lower total calcium concentration.

Valid if Run in Human Laboratory?

Yes

CBC/BIOCHEMISTRY/URINALYSIS

- Serum calcium—total calcium concentration depends on binding proteins; adjusted (corrected) calcium can be estimated by the following formulas:

$$\text{Corrected Ca} = \text{Ca (mg/dL)} - \text{albumin (g/dL)} + 3.5$$

or

$$\text{Corrected Ca} = \text{Ca (mg/dL)} - [0.4 \times \text{total protein (g/dL)}] + 3.3$$

- (These formulas are not always indicative of true ionized calcium status in the dog, and have not been well evaluated in the cat.)
- Azotemia and isosthenuria help define degree of renal impairment.

- Serum phosphorus is usually low or low-normal in patients with primary hyperparathyroidism or hypercalcemia associated with malignancy.
- Hyperphosphatemia in the absence of azotemia suggests a non-parathyroid cause of hypercalcemia.
- Combination of hyperphosphatemia and azotemia is difficult to interpret because renal failure can be the cause or effect of hypercalcemia.
- Hyperkalemia and hyponatremia suggest hypoadrenocorticism.
- Hyperglobulinemia is associated with multiple myeloma.
- Cytopenias are seen in patients with myelophthisic disease.

OTHER LABORATORY TESTS

- Serum ionized calcium is high in patients with primary hyperparathyroidism or hypercalcemia associated with malignancy; usually normal in patients with hypercalcemia associated with renal failure.
- Serum PTH measurement—intact molecule and two-site assay methods have the greatest specificity; high-normal or high concentration suggests primary hyperparathyroidism; can be high in patients with chronic renal failure; low concentration makes neoplasia more likely.
- Serum PTH-rp measurement is often high in patients with hypercalcemia associated with malignancy.
- Vitamin D assays are not widely available.

IMAGING

- Radiography is useful for assessing renal size and shape, urolithiasis, bone lysis, and occult neoplasia.

(CONTINUED)

HYPERCALCEMIA

- Ultrasonography valuable for assessing renal architecture, abdominal lymphadenomegaly, parathyroid tumors, and urolithiasis.

DIAGNOSTIC PROCEDURES

- Cytologic examination of fine-needle aspirate of lymph nodes to confirm lymphoma.
- Examination of bone marrow aspirate to confirm occult hematopoietic neoplasia.
- ACTH stimulation testing to confirm hypoadrenocorticism.

**TREATMENT**

- Inpatient care because of the deleterious effects of hypercalcemia and the need for fluid therapy.
- Consider severe hypercalcemia a medical emergency.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Normal saline—fluid of choice.
- Avoid calcium-containing fluids.
- Diuretics (furosemide) and corticosteroids can be useful.

CONTRAINDICATIONS

- Do not use glucocorticoids until the diagnosis of lymphoma is excluded; they can obfuscate the diagnosis; if hypoadrenocorticism is suspected, do not give glucocorticoids until after ACTH stimulation testing.
- Thiazide diuretics can cause calcium retention.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

Avoid the use of calcium- or phosphorus-containing compounds; they can cause soft tissue mineralization in severely hypercalcemic and hyperphosphatemic patients.

ALTERNATIVE DRUG(S)

- Sodium bicarbonate (1–4 mEq/kg) may be useful in combination with other treatments.

- Mithramycin has been used in severe hypercalcemic crises; avoid its use if possible, because of associated nephrotoxicity and hepatotoxicity.
- Calcitonin may be useful in the treatment of hypervitaminosis D.
- Pamidronate has been used successfully for treatment of hypercalcemia of various causes in dogs and cats.

**FOLLOW-UP****PATIENT MONITORING**

- Serum calcium every 12 hours (ionized calcium if possible).
- Renal function tests—the first sign of tubular damage may be casts in the urine sediment.
- Must monitor urine output, particularly if oliguric renal failure is suspected, in which case urine output should be measured carefully; oliguria cannot be determined unless the patient is fully hydrated.
- Hydration status must be monitored; indicators of overhydration include increased body weight, increased central venous pressure, and edema (pulmonary or subcutaneous).

POSSIBLE COMPLICATIONS

- Irreversible renal failure
- Soft tissue mineralization

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Calcium-containing urolithiasis

AGE-RELATED FACTORS

- Mild elevations in calcium and phosphorus may be normal in growing animals.
- Middle-aged and older dogs and cats are at increased risk for cancer.

PREGNANCY/FERTILITY/BREEDING

A fetus is at the same risk as the dam; do not alter treatment because of pregnancy.

H

HYPERCAPNIA

BASICS

DEFINITION

- An increase in the partial pressure of carbon dioxide in arterial blood.
- Normal PaCO₂ values—35–45 mmHg.
- Hypercapnia is synonymous with hypoventilation.

PATHOPHYSIOLOGY

- CO₂—end product of aerobic cellular metabolism; considered the primary drive for ventilation by stimulation of central chemoreceptors in the medulla oblongata; carried in the blood in three forms: bicarbonate (65%), bound to hemoglobin (30%), and dissolved in plasma (5%; the source of PaCO₂ values); constantly being added to alveolar gas from the pulmonary circulation and removed by alveolar ventilation.
- Uncommonly encountered in non-anesthetized, clinically normal patient; result of alveolar hypoventilation.

SYSTEMS AFFECTED

- Cardiovascular—may result in endogenous catecholamine release, which may induce cardiac arrhythmias; may cause vasodilation leading to hypotension.
- Hemic/Lymphatic/Immune—may alter acid-base balance; acute increase results in production of excess hydrogen ions and a decrease in pH (respiratory acidosis).
- Nervous—the brain is primary affected organ; cerebral blood flow related to PaCO₂ in a linear fashion; hypercapnia results in increased cerebral blood flow and intracranial pressure; PaCO₂ > 90 mmHg may lead to CO₂ narcosis and unconsciousness.

SIGNALMENT

Any breed, age, and sex of dogs and cats

SIGNS

Historical Findings

- Abnormal breathing pattern.
- Weakness—secondary to concurrent hypoxemia or primary neuromuscular disease.

Physical Examination Findings

- Anesthetized patients—usually no obvious signs; severe condition may lead to tachypnea and tachycardia.
- Hypoventilation owing to muscle weakness or neuropathy—weak respiratory efforts; decreased thoracic excursion; excessive abdominal effort; exaggerated movement of facial muscles during inspiration; possibly generalized weakness as a result of primary neuromuscular disorder (myasthenia gravis, polyradiculoneuropathy).
- Upper airway obstruction—marked, prolonged inspiratory efforts with variable expirations, depending on whether the obstruction is fixed (e.g., mass) or non-fixed (e.g., laryngeal paralysis); stridor or stertor common.

- Pleural effusion—may have shallow rapid respirations; may note a marked abdominal component; lung sounds decreased in ventral thorax.
- Pulmonary parenchymal disease—increased bronchovesicular sounds; crackles (edema, infection, contusions).

CAUSES

- Hypoventilation can result from anesthesia, muscular paralysis, upper airway obstruction, air or fluid in the pleural space, restriction in movement of the thoracic cage, diaphragmatic hernia, pulmonary parenchymal disease, and CNS disease. Can occur in spontaneously breathing patients during inhalation anesthesia (isoflurane or sevoflurane).
- Increased inspired CO₂—rebreathing of expired gases because of accumulation of exhausted CO₂ absorbent in an anesthesia machine most common cause; also inadequate fresh gas flow in a non-rebreathing anesthesia circuit (e.g., Bain and Ayres T-piece).
- Exogenous administration of sodium bicarbonate, which dissociates into CO₂, with inadequate ventilation.

RISK FACTORS

- Use of inhalation agent (isoflurane or sevoflurane) as sole anesthetic, as inhalation anesthetics are potent respiratory depressants.
- Deep planes of inhalation anesthesia.
- Inadequate fresh flow of oxygen with non-rebreathing anesthesia circuits.
- Bronchial or alveolar disease.
- Upper airway obstruction.
- Pleural disease.
- Inadequate ventilation during administration of sodium bicarbonate.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Conscious patient—hyperthermia; hypoxemia; head trauma.
- Anesthetized patient—hypoxemia.

LABORATORY FINDINGS

Drugs That May Alter Laboratory Results

N/A

Disorders That May Alter Laboratory Results

Air bubbles in the arterial blood sample and/or improper packaging of the arterial blood sample—falsely low PaCO₂ values after approximately 30 minutes.

Valid if Run in Human Laboratory?

Yes

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

- Arterial blood gas analysis—diagnosis determined from a blood sample collected in an anaerobic manner, as follows: use enough heparin to coat the needle and the inside of

the syringe; obtain sample from femoral or dorsal pedal artery; place a rubber stopper on the needle or cover the hub of the syringe to prevent room air from entering the sample.

- Analyze sample within 15 minutes if left at room temperature; place sample on ice to extend time for safe and accurate analysis to 2–4 hours.
- Bedside or portable blood gas analyzers—several models available; make analysis more convenient.

IMAGING

Thoracic radiography—may reveal bronchial, alveolar, or pleural space disease. Cervical radiography can suggest a large airway obstruction.

OTHER DIAGNOSTIC PROCEDURES

- Upper airway endoscopy used to rule out laryngeal mass or paralysis.
- Alternative method of analysis—capnometer (see Figures 1 and 2).
- End-tidal gas is almost entirely alveolar gas and provides nearly the same value for CO₂ as PaCO₂, which closely approximates the mean value of perfused alveoli.
- Advantage of capnometry—can monitor PaCO₂ on a breath-by-breath basis, whereas a blood gas sample is a finite value at a finite time.
- Disadvantages—tachypnea and insufficient tidal volume will result in falsely low PetCO₂;

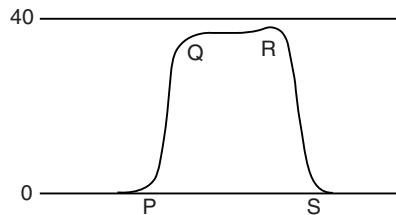

Figure 1.

Normal capnogram. The wave segment from P to Q is exhalation; Q to R is the plateau after exhalation, point R is the end tidal CO₂; R to S is inhalation.

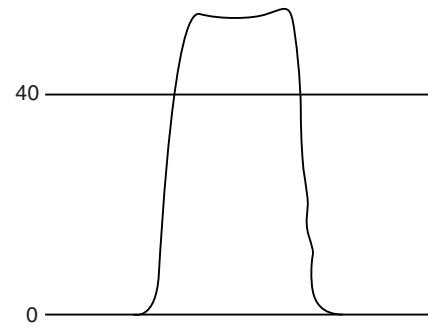

Figure 2.

Capnogram with hypercapnia. The plateau and end tidal CO₂ is above normal.

(CONTINUED)

HYPERCAPNIA

PaCO_2 much higher than PetCO_2 with pulmonary thromboembolism; open thoracic cavity (surgery) reports falsely low PetCO_2 due to excessive dead space.

**TREATMENT**

- Provide adequate alveolar ventilation.
- Anesthesia—ventilation accomplished manually or mechanically with anesthesia ventilator.
- Non-anesthetized patient with severe pulmonary or CNS disease—mechanical ventilation with critical care ventilator; generally requires heavy sedation.
- Supplemental oxygen—need determined by primary disease; providing supplemental oxygen without providing ventilation will likely not correct hypercapnia.
- Definitive treatment—treat primary cause; discontinue inhalation anesthesia or provide ventilation during anesthesia; diagnostics for neuromuscular disease.

**MEDICATIONS****DRUG(S) OF CHOICE**

Respiratory stimulants not indicated and rarely reverse hypoventilation.

CONTRAINDICATIONS

Anesthetic drugs or other respiratory depressants—contraindicated with CNS disease if adequate ventilatory support cannot

be provided; increased PaCO_2 may result in dangerous elevations of intracranial pressure and predispose patient to herniation of the brainstem.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

**FOLLOW-UP****PATIENT MONITORING**

- Assess effectiveness of supportive therapy (ventilation) and definitive treatment—should result in decreased respiratory effort.
- Reevaluate the arterial blood gas or capnometry—determine improvement; assess adequacy of ventilation.

POSSIBLE COMPLICATIONS

Concurrent CNS disease may cause high intracranial pressure and predispose the patient to herniation of the brainstem and death.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

H

HYPERCHLOREMICA

BASICS

DEFINITION

Serum chloride concentration > 122 mEq/L in dogs and > 129 mEq/L in cats.

PATHOPHYSIOLOGY

- Chloride is the most abundant anion in the extracellular fluid.
- Hyperchloremia is associated with similar conditions to those that cause hypernatremia—water loss in excess of sodium and chloride or excessive NaCl intake.
- Chloride concentration varies inversely to bicarbonate concentration; high bicarbonate loss (i.e., GI or renal wasting), followed by low renal chloride resorption in excess of bicarbonate, can cause hyperchloremia.

SYSTEMS AFFECTED

Relates to underlying cause

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

Dog and cat

SIGNS

General Comments

- Related to concurrent hypernatremia or the underlying disorder or both.
- Severity of neurologic signs is related to the degree of hypernatremia and the rate at which it develops.

Historical and Physical Examination Findings

- Polydipsia
- Disorientation
- Coma
- Seizures

CAUSES

High Total Body Chloride

- Oral ingestion—rare.
- NaCl administered IV during cardiovascular resuscitation.

Normal Total Body Chloride with Water Deficit

- Low intake (e.g., no access to water).
- High urinary water loss (e.g., diabetes insipidus).
- High insensible water loss (e.g., panting).

Low Total Body Chloride with Hypotonic Fluid Loss

Urinary loss—diabetes mellitus, osmotic diuresis, and diuresis after urinary obstruction.

Hyperchloremic Metabolic Acidosis

- Renal tubular acidosis—renal tubular disorders that cause renal wasting of bicarbonate or low hydrogen ion secretion.
- Diarrhea associated with gastrointestinal loss of bicarbonate and renal resorption of chloride.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Normal anion gap metabolic acidosis (e.g., renal tubular acidosis and gastrointestinal bicarbonate loss).
- Diabetes insipidus.
- Hypertonic dehydration.
- Severe forms of diabetes mellitus (e.g., diabetic ketoacidosis and hyperosmolar non-ketotic syndrome).
- Salt ingestion—rare.

LABORATORY FINDINGS

Drugs That May Alter Laboratory Results

- A wide variety of drugs can interfere with renal capacity to concentrate urine, leading to water loss in excess of sodium, and high sodium and chloride concentrations; these drugs include lithium, demeclocycline, and amphotericin.
- Other drugs that may increase chloride concentration include acetazolamide, ammonium chloride, androgens, and cholestyramine.
- A falsely high chloride concentration can occur with a high serum concentration of iodide or bromide—most commonly seen in patients with epilepsy treated with potassium bromide.

Disorders That May Alter Laboratory Results

Hemoglobin and bilirubin cause falsely high chloride readings if colorimetric tests are used.

Valid if Run in Human Laboratory?

Yes

CBC/BIOCHEMISTRY/URINALYSIS

- High chloride, often coupled with high sodium.
- Diabetes insipidus—low urinary specific gravity, polyuria, and low urinary sodium.
- Diabetic ketoacidosis and hyperosmolar non-ketotic syndrome—high blood glucose.

- Hypertonic dehydration—low urinary sodium and high urinary specific gravity (usually > 1.030).

- Renal tubular acidosis—hyperchloremic acidosis, urine pH > 5.3, serum potassium often low, and other causes of metabolic acidosis have been ruled-out.

OTHER LABORATORY TESTS

- Renal tubular acidosis—response to NaHCO_3 or NH_4Cl
- Anion gap
- Blood gases

IMAGING

CT scan or MRI in patients with diabetes insipidus to rule out pituitary tumor.

TREATMENT

APPROPRIATE HEALTH CARE

Hyperchloremia with hypernatremia—hypotonic fluids (5% dextrose in water); decrease sodium by 0.5 mEq/h or by no more than 20 mEq/L/day.

MEDICATIONS

DRUG(S) OF CHOICE

- Hypovolemia—isotonic saline (normal saline or lactated Ringer's solution) or isotonic fluid (5% dextrose with half-normal saline).
- Central diabetes insipidus—DDAVP (1–2 drops in the conjunctival sac q12–24h).
- Nephrogenic diabetes insipidus—chlorothiazide (10–40 mg/kg PO q12h).
- Hyperchloremic metabolic acidosis—treat underlying cause; consider bicarbonate and potassium replacement if needed.

PRECAUTIONS

- Rapid correction of hyperchloremia with hypernatremia can cause pulmonary edema.
- Hypocalcemia may develop during correction of hyperchloremia.

FOLLOW-UP

PATIENT MONITORING

Electrolytes, body weight, and hydration status

(CONTINUED)

HYPERCHLOREMIA**PREVENTION/AVOIDANCE**

Make sure animals always have access to water.

POSSIBLE COMPLICATIONS

- Related to associated hypernatremia or the underlying disorder.
- Neurologic complications include CNS thrombosis or hemorrhage; seizures; and hyperactivity.

EXPECTED COURSE AND PROGNOSIS

Varies with underlying cause

**MISCELLANEOUS****SEE ALSO**

Hypernatremia

ABBREVIATIONS

- CNS = central nervous system
- DDAVP = brand name for desmopressin, a synthetic antidiuretic hormone preparation
- GI = gastrointestinal

H

HYPERCOAGULABILITY

BASICS

OVERVIEW

- HC is an imbalance between procoagulants and anticoagulants leading to a predisposition for thrombosis.
- HC may result from platelet hyperaggregability; increased amounts or activation of clotting factors; reduced or inhibited anticoagulants (e.g., AT-III, protein C); or defective fibrinolysis.
- Thrombus formation depends on three major influences (Virchow's triad): endothelial injury, altered blood flow (stasis or turbulence), and HC. Only endothelial injury is likely to cause thrombosis independently.
- Common sites of thrombosis: pulmonary arteries, distal aorta, cranial vena cava, intestinal/mesenteric vessels, portal vein.

H

SIGNS

- HC is symptomless. Progression to thrombosis may cause site-dependent signs.
- PTE—acute severe dyspnea and tachypnea or chronic labored breathing.
- ATE—acute paresis/paralysis, limb pain, decreased femoral pulse and cold limbs. Onset in dogs may be gradual vs. very acute in cats.
- DIC—initial TE followed by bleeding (see Disseminated Intravascular Coagulation).

CAUSES & RISK FACTORS

Thrombosis is most commonly associated with conditions acting through Virchow's triad (above):

- IMHA
- DIC
- PLN (or enteropathy)
- Hyperadrenocorticism or corticosteroid therapy
- Neoplasia
- Systemic inflammation (Parvovirus infection, pancreatitis)
- Sepsis
- Cardiac disease

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- PTE may mimic pulmonary diseases such as bacterial or fungal pneumonia, pulmonary edema, and dirofilariasis.
- Distal ATE—consider other causes of paraparesis and paraplegia; absence of femoral pulses and cold limbs support distal ATE.

CBC/BIOCHEMISTRY/URINALYSIS

Reflect underlying disease or effects of thrombosis in specific organs.

OTHER LABORATORY TESTS

- D-dimer—increases are very sensitive for fibrinolysis. Thrombosis unlikely if normal. Nonspecific for type/mechanism of thrombosis.
- AT decreases (60–75% of reference) increase risk of thrombosis.
- PT, APTT—shortened clotting times are unreliable marker for HC.
- TEG-reported to identify HC states in DIC, parvovirus, IMHA, PLN, etc.
- Arterial blood gas—hypoxemia seen in PTE.

IMAGING

- Thoracic radiography—often few abnormalities despite severe dyspnea in PTE
- Abdominal ultrasonography—may confirm distal aortic occlusion in ATE.
- Echocardiography—to identify intracardiac thrombi and assess for pulmonary hypertension associated with PTE (dilation or hypertrophy of right ventricle, enlarged main pulmonary artery, tricuspid valve regurgitation).

DIAGNOSTIC PROCEDURES

- Angiography—to localize and confirm TE.
- Nuclear perfusion scintigraphy—noninvasive study may support a diagnosis of PTE.

TREATMENT

- Inpatient—to initiate thrombosis management and anticoagulant therapy.
- Supportive care—ensure hydration, maintain perfusion, minimize vascular stasis, correct and monitor acid-base and electrolyte abnormalities, use venous catheters appropriately.
- Severely restrict activity.
- Oxygen therapy—often indicated in PTE.
- Analgesics for acute pain.
- Inform owners that there is a risk of future TE events, especially if the underlying disease remains.

MEDICATIONS

DRUG(S)

Anticoagulants

- Unfractionated heparin—most common choice for initial therapy. Starting doses: 150–200 IU/kg SC q6h (dogs) and 200 IU/kg q8h (cats); titrate to achieve a 1.5- to 2-fold increase in APTT; check APTT daily (2 hours post-heparin administration).
- Low molecular weight heparin (e.g., enoxaparin, dalteparin); (safer, expensive alternate for initial therapy) APTT typically unaltered; anti-Xa activity used for assessment; appropriate starting dose of enoxaparin: 1 mg/kg (1,000 U/kg) SC q12h.
- Warfarin—(chronic therapy) vitamin K antagonist; appropriate starting doses: 0.1–0.2 mg/kg PO q24h, adjust to prolong PT to about twice the baseline.

Platelet Inhibition

- Aspirin—for initial prophylaxis or to prevent rethrombosis; 0.5–5.0 mg/kg PO q12–24h (dogs); 5 mg/cat q72h.
- Clopidogrel—for initial prophylaxis or to prevent rethrombosis; 1 mg/kg PO q24h (dogs); 18.75 mg/cat q24h. More effective than aspirin in preventing recurrence of aortic thromboembolism in cats.

Thrombolysis

- Severe side effects possible. Feline reperfusion injury is common, often fatal.

Consider for cerebral, splanchnic or renal infarction where restoring blood flow is essential.

- Streptokinase: dogs/cats, 90,000 IU IV over 1 hour, then 45,000 IU/hour up to 12 hours
- Urokinase: dogs/cats, 4,400 IU/kg over 10 minutes, then 4,400 IU/kg/hour for 12 hours.

CONTRAINdications/POSSIBLE INTERACTIONS

- Do not treat with warfarin initially or exclusively; initial HC state possible; overlap with heparin therapy for 4 days.
- High rate of interaction between warfarin and other drugs; reassess PT with any changes in medication.
- Bleeding is the major risk with anticoagulation; discontinue anticoagulant and administer protamine (for heparin overdose) or vitamin K (warfarin) and plasma as necessary to treat bleeding.

FOLLOW-UP

PT—monitor daily for 4–5 days (8 hours post-dose) and discontinue heparin when appropriate PT is achieved; check PT 6–8 hours after last heparin dose as it may decrease; following discharge, check PT twice weekly, then weekly for several weeks, then every 2 months.

HYPEREOSINOPHILIC SYNDROME (HES)

BASICS

OVERVIEW

- Idiopathic, persistent eosinophilia with infiltration of multiple organs causing dysfunction, often leading to death.
- Hypothesized to be caused by a severe reaction to an unidentified antigen or dysregulation of immunologic control of eosinophil production. • Organ damage caused by effects of eosinophil granule products and eosinophil-derived cytokines that are released in tissues from activated and/or necrotic cells.
- Common sites of infiltration: gastrointestinal tract (especially intestine and liver), spleen, bone marrow, lung (dogs mainly), and lymph nodes (especially mesenteric).
- Other sites of infiltration are reported less frequently.
- More common in cats than dogs, with rottweilers possibly being overrepresented.
- It is unclear whether this disease is a distinct entity from eosinophilic leukemia, or if it matters.
- Generally poor prognosis, especially in cats.

SIGNALMENT

- Cats—may occur more frequently in female, middle-aged domestic shorthair cats.
- Dogs—rare, but rottweilers may be predisposed.

SIGNS

- Lethargy • Anorexia • Intermittent vomiting and diarrhea • Hepatosplenomegaly
- Weight loss leading to emaciation
- Thickened (diffuse or segmental) intestine that is generally non-painful
- Mesenteric and possible peripheral lymphadenopathy
- Mass lesions caused by eosinophilic granulomatous inflammation and infiltration involving lymph nodes and/or organs
- Less frequently, fever, pruritus, and seizures

CAUSES & RISK FACTORS

- Unknown; however, believed to be a severe reaction to an underlying, yet unidentified antigenic stimulus.
- Cats—Eosinophilic enteritis may be an early form.
- A fusion gene, FIP1L1-PDGFR α , has been identified in humans with some forms of HES; no such gene has been identified in veterinary cases.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Reactive eosinophilia—parasitism, allergic/hypersensitivity reactions, infectious disease, immune-mediated disease, fungal infections and neoplasia; with these conditions, eosinophilia is usually limited in magnitude

and remains confined to a specific organ.

- Eosinophilic leukemia—differentiating criteria: eosinophilic leukemia tends to have (1) immature eosinophils seen in higher numbers in the circulation and constitute a higher percentage of the leukocyte differential, (2) anemia is more common and often more severe, (3) myeloid:erythroid (M:E) ratio in bone marrow is higher ($> 10:1$) with more immature/blast forms and disorderly maturation, (4) tissue infiltrates consist of immature eosinophils and may show a sinusoidal pattern in the liver without fibrosis, (5) in cats, chloroma-like masses in the kidneys are reported.

CBC/BIOCHEMISTRY/URINALYSIS

- Leukocytosis with marked eosinophilia, possibly with left shift in the eosinophil series (not routinely reported); mature eosinophil count range from 5,000 to $> 130,000/\mu\text{L}$.
- Basophilia.
- Mild anemia.
- With organ damage or dysfunction, appropriate CBC, biochemical and urinalysis abnormalities may be seen.

OTHER LABORATORY TESTS

Rule out identifiable causes of eosinophilia: fecal floatation, heartworm test, fungal visualization/culture, and biopsy.

IMAGING

- Intestinal mucosal irregularities and thickened intestine seen on radiographic contrast studies and ultrasound.
- Organ enlargement/infiltration may be visualized with survey radiographs and/or ultrasound.

DIAGNOSTIC PROCEDURES

- Bone marrow aspiration and/or core biopsy
- Biopsy of affected organ or mass

PATHOLOGIC FINDINGS

- Spleen—eosinophilic infiltrates in red pulp, sometimes in the white pulp.
- Gastrointestinal tract—mucosal and submucosal eosinophilic infiltrates in small intestine, sometimes in colon and stomach.
- Bone marrow—hypercellularity, eosinophilic hyperplasia (up to 40% of all nucleated cells are eosinophils), lack of morphologic abnormalities, orderly maturation and a high M:E ratio (mean 7.27:1).
- Lymph nodes—reactive hyperplasia and infiltration of cords and sinuses with eosinophils.
- Other (less frequent)—eosinophilic infiltrates in the skin, myocardium and endocardium, liver, lung, etc. or eosinophilic effusions.

TREATMENT

- Long-term maintenance therapy to control or reduce the eosinophilia and organ damage.

- Address specific organ dysfunction as indicated.
- High serum IgE concentration portends a good response to treatment with prednisone and a better prognosis.

MEDICATIONS

DRUGS

- Corticosteroids—prednisone, 1–3 mg/kg q24h initially, then taper to q48h if eosinophilia is suppressed; if eosinophilia returns, resume higher daily dose.
- Imatinib mesylate is approved in humans to treat chronic myelogenous leukemia as well as HES, used with possible efficacy in cats at 9.6 mg/kg PO q24h.
- Chemotherapeutic agents—try if eosinophilia is steroid resistant; paucity of case reports describing these therapies precludes recommending their use.
- Hydroxyurea—administer to reduce eosinophil count if not normal or near normal after 7–14 days of treatment with steroids; most likely would be used long-term if effective in conjunction with steroids.
- Cyclosporine A—suppresses production of eosinophilopoietic factors by T cells.
- Vincristine and alkylating agents such as chlorambucil, effective in human.
- Reduce dosage or discontinue drugs if bone marrow suppression or thrombocytopenia develops.

H

CONTRAINdicATIONS/POSSIBLE INTERACTIONS

- Specific drug toxicities for each agent, most notably myelosuppression.
- Imatinib mesylate may lead to protein-losing nephropathy but this association is uncertain.

FOLLOW-UP

- Serial monitoring of eosinophil count (not always indicative of tissue infiltrates) and WBC count if myelotoxic drugs are used.
- Monitor signs (e.g., anorexia, lethargy, vomiting and diarrhea) and physical abnormalities.
- Other testing for specific organ function (e.g., bile acids).

HYPERESTROGENISM (ESTROGEN TOXICITY)

BASICS

OVERVIEW

- A syndrome characterized by high serum concentration of estrogens (estradiol, estriol, or estrone).
- Can occur as a result of excessive estrogen secretion, accumulation or administration of exogenous estrogens, such as diethylstilbestrol or estriol.
- Sites of endogenous estrogen production include ovarian follicles, follicular ovarian cysts, Leydig cells, and the adrenal cortex (zona glomerulosa and fasciculata); can also occur as a result of peripheral conversion of excessive androgens.
- Endogenous estrogens in the female are responsible for normal sexual behavior and development and function of the female reproductive tract; in the male, estrogens are responsible for Leydig cell function.
- Estrogens potentiate the stimulatory effect of progesterone in the endometrium and permit cervical relaxation; these two effects increase the risk of cystic endometrial hyperplasia and pyometra. In the male, estrogens potentiate the action of androgens in the prostate. Estrogens also increase osteoblastic activity, retention of calcium and phosphorus, total body protein and metabolic rate.
- High serum concentration of estrogen provides a source of negative feedback in the hypothalamic-pituitary axis and results in suppression of gonadotropin secretion; interferes with stem cell differentiation in the bone marrow and erythrocyte iron metabolism.

SIGNALMENT

Endogenous Hyperestrogenism

- Older male dog (secondary to functional testicular tumors).
- Older female dog (secondary to granulosa cell tumors or other functional ovarian tumor types, follicular ovarian cysts).
- Young female dog (follicular ovarian cysts).

Exogenous Hyperestrogenism

- All breeds, genders, and ages in association with estrogen administration or exposure.
- Toy breed dogs are at increased risk when exposed to transdermal hormone replacement therapy.

SIGNS

Historical Findings

- Attractive to intact male dogs.
- Infertility.

- Prolonged proestrus and estrus (female).
- Decreased libido (male).
- Nymphomania (female).
- Variable vulvar bleeding and enlargement causing excessive vulvar licking.
- Epistaxis, hematuria if thrombocytopenic; lethargic, febrile if neutropenic; lethargic if anemic.

Physical Examination Findings

- Skin/Endocrine—non-pruritic, symmetric alopecia (endocrine alopecia), hyperpigmentation.
- Reproductive (male)—palpable testicular mass; testicular asymmetry (in association with a tumor mass and/or testicular atrophy); testicular atrophy: may be unilateral atrophy in the non-tumor-containing testicle, as seen in association with a functional estrogen-producing testicular tumor, or bilateral, as seen in association with exogenous hyperestrogenism; cryptorchidism (unilateral or bilateral) should be ruled out; prostatomegaly (secondary to squamous metaplasia); gynecomastia. The testicular tumor can replace most of the normal testicular tissue if advanced.
- Reproductive (female)—vulvar edema and enlargement; variable vulvar discharge depending on the presence of residual uterine tissue; gynecomastia.
- Hemic/Lymphatic/Immune—pale mucous membranes; thrombocytopenic hemorrhage; petechia; fever (due to secondary bacterial infection in association with neutropenia); depression.

CAUSES & RISK FACTORS

- Follicular ovarian cysts.
- Functional ovarian tumor (granulosa cell tumor and other ovarian tumors).
- Testicular tumor (specifically Sertoli cell tumor, but also may occur secondary to Leydig and interstitial cell tumors).
- Exogenous estrogen administration or exposure—iatrogenic.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Non-pruritic, Symmetric Alopecia (Endocrine Alopecia)

- Hypothyroidism—diagnosis based on appropriate clinical signs in conjunction with typical hematologic and biochemical abnormalities (normocytic normochromic non regenerative anemia, hypercholesterolemia) and thyroid function testing (total T₄, free T₄, cTSH).

- Hyperadrenocorticism—clinical signs usually include polyuria, polydipsia, and exercise intolerance; CBC may reveal leukocytosis and erythrocytosis; serum biochemistry abnormalities include elevated ALP, ALT, and cholesterol, and decreased BUN; additional testing includes urine cortisol creatinine ratio, ACTH stimulation, LDDS test (preferred), endogenous ACTH, abdominal ultrasonography.
- GH-responsive dermatosis.

Attractive to Male Dogs

- Vaginitis, perivulvar dermatitis—can be differentiated from hyperestrogenism via examination of vaginal cytology (lack of vaginal superficial epithelial cell predominance), lack of evidence of ovarian abnormalities, or confirmation of complete ovariectomy or ovariohysterectomy.
- Genitourinary tract infection, inflammation (foreign body) or neoplasia.

Infertility

- Testicular degeneration/atrophy/immune-mediated orchitis—diagnosis based on physical examination, lack of testicular or intra-abdominal masses, semen evaluation (azoospermia, teratospermia), and testicular FNA for cytology or testicular biopsy.
- Intersex abnormalities—uncommon; diagnosis supported by physical examination findings (abnormal external genitalia), abnormal karyotype, and histologic examination of the reproductive tract, where available.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC—changes are extremely variable; if present, initial 2–3 weeks characterized by thrombocytopenia or thrombocytosis, progressive anemia, and leukocytosis (white cell counts may exceed 100,000 WBC/ μ L); after 3 weeks, pancytopenia and aplastic anemia may be noted; hematuria (secondary to thrombocytopenia).
- Chemistry panel and urinalysis usually unremarkable.

OTHER LABORATORY TESTS

- Serum estrogen (estradiol) concentrations—may be evaluated via radioimmunoassay; however, physiologic serum concentrations may be within normal limits due to accuracy of assay. Prolonged elevation (> 30 days) of estradiol at levels expected for proestrus or estrus is responsible for the clinical signs rather than the actual level.
- Vaginal/preputial cytology—extremely reliable as a bioassay for estrogen; under the

(CONTINUED)

HYPERESTROGENISM (ESTROGEN TOXICITY)

influence of estrogen, will reveal a predominance of superficial epithelial cells that are anuclear or have pyknotic nuclei.

- Evaluation for ovarian remnant syndrome (see Ovarian Remnant Syndrome).

IMAGING/ENDOSCOPY

- Ultrasonography of the abdomen, inguinal canal, and testes—to assess for testicular masses, cystic or enlarged ovarian structures, intra-abdominal masses, prostatomegaly (not appropriate for a neutered dog), and regional lymph node size and echogenicity.
- Vaginoscopy—can be completed to evaluate the vaginal mucosa; under the influence of estrogen, the vaginal mucosa should appear edematous and pink.

DIAGNOSTIC PROCEDURES

- Fine-needle aspiration for cytology of testicular masses—can provide a cytologic diagnosis prior to pursuing surgery.
- Percutaneous ultrasound-guided aspiration of large ovarian follicular cysts rarely results in clinical resolution, as the cystic structure persists. The cystic fluid obtained can be evaluated for hormone concentration.
- Three-view metastatic radiographic evaluation of the thoracic cavity—complete prior to any surgical intervention when neoplasia is suspected.
- Complete hemogram, serum chemistries, and urinalysis—always perform preoperatively for cytopenias, hepatic dysfunction (estrogen metabolism).
- Examination and biopsy of local lymph nodes—for evaluation of metastatic disease; can be completed, if indicated, at time of surgical exploration or performed with ultrasound guidance.
- Bone marrow core biopsy—can confirm the presence of myelosuppression.
- Laparoscopy or laparotomy—can be used to identify and remove intra-abdominal masses, ovarian tissue, or cryptorchid testicular tissue, followed with histopathology.
- Skin biopsy—may reveal nonspecific changes associated with endocrine alopecia such as orthokeratotic hyperkeratosis, epidermal atrophy and melanosis, follicular keratosis, telogen hair follicles, and sebaceous gland atrophy.

**TREATMENT**

- Treatment of choice for endogenous hyperestrogenism in the intact or partially neutered female and male is surgical neutering; the prognosis is good if residual or malignant gonadal tissue can be completely removed.

- Unilateral orchiectomy or ovariecomy of the affected neoplastic testicle or cystic or neoplastic ovary may be considered in valuable breeding animals. Use of testicular prosthetic devices is not advised and is not ethical. Contralateral testicular changes (male) or endometrial changes (female) secondary to prolonged estrogen exposure can occur and contribute to subfertility even if the abnormal gonad has been removed, making the prognosis for fertility guarded. Histopathology should always be performed to evaluate neoplastic changes and for local lymphatic metastasis.

- Discontinue exogenous estrogen exposure in cases of exogenous hyperestrogenism. Small dogs are at increased risk of exposure to transdermal hormone replacement therapy (often applied to the forearms) as a consequence of being held frequently. Discontinue or reduce the dose of exogenous estrogen if used therapeutically for sphincter incompetence in the ovariectomized bitch. Both have a good prognosis.

**MEDICATIONS****DRUG(S)**

- Supportive care—including administration of appropriate antimicrobial therapy and blood products.
- Synthetic erythropoietin, darbopoietin, G-CSF, GM-CSF—may be considered to stimulate erythroid and granulocytic production at the level of the bone marrow; lithium has reportedly been of benefit in cases of estrogen-induced bone marrow aplasia.
- GnRH—unlikely to induce ovulation in cases of follicular cysts.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Administration of chemotherapeutic agents for treatment of metastatic testicular or ovarian neoplasia should be pursued with caution due to increased risk of bone marrow suppression secondary to hyperestrogenism. Consult with a veterinary oncologist.

**FOLLOW-UP**

- Repeat serial CBC analysis if myelosuppression present—to evaluate response to therapy and progression of disease.
- Repeat serial bone marrow aspiration cytology—to evaluate bone marrow response and erythroid, myeloid, and megakaryocytic regeneration when myelosuppression is

chronic. Peripheral signs of regeneration may not occur for weeks to months after initial insult.

- Concurrent administration of iron dextran intramuscularly or multiple daily doses of oral iron to support erythrocyte regeneration.
- Use of erythropoietin, darbopoietin, G-CSF, GM-CSF—closely monitor erythrocyte and leukocyte regeneration.
- Clinical signs of male feminization syndrome should resolve within 2–6 weeks after testicular tumor removal.
- Lack of resolving pancytopenia and continued bone marrow hypoplasia 3 weeks after surgical removal of ovarian or testicular neoplasia or removal of follicular cysts—associated with a grave prognosis.

H

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- Prostatomegaly metaplasia
- Cystic-endometrial hyperplasia and subfertility
- Hepatic insufficiency
- Infertility
- Bone marrow aplasia, pancytopenia
- Sepsis
- Ovarian remnant syndrome (see chapter)

Client Education Handout available online

HYPERGLYCEMIA

BASICS

DEFINITION

Transient or persistently increased serum glucose concentrations.

PATHOPHYSIOLOGY

- Insulin resistance and pancreatic amyloidosis (type 2 DM in cats).
- Insulin resistance from endogenous hormones (growth hormone) or drugs (corticosteroids).
- Absolute or relative insulin deficiency (type 1 DM in dogs).
- Increased gluconeogenesis and increased glycogenolysis (epinephrine release from stress, type 2 DM).

H

SYSTEMS AFFECTED

- Endocrine/Metabolic—insulin resistance, hepatic glycogenolysis.
- Nervous—severe hyperglycemia may cause CNS dehydration from increasing serum osmolality. Hind limb weakness and plantigrade stance from diabetic neuropathy in cats.
- Ophthalmic—persistent hyperglycemia can cause cataracts in dogs.
- Renal/Urologic—osmotic diuresis from blood glucose exceeding the renal threshold (higher in the cat than dog) causes polyuria with secondary polydipsia.

SIGNALMENT

Cat and dog of any age or breed

SIGNS

General Comments

- Clinical signs vary and often reflect underlying disease.
- Some patients are asymptomatic, especially those with drug, stress-induced, and post-prandial hyperglycemia.

Historical Findings

- Variable by species and duration of hyperglycemia.
- May be normal.
- Dogs with diabetes: polydipsia, polyuria, depression, weight loss, obesity, polyphagia.
- Cats with diabetes: obesity, plantigrade stance, anorexia, vomiting, diarrhea, polydipsia/polyuria.
- CNS depression, coma—severe hyperglycemia with hyperosmolality.

Physical Examination Findings

- May be normal
- Obesity in cats with type 2 DM
- Plantigrade stance in cats
- Cataracts in dogs
- Emaciation in dogs with type 1 DM
- Hepatomegaly resulting from diabetic hepatopathy
- Chronic infections: respiratory, skin
- Poor hair coat

CAUSES

- Relative or absolute insulin deficiency—type 1 and type 2 DM.
- Insulin resistance—type 2 DM in cats, hyperadrenocorticism, pheochromocytoma, glucagonoma, hypersomatotropism, hyperthyroidism, high progesterone during diestrus (dogs), renal insufficiency, urinary tract infection.
- Physiologic—post-prandial fluctuation and stress (epinephrine-induced) in cats.
- Drugs—thiazide diuretics, morphine, dextrose-containing fluids, progestins (e.g., megestrol acetate), growth hormone, glucocorticoids, and ACTH.
- Regulation problems in treated diabetics—high carbohydrate diets (cats), insulin administration problems, insulin-induced hypoglycemic hyperglycemia (rare).
- Parenteral administration of nutritional solutions.
- Laboratory error.

RISK FACTORS

- Stress in cats
- Concurrent disease—hyperadrenocorticism, acromegaly, and acute pancreatitis
- Diabetogenic drugs—steroids, progestagens
- Dextrose-containing fluids

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Mild, transiently high blood glucose can be associated with stress.
- In patients with mild hyperglycemia and no history of polydipsia/polyuria, repeat blood glucose determination after 12-hour fast and perform serum fructosamine.

LABORATORY FINDINGS

Drugs That May Alter Laboratory Results

High blood glucose concentration—glucocorticoids, ACTH, dextrose-containing fluids, epinephrine, asparaginase, $\alpha\beta\gamma\delta$ -adrenergic agonists, and diazoxide.

Disorders That May Alter Laboratory Results

- Lipemia, hemolysis, and icterus may interfere with spectrophotometric assays.
- Delayed serum separation artificially lowers glucose concentration; must separate serum within 1 hour of collection to prevent cellular glucose use.
- Use of human glucometers—may read 25% below actual blood glucose value, repeat with monitor validated in dog or cat whole blood.
- Blood glucose reagent strips require whole blood.
- Measure glucose concentration in whole blood within 30 minutes of collection.

Valid if Run in Human Laboratory?

Yes

CBC/BIOCHEMISTRY/URINALYSIS

- Hyperglycemia may be the only abnormal finding.
- CBC—may be normal; possible inflammatory leukogram in patients with sepsis.
- Urinalysis—may be normal; glucosuria, pyuria, bacteruria, and ketonuria.
- Fasting hyperglycemia plus glucosuria suggests DM.
- Lipemia in patients with low lipoprotein lipase (miniature schnauzers), hyperadrenocorticism, acute pancreatitis, and post-prandial blood sampling.
- High amylase and lipase activity suggests acute pancreatitis, especially in non-azotemic patients.
- Increased plasma lipase immunoreactivity in patients with acute pancreatitis.
- High liver enzyme activity may accompany fatty infiltration with diabetes.

OTHER LABORATORY TESTS

- Fructosamine—normal values rule-out diabetes as cause of hyperglycemia.
- ACTH stimulation or low-dose dexamethasone-suppression test to rule-out hyperadrenocorticism.

IMAGING

N/A

TREATMENT

- Insulin therapy (dogs and some cats), oral hypoglycemic agents (cats).
- Discontinue diabetogenic drugs.
- Dextrose-free fluids.

DIET

- High-protein, low-carbohydrate diet in cats with diabetes mellitus.
- High soluble fiber, low-fat diet in dogs with diabetes mellitus.

MEDICATIONS

DRUG(S) OF CHOICE

- Insulin—regular (crystalline) insulin for diabetic ketoacidosis, Lente insulin (dogs).
- Insulin glargine or PZI insulin in cats with DM.
- Oral hypoglycemics such as glipizide (cats with type 2 DM).

CONTRAINDICATIONS

- Diabetogenic drugs (e.g., glucocorticoids)
- Dextrose-containing fluids

PRECAUTIONS

Avoid rapid and aggressive insulin therapy that lowers blood glucose abruptly and causes hypoglycemia or cerebral edema.

(CONTINUED)

HYPERGLYCEMIA**ALTERNATIVE DRUG(S)**

Acarbose 12.5 mg PO q12h; intestinal starch blocker

**FOLLOW-UP****PATIENT MONITORING**

- For return of clinical signs of diabetes such as polyuria, polydipsia, and polyphagia.
- Blood glucose after discontinuing diabetogenic drugs.
- Glycosylated hemoglobin and fructosamine on an outpatient basis to monitor long-term glucose control.

POSSIBLE COMPLICATIONS

- High incidence of sepsis (and infection).
- Severe hyperglycemia may be associated

with CNS depression and coma because of hyperosmolarity.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- Hyperosmolarity
- Uremia may be associated with hyperglycemia

PREGNANCY/FERTILITY/BREEDING

N/A

SYNONYMS

High blood sugar

H

H HYPERKALEMIA

BASICS

DEFINITION

Serum potassium concentration higher than the testing laboratory's upper limit of normal, generally > 5.7 mEq/L (mmol/L).

PATHOPHYSIOLOGY

- Potassium is primarily intracellular; serum concentrations do not accurately reflect tissue concentrations.
- Hyperkalemia is often associated with cellular injury (e.g., trauma and ischemia) and other causes of translocation of potassium out of the intracellular space (e.g., acidosis).
- Potassium is eliminated in the kidneys and elimination is enhanced by aldosterone; conditions that inhibit renal elimination of potassium will cause hyperkalemia.

SYSTEMS AFFECTED

- Cardiovascular**—potassium affects cardiac conduction, and changes are reflected on the ECG; as potassium rises, the T waves become tall and spiked with a narrow base, the QRS complexes widen, and the P-R intervals lengthen; the P waves become smaller and wider and, in animals with severe hyperkalemia, disappear (atrial standstill); higher concentrations of potassium cause fusion of the QRS-T, which causes a wide complex idioventricular rhythm followed by ventricular fibrillation or asystole; ECG changes in animals with hyperkalemia vary and are diminished by hypernatremia, hypercalcemia, and alkalosis.
- Nervous—neuromuscular function** affected.

SIGNALMENT

- Dog and cat
- Pseudohyperkalemia in certain East Asian dog breeds (e.g., Akita, Shiba, Jindo, and Chinese Shar-Pei)

SIGNS

Historical Findings

- Weakness
- Collapse
- Flaccid paralysis
- Death

Physical Examination Findings

In addition to historical findings, arrhythmias, especially bradycardia, in some animals.

CAUSES

- Pseudohyperkalemia**—some blood cells (i.e., RBCs [reported in East Asian dog breeds including Akita, Shiba, Jindo, and Chinese Shar-Pei] due to the presence of a Na-K pump in the mature RBC membrane in some animals], platelets, WBCs), contain high concentrations of potassium; if the blood sample is not analyzed or separated promptly, this intracellular potassium is released into the serum, causing the potassium concentration to be artificially high (pseudohyperkalemia).
- Low potassium elimination**—anuric or oliguric renal failure; renal hypoperfusion (complete AV block); urinary tract rupture or urethral obstruction; administration of

potassium-sparing diuretics, ACE inhibitors, trimethoprim, nonsteroidal anti-inflammatory drugs, or heparin (causing hypoaldosteronism); some gastrointestinal diseases (e.g., salmonellosis, trichuriasis, duodenal perforation). • Translocation of potassium—acidosis, reperfusion syndrome, thrombolysis in feline aortic thromboembolism, tumor lysis syndrome, muscle injury (trauma, phosphofructokinase deficiency), severe digitalis overdose, infusion of mannitol, and hyperglycemia causing hyperosmolality. • High potassium intake—oral or parenteral potassium supplements. Potassium bromide toxicosis

- Miscellaneous—pleural effusion and ascites.

RISK FACTORS

- Fluid therapy with potassium supplementation.
 - Parenteral nutrition.
 - Administration of potassium-sparing diuretics (e.g., spironolactone) and ACE inhibitors (e.g., enalapril, benazepril), primarily in patients with renal disease.
 - Conditions associated with acidosis.
 - Trauma.
 - Renal disease.
 - Lower urinary tract disease in male cats.
 - Cystic calculi in male dogs.
 - Thrombocytosis and leukemia.
 - Akita, Shiba, Jindo, and Chinese Shar-Pei—pseudohyperkalemia. Not all animals within a breed are at risk for pseudohyperkalemia.
- Approximately 20% of Akitas have the high potassium phenotype.
- Phosphofructokinase deficiency.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Waxing and waning history of gastrointestinal complaints, weakness, collapse—consider hypoadrenocorticism.
- Straining to urinate or low urine output—consider urinary obstruction or oliguric/anuric renal failure.

LABORATORY FINDINGS

Disorders That May Alter Laboratory Results

Thrombocytosis (> 1,000,000 cells/mm³), leukocytosis (> 200,000 cells/mm³), and abnormal (leukemic) leukocytes can cause release of large amounts of potassium into the serum if not separated quickly.

CBC/BIOCHEMISTRY/URINALYSIS

- In patients with Na:K ratio < 27, consider hypoadrenocorticism; some patients with diarrhea and metabolic acidosis, ascites, chylothorax, or pregnancy may also have a low Na:K ratio.
- In patients with azotemia, consider hypoadrenocorticism, anuric or oliguric renal failure, and ruptured or obstructed urinary tract.
- In patients with high creatine kinase, aspartate aminotransferase, and lactic dehydrogenase, consider muscle injury.
- In patients with

severe thrombocytosis or leukocytosis or if the patient is an East Asian dog breed, consider pseudohyperkalemia.

OTHER LABORATORY TESTS

ACTH response test to rule out hypoadrenocorticism.

IMAGING

Radiographic contrast studies or ultrasound to rule out urinary tract rupture or obstruction.

TREATMENT

- Varies, depending on the underlying cause of hyperkalemia.
- Aggressiveness is dictated by patient's appearance and severity of ECG abnormalities.
- Initiate supportive measures to lower potassium while pursuing definitive diagnosis.
- Saline (0.9%) is the fluid of choice for lowering potassium concentrations and blunting the effects of hyperkalemia on cardiac conduction; if the patient is dehydrated or hypotensive, fluids can be administered rapidly (dogs, up to 90 mL/kg/h; cats, 60 mL/kg/h or faster with monitoring of central venous pressure).
- Reduced potassium diet in animals with hyperkalemia secondary to chronic renal disease.

MEDICATIONS

DRUG(S) OF CHOICE

- Can administer sodium bicarbonate to patients with severe hyperkalemia to induce translocation of potassium into cells; if blood pH and base deficit cannot be determined, administer 1–2 mEq/kg slowly IV; to calculate bicarbonate dose more accurately:
 - Dogs, 0.3 × body weight (kg) × (21 – patient's HCO₃⁻)
 - Cats, 0.3 × body weight (kg) × (19 – patient's HCO₃⁻)
- Administer half of dose and reevaluate.
- Can administer dextrose and regular insulin to patients with severe hyperkalemia to induce translocation of potassium into cells (regular insulin, 0.5 U/kg IV with 50% dextrose, 1 g/kg IV); dextrose can also be used without insulin.
- For patients with life-threatening hyperkalemia, administer calcium gluconate 10% (0.5–1 mL/kg slowly IV over 10 minutes) while monitoring the ECG; calcium antagonizes the effect of potassium on the conduction system without lowering the potassium concentration.

CONTRAINdications

- Avoid potassium-containing fluids and fluids that cause hyponatremia, acidosis, or hypocalcemia.
- Avoid drugs that contain potassium or interfere with potassium elimination (e.g., ACE inhibitors, trimethoprim antibiotics, and potassium-sparing diuretics).

(CONTINUED)

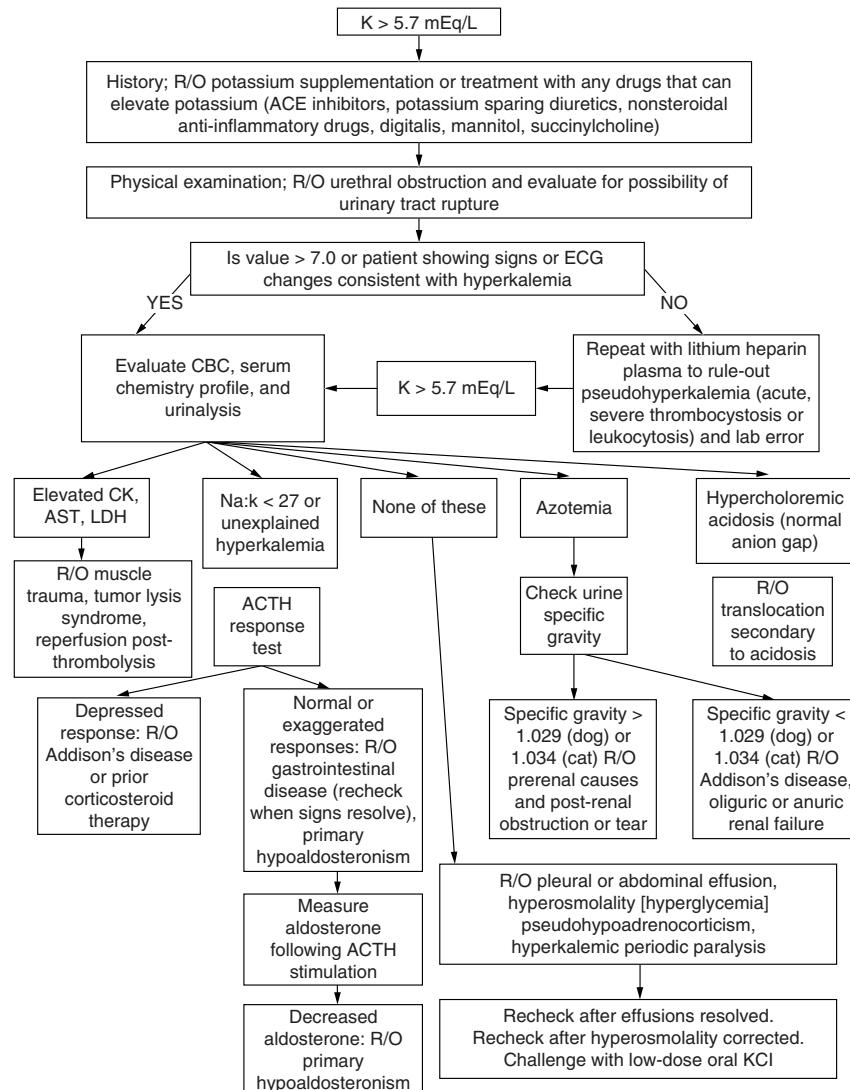

H HYPERKALEMIA

Figure 1.

Algorithm for diagnosing hyperkalemia.

PRECAUTIONS

- Kayexalate and sodium bicarbonate cause a sodium load that may lead to fluid retention in patients with cardiac or renal failure.
- Sodium bicarbonate lowers ionized calcium levels. Use cautiously in hypocalcemic patients.

ALTERNATIVE DRUG(S)

Sodium polystyrene sulfonate (Kayexalate) per os or per rectum binds potassium within the intestinal tract, limiting absorption and reabsorption; rarely used in veterinary practice.

**FOLLOW-UP****PATIENT MONITORING**

- Recheck potassium at frequency dictated by

the underlying disease. • Check ECG frequently until rhythm disturbances resolve.

PREVENTION/AVOIDANCE

- Monitor potassium in patients receiving drugs that alter potassium elimination.
- Administer IV potassium at a rate less than 0.5 mEq/kg/h.

POSSIBLE COMPLICATIONS

Death of animals with severe hyperkalemia

**MISCELLANEOUS****PREGNANCY/FERTILITY/BREEDING**

Combined hyperkalemia and hyponatremia reported in several pregnant dogs.

HYPERLIPIDEMIA

BASICS

DEFINITION

- Increased concentration of lipid in the blood of a fasted (> 12 hours) patient; includes hypercholesterolemia, hypertriglyceridemia, or both.
- Lipemic—serum or plasma separated from blood that contains an excess concentration of triglycerides (> 200 mg/dL).
- Lactescence—opaque, milk-like appearance of serum or plasma that contains an even higher concentration of triglycerides (> 1,000 mg/dL) than lipemic serum.

H PATHOPHYSIOLOGY

Primary Hyperlipidemia

- Primary (idiopathic) hyperlipidemia—defect in lipid metabolism causing hypertriglyceridemia with or without hyperchylomicronemia; likely hereditary in miniature schnauzer but the genetic defect has yet to be determined.
- Idiopathic hyperchylomicronemia in cats—familial, autosomal recessive defect in lipoprotein lipase activity.
- Primary hypercholesterolemia—occurs in some families of briard, rough collie, Shetland sheepdog, Doberman pinscher, and rottweiler; LDL cholesterol is high.

Secondary Hyperlipidemia

- Postprandial—absorption of chylomicrons from the gastrointestinal tract occurs 30–60 minutes after ingestion of a meal containing fat; may increase serum triglycerides for up to 12 hours.
- Diabetes mellitus—low lipoprotein lipase activity; high synthesis of very-low-density lipoprotein by the liver.
- Hypothyroidism—low LPL activity and lipolytic activity by other hormones (e.g., catecholamines); reduced hepatic degradation of cholesterol to bile acids.
- Hyperadrenocorticism—increased synthesis of VLDL by the liver and low LPL activity causes both hypercholesterolemia and hypertriglyceridemia.
- Liver disease—hypercholesterolemia caused by reduced excretion of cholesterol in the bile; cholestasis.
- Nephrotic syndrome—common synthetic pathway for albumin and cholesterol and possibly low oncotic pressure lead to increased cholesterol synthesis.
- Pancreatitis—associated with hypertriglyceridemia in dogs, but causal relationship not established.
- Obesity—excessive hepatic synthesis of VLDL.

Drug-Induced Hyperlipidemia

- Glucocorticoids
- Megestrol acetate (cat)

SYSTEMS AFFECTED

- Endocrine/Metabolic

- Gastrointestinal
- Hepatobiliary
- Nervous
- Ophthalmic

SIGNALMENT

- Dog and cat.
- Variable, depending on the cause.
- Hereditary hyperlipidemias—age of onset is > 8 months in cats and > 4 years in predisposed breeds of dog such as the miniature schnauzer.

SIGNS

Historical Findings

- Asymptomatic
- Recent ingestion of a meal
- Seizures, neurologic signs
- Abdominal pain and distress
- Neuropathies

Physical Examination Findings

- Lipemia retinalis
- Lipemic aqueous
- Neuropathy
- Cutaneous xanthomata
- Lipid granulomas in abdominal organs

CAUSES

Increased Absorption of Triglycerides or Cholesterol

Postprandial

Increased Production of Triglycerides or Cholesterol

- Idiopathic
- Nephrotic syndrome
- Pregnancy
- Defects in lipid clearance enzymes or lipid carrier proteins
- Idiopathic hyperchylomicronemia
- Hyperchylomicronemia in cats

Decreased Clearance of Triglycerides or Cholesterol

- Hypothyroidism
- Hyperadrenocorticism
- Diabetes mellitus
- Pancreatitis
- Cholestasis

RISK FACTORS

- Obesity
- High dietary intake of fats
- Genetic predisposition in miniature schnauzer and Himalayan cat
- Idiopathic hypercholesterolemia observed in families of briard, rough collie, Shetland sheepdog, Doberman pinscher, and rottweiler

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Fasting Hyperlipidemia

Rule out postprandial lipemia with a 12-hour fast.

Primary Hyperlipoproteinemia

- Idiopathic hyperlipidemia is observed most commonly in the miniature schnauzer breed.
- Hyperchylomicronemia in cats often manifests as polyneuropathies and lipogranulomas.
- Idiopathic hypercholesterolemia is observed in a variety of breeds; animals are often asymptomatic.

Secondary Hyperlipidemia

- Diabetes mellitus—signs include polyphagia, weight loss, polydipsia, and polyuria; glycosuria and fasting hyperglycemia confirm the diagnosis.
- Hypothyroidism—signs include lethargy, hypothermia, heat-seeking, and dermatologic changes (e.g., alopecia and hyperpigmentation).
- Pancreatitis—signs include abdominal pain, vomiting, diarrhea, and anorexia; often hyperlipidemia is accompanied by high liver enzyme activities and high lipase and amylase.
- Hyperadrenocorticism—signs include polydipsia, polyuria, polyphagia, dermatologic changes (e.g., alopecia and thin skin), and hepatomegaly; hypercholesterolemia often is attended by high ALP enzyme activity.
- Hepatic disease and cholestatic disorders—signs include anorexia, weight loss, and icterus.
- Nephrotic syndrome—signs include ascites and peripheral edema; hypercholesterolemia is observed in conjunction with hypoproteinemia and proteinuria.

LABORATORY FINDINGS

Sample Handling

- Submit serum.
- Lipemia causes hemolysis if serum remains in RBC for a long time; inquire about the laboratory method of clearing lipemic samples before submission.
- Two samples may be submitted: one for biochemical analysis, which may be cleared, and one for triglycerides and cholesterol concentrations.

Drugs That May Alter Laboratory Results

- Corticosteroids
- Phenytoin
- Prochlorperazine.
- Thiazides
- Phenothiazines

Disorders That May Alter Laboratory Results

- Falsely high cholesterol
- Non-fasted samples (< 12 hours)
- Icterus—spectrophotometric techniques
- Fluoride and oxalate anticoagulants—enzymatic techniques
- Lipemia

Valid If Run in Human Laboratory?

Yes

CBC/BIOCHEMISTRY/URINALYSIS

- Results of hemogram usually normal.

(CONTINUED)

- Hyperadrenocorticism—elevated ALP activity, polycythemia, nucleated RBCs.
- Hypothyroidism—mild normocytic, normochromic anemia.
- High triglycerides—dogs, > 150 mg/dL; cats, > 100 mg/dL.
- High cholesterol—dogs, > 300 mg/dL; cats, > 200 mg/dL.
- Nephrotic syndrome—low albumin, proteinuria.
- Diabetes mellitus—high fasted serum glucose, glycosuria.
- Pancreatitis—high PLI (species-specific), hypocalcemia.
- Results of urinalysis often normal.

OTHER LABORATORY TESTS

- HDL and LDL determinations—used in human medicine; values reported for HDL and LDL in dogs and cats cannot be assumed to be reliable.
- Chylomicron test—obtain serum sample after a 12-hour fast and refrigerate for 12–14 hours; do not freeze; chylomicrons rise to the surface and form a creamy layer.
- Lipoprotein electrophoresis—separates LDL, VLDL, HDL1, and HDL2.
- LPL activity—collect serum for triglycerides and cholesterol concentrations and lipoprotein electrophoresis before and 15 minutes after IV administration of heparin (90 IU/kg); if there is no change in values before and after heparin administration, a defective LPL enzyme system should be suspected.
- T₄, free T₄, and TSH determinations indicated if hypothyroidism is suspected.
- Adrenocorticotropic hormone (ACTH) stimulation test or low-dose dexamethasone-suppression test (LDDS) indicated if hyperadrenocorticism is suspected.

**TREATMENT**

Diet should contain < 10% fat (e.g., Waltham Royal Canin Low Fat, Hill's Prescription Diet r/d or w/d, Iams Restricted Calorie, Purina OM).

**MEDICATIONS****DRUG(S) OF CHOICE**

- Initial management is dietary.
- See “Alternative Drug(s)” if diet fails to control hyperlipidemia.

ALTERNATIVE DRUG(S)

- Gemfibrozil 7.5 mg/kg PO q12h; 200 mg/dog/day
- Fish oils—omega-3 polyunsaturated fat, 50–300 mg/kg PO q24h
- Niacin 25–100 mg/dog/day (slow release)

**FOLLOW-UP****PATIENT MONITORING**

- Keep triglyceride concentrations < 500 mg/dL to avoid possibly fatal episodes of acute pancreatitis.
- Checking cholesterol often is not necessary because hypercholesterolemia is not associated with clinical signs.

POSSIBLE COMPLICATIONS

- Pancreatitis and seizures are common complications of hyperlipidemia in the miniature schnauzer.
- In cats with hereditary chylomicronemia, xanthoma formation, lipemia retinalis, and neuropathies have been reported; peripheral neuropathies usually resolve 2–3 months after institution of a low-fat diet.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- Pancreatitis
- Seizures
- Neuropathies

AGE-RELATED FACTORS

None

PREGNANCY/FERTILITY/BREEDING

Potential cause of high cholesterol

SYNONYMS

- Lipemia—turbid serum or plasma secondary to significant hypertriglyceridemia
- Hyperlipoproteinemia—increased blood concentration of lipoproteins

HYPERMAGNESEMIA

BASICS

DEFINITION

- Dogs—serum magnesium > 2.5 mg/dL
- Cats—serum magnesium > 2.3 mg/dL

PATOPHYSIOLOGY

- Hypermagnesemia is less clinically significant than low total body magnesium in veterinary patients.
- Magnesium is second only to potassium as the most abundant intracellular cation; is found primarily in bone and muscle; is required for many metabolic functions.
- Serum magnesium is present in three forms: protein-bound form (approximately 25–30%) and chelated and ionized forms (together account for 70–75%).
- Magnesium absorption occurs primarily in the ileum. Absorption also occurs in the jejunum and colon.
- Magnesium is an important cofactor in the sodium-potassium ATPase pump that maintains electrical gradients across membranes.
- Interference with the electrical gradient can change resting membrane potentials; repolarization disturbances result in neuromuscular and cardiac abnormalities.
- The kidneys maintain magnesium balance with 10–15% reabsorbed in the proximal tubule, 60–70% in the thick ascending limb of the loop of Henle, and 10–15% reabsorbed in the distal convoluted tubule. Reabsorption within the distal convoluted tubule is under hormonal and neurohormonal control and determines the final urine concentration of magnesium.
- Any condition that severely lowers the glomerular filtration rate can elicit hypermagnesemia because magnesium homeostasis is largely controlled by renal elimination.
- High magnesium concentration impairs transmission of nerve impulses and decreases post-synaptic responses at the neuromuscular junction. When magnesium was given to anesthetized dogs at 0.12 mEq/kg/min, cardiovascular effects were not noted until plasma levels exceeded 12.2 mEq/L. The total dose of magnesium required to reach that level was 1–2 mEq/kg. It took cumulative doses of 5.9–10.9 mEq/kg to cause fatal cardiac arrhythmias (ventricular fibrillation).
- Magnesium has been called nature's calcium blocker; the most serious complications of hypermagnesemia result from calcium antagonism in the cardiac conduction system.

SYSTEMS AFFECTED

- Cardiovascular
- Musculoskeletal
- Nervous

INCIDENCE/PREVALENCE

Hypermagnesemia was found in 18% of hospitalized cats and 13% of hospitalized

dogs. Most of these patients also had renal insufficiency or post-renal azotemia.

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Dog and cat

Breed Predilections

N/A

SIGNS

General Comments

- Usually caused by renal failure; clinical signs might be referable to azotemia and renal insufficiency. Clinical hypermagnesemia is reported most often in patients with preexisting renal disease that are oversupplemented with parenteral magnesium salts.
- Characterized by progressive loss of neuromuscular, respiratory, and cardiovascular function.

Historical and Physical Examination Findings

- Nausea, vomiting, weakness, bradycardia, flaccid paralysis, mental depression, and hyporeflexia.
- Hypotension and ECG changes, including delayed intraventricular conduction and prolonged QT interval, occur with increased serum magnesium.
- Atrioventricular block, respiratory depression, coma, and cardiac arrest have been observed in humans with serum magnesium concentrations > 16 mg/dL.

CAUSES

- Renal failure.
- Intestinal hypomotility disorders and constipation.
- Endocrine disorders including hypoadrenocorticism, hypothyroidism, and hyperparathyroidism.
- Combined angiotensin-converting enzyme inhibitors and spironolactone administration.
- Excessive magnesium administration from magnesium-containing cathartic solutions given in conjunction with activated charcoal, magnesium-containing laxatives, and excess magnesium in peritoneal dialysis solutions.
- Iatrogenic oversupplementation in patients with concurrent renal disease.

RISK FACTORS

- Renal disease
- Intestinal hypomotility
- Massive hemolysis
- Hypoadrenocorticism
- Hyperparathyroidism
- Patients receiving angiotensin-converting enzyme inhibitors and spironolactone concurrently
- Excessive use of magnesium-containing cathartic solutions, especially in patients with renal insufficiency

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Signs are most similar to those of hypocalcemia, which often occurs simultaneously.
- Bradycardia can be caused by neurologic disease, hyperkalemia, hypertension, hypothyroidism, sick sinus syndrome, and various drugs.

LABORATORY FINDINGS

Note: 12 mg of magnesium = 1 mEq of magnesium; to convert from mg/dL to mEq/L, divide by 1.2.

Drugs That May Alter Laboratory Results

- Serum is favored over plasma because the anticoagulant used for plasma samples can contain citrate or other ions that can bind magnesium.
- EDTA, sodium fluoride-oxalate, sodium citrate, and intravenous calcium gluconate can cause falsely low serum magnesium values.

Disorders That May Alter Laboratory Results

- Hemolysis can result in falsely increased serum magnesium; the magnesium concentration in erythrocytes is approximately three times that in serum.
- Storage of serum or urine in metal containers can falsely elevate magnesium values.
- Hyperbilirubinemia can cause falsely decreased serum magnesium.

Valid if Run in Human Laboratory?

Yes

CBC/BIOCHEMISTRY/URINALYSIS

- Serum magnesium—dogs, > 2.5 mg/dL; cats, > 2.3 mg/dL
- Hypocalcemia is common
- Azotemia in some patients

OTHER LABORATORY TESTS

Ionized magnesium can be measured with an ion-selective electrode or by ultrafiltration of plasma; alternative methods of evaluating magnesium status include mononuclear blood cell magnesium levels or quantifying retention from a loading dose.

DIAGNOSTIC PROCEDURES

Electrodiagnostics (e.g., electromyography and electrocardiography) reveal effects of hypermagnesemia but do not differentiate the cause.

TREATMENT

APPROPRIATE HEALTH CARE

- Management involves enhancing elimination from the body and symptomatic therapy.

(CONTINUED)

- Discontinue all magnesium-containing medications and nutritional supplements.
- Saline diuresis and loop diuretics enhance renal clearance of magnesium.
- Fluid therapy with 0.9% NaCl provides fluid volume to address hypovolemia, hypotension and azotemia.
- Patients with oliguria might require peritoneal dialysis to treat severe hypermagnesemia.
- Parenteral calcium supplementation directly antagonizes the effects of magnesium, reversing respiratory depression, cardiac arrhythmias, and hypotension; calcium also enhances magnesium excretion.
- Hypermagnesemia associated with combined angiotensin-converting enzyme inhibitors and spironolactone is rare, mild, and unlikely to be clinically significant.

NURSING CARE

Patients with neurologic manifestations of hypermagnesemia might require intensive nursing care to prevent aspiration pneumonitis, pulmonary atelectasis, pressure necrosis (bed sores), and urine and fecal scalding.

DIET

Any magnesium supplementation should be discontinued.

CLIENT EDUCATION

Clients should be advised if preexisting conditions contributed to hypermagnesemia.

ACTIVITY

Patient activity is dependent on underlying conditions and response to therapy.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Furosemide promotes renal excretion of magnesium by decreasing absorption of magnesium in the loop of Henle.

- Enteral and parenteral calcium administration helps reverse clinical manifestations of hypermagnesemia and correct concurrent hypocalcemia; oral supplementation with any preparation can be given at a dosage of 25–50 mg/kg/day; severe hypermagnesemia can be treated with 10% calcium gluconate: 1–2 mL/kg (diluted 1:1 with saline) IV or SC q8h, administered slowly.

CONTRAINdications

Magnesium-containing compounds and fluids

PRECAUTIONS

Monitor ECG during calcium infusion

**FOLLOW-UP****PATIENT MONITORING**

- Serum magnesium and calcium concentrations
- Renal function—azotemia and urine output
- Continuous electrocardiogram if possible

PREVENTION/AVOIDANCE

Magnesium supplementation should be approached cautiously in patients with renal insufficiency.

POSSIBLE COMPLICATIONS

- Severe hypermagnesemia and hypocalcemia can be fatal.
- Hypermagnesemic dogs were 2.6 times less likely to survive their illness than patients with normal serum magnesium levels.

EXPECTED COURSE AND PROGNOSIS

Veterinary patients with iatrogenic overdose can have a good outcome with prompt recognition and supportive care.

HYPERMAGNESEMIA**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- Hypocalcemia
- Hyperphosphatemia
- Azotemia

PREGNANCY/FERTILITY/BREEDING

Effects on the fetus are identical to effects on the dam.

SEE ALSO

Hypocalcemia

ABBREVIATIONS

- ECG = electrocardiogram
- Mg = magnesium

H

HYPERMETRIA AND DYSMETRIA

BASICS

OVERVIEW

- Dysmetria—incoordination of the limbs during voluntary movement characterized by an inability to judge the rate, range, and force of movements.
- Hypermetria—overreaching limb movements giving a characteristic goose-stepping gait. The term dysmetria includes both hypo- and hypermetria.
- The cerebellum plays a central role in generating skilled movements and maintaining muscle tone and body posture. It does not initiate but coordinates and smoothes out movements.
- Damage to the cerebellum results in inaccurate gauging of voluntary movements. Motor strength is preserved; conscious proprioception is unaffected.
- Rarely, compression of the spinocerebellar tracts in spinal cord disorders can produce dysmetria. This is more likely to occur with dorsally located lesions.
- The hereditary ataxias are an important cause of cerebellar disease in dogs.

SIGNALMENT

Dog and cat of any age, breed, or sex

SIGNS

Other signs of cerebellar disease that may be present include truncal sway, intention tremor, wide-based stance, head tilt, loss of menace response with normal vision, and anisocoria.

CAUSES

Cerebellar

- Dogs—hypoplasia (inherited or secondary to infection with canine herpesvirus in the perinatal period); hereditary ataxia (cerebellar abiotrophy or cerebellar cortical degeneration); lysosomal storage diseases; CDV; protozoal infections (*Toxoplasma gondii* and *Neospora caninum*); rickettsial infections (*Ehrlichia canis* and Rocky Mountain spotted fever); *Cryptococcus* and other fungal infections; granulomatous meningoencephalitis; meningoencephalitis of unknown etiology; steroid-responsive shaker/tremor syndrome; neoplasia; trauma; infarct; hemorrhage; metronidazole toxicity.
- Cats—hypoplasia secondary to *in utero* infection with feline panleukopenia virus; lysosomal storage diseases; FIP, FeLV, FIV (associated immunosuppression predisposes to other encephalitides and to neoplasia); toxoplasmosis; *Cryptococcus* and other fungal infections; neoplasia; hemorrhage; trauma.

Spinal

- While there are many causes of spinal cord disease, centrodorsally located cervical lesions are more likely to produce hypermetria.

- Dogs—subarachnoid diverticula; neoplasia; vertebral malformation (atlantoaxial subluxation); and calcinosis circumscripta.

RISK FACTORS

Cerebellar

- Hereditary ataxia reported in Gordon and Irish setters, Kerry blue terriers, Airedale terriers, Finnish harriers and hounds, Samoyeds, Bern running dogs, cocker spaniels, cairn terriers, Australian kelpies, bull mastiffs, Italian spinones, the terrier group, Old English sheepdogs, Rhodesian ridgebacks, border and rough-coated collies, Brittany spaniels, beagles and Scottish terriers.
- Cerebellar hypoplasia has been reported in chow chows, Irish setters, and wire fox terriers.
- Lysosomal storage diseases causing dysmetria have been reported in Siamese, Balinese, Persian, and domestic shorthair cats, and in English springer spaniels, American Staffordshire terriers, Portuguese water dogs, German shorthaired pointers, Australian silky terriers, schipperkes, English setters, border collies, salukis, Chihuahuas, Queensland blue heelers, dachshunds, Yugoslavian shepherds, and Tibetan terriers.
- Small-breed white dogs, such as Maltese and West Highland white terriers, are predisposed to steroid-responsive (idiopathic) tremor syndrome.
- Metronidazole at dosages > 60 mg/kg/day can induce cerebello-vestibular signs in dogs. Signs are induced in some dogs at lower doses.
- Vascular events, both thromboembolic and hemorrhagic, can cause cerebellar signs, typically due to thrombosis of the rostral cerebellar artery. Disorders that cause hypercoagulable state (such as hyperadrenocorticism) or hypertension (such as hyperthyroidism in cats, or chronic renal disease) can predispose to stroke. Hypothyroidism has also been associated with cerebellar stroke. Thrombosis of the rostral cerebellar artery occurs in older dogs; an underlying cause is not always identified.

Spinal

- Giant-breed dogs are predisposed to vertebral malformation and instability.
- Young large-breed dogs are predisposed to subarachnoid diverticula and calcinosis circumscripta.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Some dogs, especially small breeds, have a high-stepping gait in their thoracic limbs as a normal finding. If there are no other signs of cerebellar disease, establish whether a high-stepping thoracic limb gait is normal for the dog.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC may reflect infectious/inflammatory disease.
- Storage products may be present in leukocytes in some lysosomal storage diseases.

OTHER LABORATORY TESTS

- Acute and convalescent serologic titers—to diagnose rickettsial, protozoal, fungal, and viral diseases.
- CSF antibody or antigen (*Cryptococcus*) titers—for some infections (e.g., *Toxoplasma*, *Cryptococcus*), measure in addition to serologic titers.
- PCR on CSF and serum—to diagnose rickettsial, bacterial, protozoal, fungal, and viral diseases; sensitive and specific if the infectious agent is present in the CSF or serum.
- Genetic tests available for hereditary ataxia in beagles, Finnish hounds, Italian spinone, Gordon setter, Old English sheepdog and the terrier group (Jack and Parson Russell terriers).

IMAGING

- Thoracic radiography—to identify metastatic disease in older patients.
- Abdominal ultrasonography—if intra-abdominal neoplasia is suspected.
- Brain CT or MRI—to diagnose neoplasia, vascular disease, encephalitis, cerebellar atrophy due to hypoplasia or abiotrophy; MRI is the preferred modality for evaluating the caudal fossa.
- Survey spinal radiography—if spinal cord disease is suspected; may be helpful in identifying vertebral malformations and calcinosis circumscripta.
- Spinal MRI—non-invasive and informative about spinal cord parenchyma.

DIAGNOSTIC PROCEDURES

- Fundic examination—to identify chorioretinitis (evidence of infectious/inflammatory disease) and vascular lesions associated with vasculitis or hypertension.
- CSF—to diagnose encephalitis; storage products may be present in CSF leukocytes in some lysosomal storage diseases.
- Liver biopsy—may be helpful in diagnosing certain lysosomal storage diseases in animals with hepatomegaly.

TREATMENT

APPROPRIATE HEALTH CARE

- Severe and/or rapidly progressive clinical signs—hospitalization for diagnostic workup and treatment.
- Mild and slowly progressive clinical signs—outpatient, but diagnostic tests requiring anesthesia necessitate hospitalization.

(CONTINUED)

HYPERMETRIA AND DYSMETRIA

- Patients should be restricted to areas and activities where they are unlikely to fall and injure themselves.
- Appropriate treatment of the underlying cause should be undertaken once a diagnosis has been established.

SURGICAL CONSIDERATIONS

Surgical decompression of the spinal cord indicated for compressive myelopathies.

**MEDICATIONS****DRUG(S) OF CHOICE**

Discontinue metronidazole, regardless of the dose rate, to see if signs improve.

**FOLLOW-UP****PATIENT MONITORING**

- Periodic repeat neurologic examinations.
- Additional monitoring will depend on the underlying cause (e.g., serial monitoring of blood pressure in hypertensive patients).

**MISCELLANEOUS****ZOONOTIC POTENTIAL**

Fungal infections can be zoonotic.

ABBREVIATIONS

- CDV = canine distemper virus
- CSF = cerebrospinal fluid
- FeLV = feline leukemia virus
- FIP = feline infectious peritonitis
- FIV = feline immunodeficiency virus
- PCR = polymerase chain reaction

Consulting Editor Joane M. Parent

H

HYPERNATREMIA

BASICS

DEFINITION

Serum sodium concentration > 158 mEq/L in dogs or > 165 mEq/L in cats.

PATHOPHYSIOLOGY

- Sodium is the most abundant cation in the extracellular fluid, so hypernatremia usually reflects hyperosmolality.
- Hypernatremia can be caused by excessive water loss, increased intake of sodium, or a combination of both.
- Common causes of hypernatremia include renal or gastrointestinal loss of water in excess of sodium loss and low water intake.

H

SYSTEMS AFFECTED

- Endocrine/Metabolic
- Nervous

SIGNALMENT

Dog and cat

SIGNS

- Polydipsia
- Disorientation
- Coma
- Seizures
- Other findings depend on underlying cause
- Severity of signs usually correlates to the degree of hypernatremia

CAUSES

- Total body sodium high—oral ingestion (rare); IV administration of NaCl during cardiovascular resuscitation; hyperaldosteronism (rare); hyperadrenocorticism (may cause mild changes).
- Total body sodium normal plus water deficit—low water intake (e.g., no access to water and adipsia or hypodipsia); high urinary water loss (e.g., diabetes insipidus); high insensible water loss (e.g., panting and hyperthermia).
- Total body sodium low and hypotonic fluid loss (i.e., loss of fluid containing sodium without adequate water replacement)—urinary loss (e.g., diabetes mellitus, osmotic diuresis, and diuresis after acute urinary obstruction); gastrointestinal sodium loss (e.g., administration of osmotic cathartic, vomiting, and diarrhea).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Diabetes insipidus
- Hyperosmolar non-ketotic syndrome
- Hypertonic dehydration
- Alterations in thirst reaction pathway: rare
- Salt ingestion—rare

LABORATORY FINDINGS

Drugs That May Alter Laboratory Results

A wide variety of drugs interfere with renal capacity to concentrate urine, leading to water loss in excess of sodium and high serum sodium concentration; these drugs include lithium, demeclocycline, and amphotericin.

Disorders That May Alter Laboratory Results

Lipemia or hyperproteinemia (> 11 g/dL) can artificially raise sodium concentration when the flame photometry method is used.

Valid if Run in a Human Laboratory?

Yes

CBC/BIOCHEMISTRY/URINALYSIS

- High serum sodium concentration.
- Diabetes insipidus—polyuria, low urinary specific gravity, and low urinary sodium concentration.
- Hyperosmolar non-ketotic syndrome—high blood glucose, low urine output, and high urinary specific gravity (usually > 1.025).
- Hypertonic dehydration—low urinary sodium concentration and high urinary specific gravity (usually > 1.030).

OTHER LABORATORY TESTS

- Modified water deprivation test (see Appendix II for test protocol) to differentiate diabetes insipidus from other causes of polyuria and polydipsia; performed after results of CBC, biochemical analysis, urinalysis, and endocrine testing are evaluated to rule-out hyperadrenocorticism.
- After water restriction, patients with diabetes insipidus have little or no increase in urinary specific gravity or osmolality.
- After ADH or DDAVP administration, patients with nephrogenic diabetes insipidus have < 10% increase in urinary specific gravity; those with central diabetes insipidus have a 10–800% increase.

IMAGING

CT scan or MRI in patients with diabetes insipidus to rule out pituitary tumor.

TREATMENT

- After resolution of the hypernatremia, consider a sodium-restricted diet (especially in patients with nephrogenic diabetes insipidus).
- Water must be available at all times for patients with diabetes insipidus.

MEDICATIONS

DRUG(S) OF CHOICE

- If hypovolemia is severe—replace volume with isotonic saline (i.e., lactated Ringer's or normal saline) or isotonic fluids (i.e., 5% dextrose with half-normal saline).
- Hypernatremia—administer hypotonic fluids (e.g., 5% dextrose in water) to reduce serum sodium by 0.5 mEq/h or by no more than 20 mEq/L/day; supplement with potassium and phosphate if needed.
- Central diabetes insipidus—DDAVP (one to two drops in subconjunctival sac q12–24h).
- Nephrogenic diabetes insipidus—hydrochlorothiazide (2–4 mg/kg PO q12h).

CONTRAINDICATIONS

Refer to manufacturer's literature

PRECAUTIONS

- Rapid correction of hypernatremia can cause pulmonary edema.
- Hypocalcemia may develop during correction of hypernatremia.

FOLLOW-UP

PATIENT MONITORING

- Acute setting—electrolytes, urine output, and body weight
- Diabetes insipidus—water intake

(CONTINUED)

HYPERNATREMIA**POSSIBLE COMPLICATIONS**

- CNS thrombosis or hemorrhage.
- Hyperactivity.
- Seizures.
- Serum sodium > 180 mEq/L often associated with residual CNS damage.
- Many patients recover, but possibility of neurologic damage is high.

H

HYPEROSMOLARITY

BASICS

DEFINITION

- Osmolarity—expressed in mOsm/L; represents the number of solute particles per liter of solution.
- Osmolality—expressed in mOsm/kg; represents the number of solute particles per kilogram of solution.
- Hyperosmolarity—a high concentration of solute particles per liter of solution.
- Serum concentrations > 310 mOsm/L in dogs and > 330 mOsm/L in cats are usually considered hyperosmolar.
- Morbidity from hyperosmolarity is related more to rapid changes in osmolarity than to the actual amount of change.

H

PATOPHYSIOLOGY

- Serum sodium is responsible for most of the osmotically active particles that contribute to serum osmolarity; serum glucose and urea also contribute to serum osmolarity.
- Anything that causes water loss increases concentrations of solutes in plasma or serum, thereby increasing serum osmolarity.
- Blood volume, hydration status, and ADH are intimately involved in controlling extracellular fluid volume.
- Low circulating blood volume stimulates carotid and aortic baroreceptors to respond to changes in blood pressure, causing ADH secretion.
- Hyperosmolarity affects the osmoreceptors in the hypothalamus and stimulates ADH secretion from the neurohypophysis; the hypothalamic thirst center is also stimulated and causes an increase in water consumption to counteract serum hyperosmolarity by solute dilution.
- Rapid increases in serum osmolarity cause water movement along its concentration gradient from intracellular to extracellular spaces, resulting in neuronal dehydration, cell shrinkage, and cell death; cerebral vessels may weaken and hemorrhage.

SYSTEMS AFFECTED

- Cardiovascular—hypotension and decreased ventricular contractility.
- Nervous—excessive thirst may be the first sign of hyperosmolarity. Central nervous system depression may lead to coma.
- Renal/Urologic—low urine output.

SIGNALMENT

- Dog and cat.
- Hypodipsia and hyperosmolarity have been reported in young female miniature schnauzers.

SIGNS

General Comments

- Primarily neurologic or behavioral.
- Severity is related more to how quickly hyperosmolarity occurs than to the absolute magnitude of change.
- Most likely to occur if serum osmolarity is > 350 mOsm/L and usually severe if > 375 mOsm/L.

Historical Findings

Anorexia, lethargy, vomiting, weakness, disorientation, ataxia, seizures, and coma; polydipsia followed by hypodipsia.

Physical Examination Findings

- Normal, or abnormalities may reflect underlying disease.
- In addition to historical findings, dehydration, tachycardia, hypotension, weak pulses, and fever may be detected.

CAUSES

Increased Solutes

Hypernatremia, hyperglycemia, severe azotemia, ethylene glycol toxicosis, salt poisoning, sodium phosphate enemas in cats and small dogs, mannitol, radiographic contrast solution, administration of ethanol, aspirin toxicosis, shock, lactate in patients with lactic acidosis, acetoacetate and β -hydroxybutyrate in patients with ketoacidosis, liquid enteral nutrition, and parenteral nutrition solutions.

Decreased Extracellular Fluid Volume

Dehydration—gastrointestinal loss, cutaneous loss, third space loss, low water consumption, and polyuria without adequate compensatory polydipsia.

RISK FACTORS

- Medical conditions that predispose—renal failure, diabetes insipidus, diabetes mellitus, hyperadrenocorticism, hyperaldosteronism, and heat stroke.
- Therapeutic hyperosmolar solutions—hypertonic saline, sodium bicarbonate, sodium phosphate enemas in cats and small dogs, mannitol, and parenteral nutrition solutions.
- High environmental temperatures.
- Fever.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Primary CNS disease and neoplasia may be characterized by altered mentation, but serum osmolarity is usually normal.
- Physical evidence or history of injury usually helps to rule out CNS depression caused by cranial trauma.
- Perform a thorough physical examination to assess hydration status and obtain information regarding previous therapy that may have included sodium-containing fluids or hyperosmolar solutions.

LABORATORY FINDINGS

Drugs That May Alter Laboratory Results

Excessive administration of sodium-containing fluids or hyperosmolar solutions increase serum osmolarity.

Disorders That May Alter Laboratory Results

N/A

Valid if Run in Human Laboratory?

Yes

CBC/BIOCHEMISTRY/URINALYSIS

- High PCV, hemoglobin, and plasma proteins in dehydrated patients; serum electrolytes may also be increased.
- Hyperosmolarity is an indication to evaluate serum sodium and glucose concentrations.
- Without the presence of excessive unmeasured osmoles, estimated serum osmolarity may be calculated from serum chemistries as follows:

$$\frac{2(\text{Na}^+ + \text{K}^+) + \text{glucose}/18 + \text{BUN}/2.8}{\text{mOsm/L}}$$

- Normally, calculated osmolarity should not exceed measured osmolarity; if it does, consider laboratory error.
- If measured osmolarity exceeds the calculated osmolarity, determine the osmolar gap.
- Osmolar gap = measured osmolarity – calculated osmolarity.
- High measured osmolarity and normal calculated osmolarity with a high osmolar gap indicate the presence of unmeasured solutes (not Na, K, glucose, BUN).
- High measured osmolarity and high calculated osmolarity with a normal osmolar gap usually indicate that the hyperosmolarity is caused by hyperglycemia or hypernatremia.
- Serum sodium concentration may be artificially low in patients with severe hyperglycemia and hyperosmolarity.
- Fasting hyperglycemia and glucosuria support a diagnosis of diabetes mellitus.
- Numerous calcium oxalate crystals in the urine suggest ethylene glycol toxicosis.
- High urinary specific gravity rules out diabetes insipidus.
- Low urinary specific gravity, especially hyposthenuria, suggests diabetes insipidus.

OTHER LABORATORY TESTS

Urinary osmolarity lower than serum osmolarity suggests diabetes insipidus; concentrated urine rules out diabetes insipidus.

IMAGING

Renal ultrasonography may reveal bright hyperechoic kidneys in patients with ethylene glycol toxicosis.

TREATMENT

- Mild hyperosmolarity without clinical signs may not warrant specific treatment, but diagnose and treat underlying diseases.
- Hospitalize patients with moderate-to-high osmolarity (> 350 mOsm/L) and patients exhibiting clinical signs and gradually lower serum osmolarity with intravenous fluids while a definitive diagnosis is pursued.
- Administer D5W or 0.45% saline slowly IV.
- Free water deficit can be calculated by the following formula:

$$\text{Free water deficit} = 0.4 \times \text{lean body weight in kg} \times [(\text{Plasma Na}/140) - 1]$$

(CONTINUED)

- The goal is to not drop sodium more than 15 mEq/L in an 8-hour period; that is, the ultimate goal is to not drop the sodium by more than 2 mEq/L/hour.
- Initially, 0.9% saline may be used to restore normal hemodynamics and replace dehydration deficits; replace one-half of dehydration deficits over 12 hours and the remainder over 24 hours; then switch to D₅W or 0.45% saline.

MEDICATIONS

DRUG(S) OF CHOICE

Seizures can be controlled with diazepam, phenobarbital, propofol, or pentobarbital.

CONTRAINDICATIONS

Hypertonic saline and hyperosmolar solutions

PRECAUTIONS

- May use normal saline initially, but rapid administration may worsen neurologic signs.
- Rapid administration of hypotonic fluids (e.g., D₅W and 0.45% saline) may also cause cerebral edema and worsen neurologic signs.

ALTERNATIVE DRUG(S)

Regular insulin 0.1 unit/kg IM or IV can be administered if a hyperglycemic crisis occurs secondary to parenteral nutrition administration.

FOLLOW-UP

PATIENT MONITORING

- Hydration status; avoid overhydration.
- Bladder size, urine output, and breathing patterns during IV fluid administration.
- Anuria, irregular breathing patterns, worsening depression, coma, or seizures may be signs of deterioration.

POSSIBLE COMPLICATIONS

Altered consciousness and abnormal behavior

MISCELLANEOUS

ASSOCIATED CONDITIONS

Hypernatremia and hyperglycemia

AGE-RELATED FACTORS

HYPERPARATHYROIDISM

BASICS

DEFINITION

A pathologic, sustained, high, circulating concentration of PTH.

PATHOPHYSIOLOGY

- PTH—secreted by the parathyroid glands in response to changes in the concentration of ionized calcium in the serum; raises the serum calcium concentration through its effects on bone and renal tubular calcium resorption and vitamin D-dependent intestinal calcium absorption.
- Can develop as a primary condition or be secondary to a disorder of calcium homeostasis; primary hyperparathyroidism is associated with benign (usually) adenoma of the parathyroid gland(s); secondary hyperparathyroidism can be caused by a deficiency of calcium and vitamin D associated with malnutrition or chronic renal disease.

SYSTEMS AFFECTED

- Cardiovascular
- Gastrointestinal
- Neuromuscular
- Renal/Urologic

GENETICS

- None known for primary hyperparathyroidism, but its association with certain breeds suggests a possible hereditary basis in some cases.
- Secondary hyperparathyroidism can develop in association with hereditary nephropathy, but is not inherited per se.

INCIDENCE/PREVALENCE

- Prevalence of primary form is unknown.
- More commonly diagnosed in dogs than in cats.
- Fairly common among causes of hypercalcemia, but much less common than hypercalcemia of malignancy in dogs.
- Nutritional secondary hyperparathyroidism is decreasing in prevalence as the public becomes more educated in pet nutrition.
- Chronic renal failure with secondary hyperparathyroidism is extremely common, more so in cats than in dogs.

SIGNALMENT

Species

Cat and dog

Breed Predilections

- Keeshonden
- Siamese cats

Mean Age and Range

- Cats—mean age, 13 years; range 8–15 years
- Dogs—mean age, 10 years; range 5–15 years

Predominant Sex

None

SIGNS

General Comments

- Most dogs and cats with primary hyperparathyroidism do not appear ill.
- Signs are usually mild and are due solely to the effects of hypercalcemia.
- Signs become apparent when hypercalcemia is severe and chronic.

Historical Findings

- Polyuria
- Polydipsia
- Anorexia
- Lethargy
- Vomiting
- Weakness
- Urolithiasis
- Stupor and coma

Physical Examination Findings

- Often unremarkable.
- Parathyroid adenoma is not palpable in dogs but often is in cats.
- Nutritional secondary disease is sometimes associated with pathologic bone fractures and general poor body condition.

CAUSES

- Primary hyperparathyroidism—PTH-secreting adenoma of the parathyroid gland. In most cases only one gland is adenomatous. Malignant tumors of the parathyroid glands are uncommon and usually non-invasive.
- Renal secondary hyperparathyroidism—renal calcium loss and reduced gut absorption of calcium due to deficiency in calcitriol production by the renal tubular cells.
- Nutritional secondary hyperparathyroidism—a nutritional deficiency of calcium and vitamin D.

RISK FACTORS

- Primary hyperparathyroidism—unknown.
- Secondary hyperparathyroidism—coexisting renal tubular disease or calcium/vitamin D malnutrition.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- The differential list includes causes of hypercalcemia.
- Lymphoma—common in dogs, rare in cats.
- Anal sac apocrine gland adenocarcinoma—dogs.
- Other miscellaneous carcinomas—dogs and cats.
- Myeloproliferative disease—cats.
- Fibrosarcoma—cats.
- Chronic renal failure.
- Hypoadrenocorticism.
- Vitamin D intoxication—rodenticides are not currently marketed in the United States, but exposure can come from plant sources and vitamin supplements.

- Granulomatous diseases.
- Idiopathic hypercalcemia in cats.

CBC/BIOCHEMISTRY/URINALYSIS

- High serum calcium concentration.
- Low or low-normal serum phosphorus concentration in primary hyperparathyroidism.
- Hyperphosphatemia in secondary hyperparathyroidism or hypervitaminosis D.
- BUN and creatinine concentrations are usually normal in patients with primary hyperparathyroidism, except those with hypercalcemia-induced renal failure.

OTHER LABORATORY TESTS

- Serum ionized calcium determination is often normal in patients with chronic renal failure and high in patients with primary hyperparathyroidism or hypercalcemia associated with malignancy.
- High serum PTH concentration is diagnostic for primary hyperparathyroidism in the absence of azotemia; assays that measure the intact PTH molecule are most useful. A normal serum PTH concentration in an animal with hypercalcemia may be considered abnormal and can signal parathyroid-dependent hypercalcemia.

IMAGING

- Radiography can be useful to assess urolithiasis, renal morphology, and bone density and to identify occult neoplasia.
- Ultrasonography of the ventral cervical area sometimes reveals a parathyroid gland adenoma.
- Ultrasound of the abdomen can reveal lymphadenomegaly, urolithiasis, or renal morphologic abnormalities.

DIAGNOSTIC PROCEDURES

Surgical exploration of the ventral cervical area

PATHOLOGIC FINDINGS

- Parathyroid adenoma is usually a solitary, small (= 1 cm), round, light brown or reddish mass located in the proximity of the thyroid gland.
- Occasionally multiple adenomas are found.
- The histologic distinctions between adenomas, hyperplasia, and carcinomas of the parathyroid gland are often unclear.

TREATMENT

APPROPRIATE HEALTH CARE

- Primary hyperparathyroidism generally requires inpatient care and surgery.
- Nutritional or renal secondary hyperparathyroidism in non-critical patients can be managed on an outpatient basis.

ACTIVITY

No alterations recommended

(CONTINUED)

HYPERPARATHYROIDISM**DIET**

Calcium supplementation for secondary forms

CLIENT EDUCATION

Explain signs referable to changes in calcium status, because hypocalcemia is a potential complication of parathyroidectomy.

SURGICAL CONSIDERATIONS

- Surgery is the treatment of choice for primary hyperparathyroidism and is often important in establishing the diagnosis.
- Percutaneous ultrasound-guided heat ablation has been used successfully for treatment of parathyroid adenoma, and may be recommended if available.
- Percutaneous ultrasound-guided ethanol ablation has been reported to be less successful than surgery or heat ablation.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Normal saline is the fluid of choice for treatment of hypercalcemia.
- Diuretics (furosemide) and corticosteroids can be useful in treating hypercalcemia.
- No medical treatment exists for primary hyperparathyroidism per se.
- Renal secondary hyperparathyroidism is sometimes treated with calcitriol, but its use has not gained wide acceptance.
- A new class of calcimimetic drugs is being used to treat renal secondary hyperparathyroidism in human patients, but studies of these drugs in dogs and cats have not been reported.

CONTRAINDICATIONS

- Do not use glucocorticoids until the diagnosis of lymphoma has been excluded; they can obfuscate the diagnosis.
- Avoid calcium-containing fluids.

PRECAUTIONS

Use furosemide only in patients with adequate hydration.

ALTERNATIVE DRUG(S)

Pamidronate has been used to treat hypercalcemia of various causes in dogs and cats.

**FOLLOW-UP****PATIENT MONITORING**

- Postoperative hypocalcemia is relatively common after treatment of primary hyperparathyroidism. Recent studies have shown that preoperative ionized calcium and PTH concentrations are poor predictors of post-surgical hypocalcemia, so monitoring is essential in all cases.
- Postoperative hypocalcemia requires treatment with vitamin D (calcitriol is recommended) and calcium supplements (see treatment of hypoparathyroidism), and ionized calcium should be monitored to guide dosage adjustments.
- In patients with renal impairment, check serum concentrations of urea nitrogen and creatinine.

PREVENTION/AVOIDANCE

- No strategies exist for prevention of primary hyperparathyroidism.
- Nutritional secondary hyperparathyroidism is prevented by proper nutrition.

POSSIBLE COMPLICATIONS

Irreversible renal failure secondary to hypercalcemia.

EXPECTED COURSE AND PROGNOSIS

- Untreated disease usually progresses to end-stage kidney or neurologic disease.
- Prognosis for treatment of parathyroid adenoma is excellent.
- Recurrence is seen in a small percentage of cases.
- In animals that develop postoperative hypoparathyroidism, the return of normal parathyroid function is unpredictable and can take weeks to months.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Calcium-containing urolithiasis

available online

HYPERPARATHYROIDISM, RENAL SECONDARY

BASICS

OVERVIEW

- Clinical syndrome characterized by a high concentration of biologically active PTH secondary to chronic kidney disease; results from impaired renal excretion of phosphorus leading to elevated levels of fibroblastic growth factor-23 (FGF-23) and associated suppression of renal calcitriol synthesis; low concentrations of ionized calcium and hyperphosphatemia also contribute.
- Hyperphosphatemia secondary to declining renal function is associated with an increase in phosphatonin FGF-23 which enhances renal phosphaturia and reduces the activity of 1- α -hydroxylase in the kidney, which in turn reduces production of calcitriol (1,25-dihydroxycholecalciferol). In more advanced CKD, reduced renal tubular mass also contributes to reduced calcitriol synthesis. Normal calcitriol concentrations exert a negative effect on PTH synthesis within the parathyroid gland nucleus. Low calcitriol and serum ionized calcium concentrations and hyperphosphatemia result in increased PTH production and parathyroid gland hyperplasia.
- PTH may act as a uremic toxin and may promote nephrocalcinosis and progression of chronic renal failure.

H

SIGNALMENT

Dog and cat. See Renal Failure, Chronic, for age and breed predilections.

SIGNS

- Those associated with underlying chronic kidney disease are the usual reason for examination.
- Severe renal osteodystrophy or "rubber jaw" occurs in some patients, most commonly young dogs with severe renal secondary hyperparathyroidism.
- Pain around the head or bone pain—sometimes very marked.

CAUSES & RISK FACTORS

- Any disease that causes chronic kidney disease
- Excess consumption of dietary phosphorus

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hypercalcemic nephropathy—renal disease (or failure) caused by ionized hypercalcemia; can be difficult to differentiate from long-standing renal secondary hyperparathyroidism in which hyperplasia of the parathyroid glands limits their ability to stop releasing PTH in

the face of high concentrations of ionized calcium (tertiary hyperparathyroidism).

- The total serum calcium concentration is usually higher in patients with hypercalcemic nephropathy than in those with renal secondary hyperparathyroidism; the ionized serum calcium concentration is usually low or normal with renal secondary hyperparathyroidism, but high with hypercalcemic nephropathy.
- Serum PTH concentration is low and PTHrP high in animals with hypercalcemia of malignancy; may detect underlying causes of hypercalcemia such as lymphoma or apocrine gland adenocarcinoma of the anal sac.
- Primary hyperparathyroidism—initially characterized by hypercalcemia (ionized and total), normal or low serum phosphorus concentration, and high PTH concentration; renal function is initially normal but may become compromised later in the course of disease.

CBC/BIOCHEMISTRY/URINALYSIS

- Azotemia.
- Hyperphosphatemia.
- Urine specific gravity < 1.030 in dogs and < 1.035 in cats.
- Total serum calcium concentration may be low, normal, or slightly increased; see Renal Failure, Chronic.

OTHER LABORATORY TESTS

- Definitive diagnosis and therapeutic monitoring of renal secondary hyperparathyroidism require measurement of serum PTH concentration; an immunoassay for PTH directed against the amino-terminal or intact PTH molecule and validated for dogs or cats is necessary for reproducible and meaningful results.
- A low-to-normal ionized serum calcium concentration is useful to differentiate renal secondary hyperparathyroidism from other causes of hypercalcemia.

IMAGING

Radiographs may reveal low bone density, loss of the lamina dura around the teeth, and soft-tissue mineralization of the gastric mucosa or other tissues.

TREATMENT

- See Renal Failure, Chronic, for general treatment principles.
- Minimize serum phosphorus concentration by feeding a diet low in phosphorus content (preferably formulated for dogs or cats with CKD) and, if indicated, intestinal phosphate binders.
- Provide free access to fresh water to maintain hydration.

MEDICATIONS

DRUG(S)

Intestinal Phosphate Binders

- Prescribe if dietary management does not return phosphorus concentration to recommended levels: serum phosphate < 4.5 mg/dL for dogs and cats in IRIS CKD stage 2; < 5.0 mg/dL in IRIS CKD stage 3; and < 6.0 mg/dL in IRIS CKD stage 4.
- Aluminum hydroxide (30–90 mg/kg/day PO with meals), calcium carbonate (90–150 mg/kg/day PO with meals), calcium acetate (60–90 mg/kg/day PO with meals), or lanthanum carbonate (same dosing as aluminum hydroxide). Dose to effect to achieve stated serum phosphorus concentration target, but do not exceed recommended dosage.
- Hypercalcemia may develop when a calcium-containing phosphate binder is combined with calcitriol; calcium-containing phosphate binders should be avoided with calcitriol therapy. Chemically different phosphate binders can be used in combination to reduce the dosage of each and minimize the risk of hypercalcemia or aluminum toxicity.

Calcitriol

- Low-dose calcitriol (2.0–3.5 ng/kg PO q24h)—may use after initiation of dietary phosphorus restriction and oral phosphate binders; note that this dose is in ng/kg rather than mg/kg; a pharmacy that specializes in reformulation of calcitriol into low doses is needed to provide this prescription. Calcitriol should be administered on an empty stomach and before bedtime (i.e., no food for 6–8 hours after administration).
- Maintain serum phosphorus concentration within the target range before and during calcitriol therapy: serum phosphorus < 4.5 mg/dL in CKD stage 2; < 5.0 mg/dL in CKD stage 3; and < 6.0 mg/dL in CKD stage 4.

CONTRAINdicATIONS/POSSIBLE INTERACTIONS

- Calcitriol administration may result in hypercalcemia, especially if combined with a calcium-containing intestinal phosphate binder. Increased total calcium concentration sometimes develops in patients with long-standing chronic kidney disease but is not related to calcitriol treatment. In these instances, ionized calcium concentration is normal or low, and hypercalcemia does not resolve when calcitriol treatment is discontinued.
- Do not use calcium-containing intestinal phosphate binders in patients with a calcium × phosphorus product > 70. Use

(CONTINUED)

aluminum-containing or lanthanum-containing intestinal phosphate binders initially to correct hyperphosphatemia. Calcium-containing intestinal phosphate binders can be reconsidered once the serum phosphorus concentration is within the target range.

FOLLOW-UP

PATIENT MONITORING

- Initially and in unstable patients, serum concentrations of calcium, phosphorus, creatinine, and urea nitrogen—monitor weekly to monthly depending on therapy and the severity of chronic kidney disease.
- Patients receiving calcitriol should be monitored for hypercalcemia and/or hyperphosphatemia weekly for 4 weeks, then monthly if the patient is stable, and then every 3–4 months.
- Serial evaluations of PTH concentration—most dogs and cats treated with low doses of calcitriol achieve near-normal levels of PTH within 3 months; it may be necessary to increase the dose in those with severe parathyroid gland hyperplasia.

HYPERPARATHYROIDISM, RENAL SECONDARY

- If hypercalcemia develops, discontinue use of calcitriol. Measurement of ionized calcium is recommended since some animals with chronic kidney disease develop non-ionized hypercalcemia that is unrelated to calcitriol treatment. If hypercalcemia is due to calcitriol treatment (high-ionized calcium), it should abate within 5 days. Intermittent-dose calcitriol treatment at twice the dose every other day may alleviate a mild degree of hypercalcemia. Patients with more severe hypercalcemia may benefit from 3.5 times the normal dose given every 3.5 days. These effects on reduction in hypercalcemia are due to decreased programming of intestinal epithelial cells for calcium absorption.

PREVENTION/AVOIDANCE

Dietary phosphorus restriction in patients with chronic kidney disease may delay the onset of renal secondary hyperparathyroidism.

POSSIBLE COMPLICATIONS

Renal osteodystrophy and pathologic fractures (rare)

EXPECTED COURSE AND PROGNOSIS

- Progression of the underlying chronic kidney disease may be slowed by minimizing phosphorus retention and renal secondary hyperparathyroidism.

- Long-term prognosis is guarded to poor for patients with chronic kidney disease and renal secondary hyperparathyroidism.

MISCELLANEOUS

AGE-RELATED FACTORS

Young animals can develop severe renal osteodystrophy and may benefit from treatment with calcitriol.

Consulting Editor Carl A. Osborne

H

HYPERPHOSPHATEMIA

BASICS

DEFINITION

- Serum total phosphorus > 5.5 mg/dL (dogs)
- Serum total phosphorus > 6 mg/dL (cats)

PATHOPHYSIOLOGY

- Control of phosphorus is complex and is influenced by the actions of PTH and vitamin D and the interaction of these hormones with the gut, bone, kidneys, and parathyroid glands.
- High serum phosphorus results from excessive gastrointestinal absorption of phosphorus, excessive bone resorption of phosphorus, and reduced renal excretion of phosphorus.

SYSTEMS AFFECTED

- Endocrine
- Metabolic
- Renal

SIGNALMENT

- Dogs and cats.
- Any age, but commonly young, growing animals or old animals with renal insufficiency.

SIGNS

Historical Findings

- Depends on the underlying cause of hyperphosphatemia.
- No specific signs directly attributable to hyperphosphatemia
- Acute hyperphosphatemia causes hypocalcemic tetany and/or vascular collapse.

Physical Examination Findings

Chronic hyperphosphatemia causes calcification of soft tissues, resulting in chronic renal failure and tumoral calcinosis.

CAUSES

- Reduced glomerular filtration rate
- Prerenal azotemia
- Renal azotemia
- Post-renal azotemia
- Hyperphosphatemia secondary to excessive bone resorption or muscle breakdown
- Young growing dogs
- Hypoparathyroidism
- Hypersomatotropism
- Hyperphosphatemia caused by excessive gastrointestinal absorption of phosphorus
- Osteolysis
- Disease osteoporosis
- Osseous neoplasia
- Hyperthyroidism
- Phosphorus-containing enemas
- Vitamin D toxicosis
- Phosphorus dietary supplementation
- Nutritional secondary hyperparathyroidism

RISK FACTORS

- Renal disease
- Use of phosphorus-containing enemas in small animals such as cats

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hypoparathyroidism—also characterized by clinical signs of hypocalcemia such as seizures and tetany.
- Prerenal azotemia as a cause of hyperphosphatemia—associated with disease states that result in low cardiac output such as congestive heart failure, dehydration, hypoadrenocorticism, and shock.
- Renal insufficiency, either acute or chronic renal failure—attended by azotemia and abnormal findings on urinalysis (low urinary specific gravity).
- Young, growing animals—can have serum phosphorus concentrations twice those of adults.
- Vitamin D intoxication—history of vitamin D supplementation or ingestion of rodenticides (e.g., Rampage).
- Nutritional secondary hyperparathyroidism—history of dietary calcium-phosphorus imbalance.
- Hyperthyroidism in cats—clinical signs of weight loss, polyphagia, and polydipsia and polyuria.
- Hypersomatotropism—attended by a history of progesterone administration in dogs and insulin-resistant diabetes mellitus in cats.
- Non-azotemia tumoral calcinosis—observed in human beings as an autosomal dominant disorder; rare cause of hyperphosphatemia associated with large bone lesions.
- Jasmine toxicity—history of plant ingestion.
- Factitious.

LABORATORY FINDINGS

Drugs That May Alter Laboratory Results

- Phosphorus-containing enemas
- Intravenous potassium phosphate
- Anabolic steroids
- Furosemide
- Hydrochlorothiazide
- Minocycline

Disorders That May Alter Laboratory Results

- Hemolysis and lipemia can falsely raise phosphorus concentrations.
- Collection in citrate, oxalate, or EDTA.

Valid If Run in Human Laboratory?

Yes

CBC/BIOCHEMISTRY/URINALYSIS

- Serum phosphorus > 6 mg/dL.
- Low serum calcium in patients with primary hypoparathyroidism.
- High serum calcium in patients with vitamin D intoxication.
- Azotemia and isosthenuria help define degree of renal impairment.

- Hyperkalemia and hyponatremia suggest hypoadrenocorticism.

OTHER LABORATORY TESTS

- Serum PTH measurement—intact molecule and two-site assay methods have the greatest specificity; high-normal or high concentrations suggest primary hyperparathyroidism; low concentrations suggest neoplasia.
- Thyroxine concentrations—indicated in cats with hyperphosphatemia and clinical signs consistent with hyperthyroidism.
- Insulin-like growth factor 1 concentrations—indicated in dogs or cats with unexplained hyperphosphatemia and clinical signs consistent with acromegaly; IGF-1 concentrations are elevated in animals with hypersomatotropism.
- Vitamin D assays are not readily available.
- ACTH stimulation testing to confirm hypoadrenocorticism.

IMAGING

- Abdominal radiography to assess renal size and symmetry
- Renal ultrasonography to detect soft-tissue mineralization
- Thyroid scan to rule out hyperthyroidism
- Radiography of long bones to detect osteoporosis or neoplasia

DIAGNOSTIC PROCEDURES

Renal biopsy

TREATMENT

- Inpatient, because of the deleterious effects of hyperphosphatemia and the need for fluid therapy; consider severe hyperphosphatemia a medical emergency.
- Restrict dietary phosphorus.
- Normal saline is the fluid of choice.

MEDICATIONS

DRUG(S) OF CHOICE

Acute Hyperphosphatemia

- Dextrose (1 g/kg IV) and insulin (0.5 U/kg IV).
- Avoid phosphorus-containing fluids.

Chronic Hyperphosphatemia

- Oral administration of phosphorus binders (e.g., aluminum hydroxide or aluminum carbonate, 30–100 mg/kg/day PO with meals).

CONTRAINdications

N/A

ALTERNATIVE DRUG(S)

N/A

(CONTINUED)

FOLLOW-UP

PATIENT MONITORING

- Serum calcium every 12 hours.
- Renal function tests—urine output must be monitored, particularly if oliguric renal failure is suspected, in which case urine output should be measured carefully; oliguria cannot be determined unless the patient is fully hydrated.
- Hydration status—indicators of overhydration include increased body weight, increased central venous pressure, and edema (pulmonary or subcutaneous).

POSSIBLE COMPLICATIONS

- Hypophosphatemia resulting in hemolysis
- Soft tissue mineralization

MISCELLANEOUS

ASSOCIATED CONDITIONS

Hypocalcemia

AGE-RELATED FACTORS

Mild elevations in phosphorus may be normal in growing animals.

PREGNANCY/FERTILITY/BREEDING

N/A

SEE ALSO

- Hypoparathyroidism
- Renal Failure, Acute
- Renal Failure, Chronic

HYPERPHOSPHATEMIA

ABBREVIATIONS

- ACTH = adrenocorticotropin
- EDTA = ethylene diamine tetra-acetic acid
- IGF-1 = insulin-like growth factor I
- PTH = parathyroid hormone

H

HYPERTENSION, PORTAL

BASICS

DEFINITION

Portal pressure > 13 cm H₂O or 10 mm Hg

PATHOPHYSIOLOGY

- Causes—increased portal blood flow (arterialized system); increased resistance to portal blood flow, or a combination of factors.
- Portal vein—lacks valves; blood follows a path of least resistance.
- Increased Portal Flow—arterialization of portal circulation occurs in AV malformation or subsequent to increased hepatic resistance; causing retrograde blood flow into the valveless splanchnic portal circulation.
- Hepatofugal—portal splanchnic circulation away from the liver.

Increased Resistance Relative to the Liver

- Prehepatic: abdominal portion of portal vein.
- Hepatic: within the liver.
- Posthepatic: cranial to the liver: terminal hepatic veins, vena cava, heart, pericardium.

Intrahepatic Increase in Resistance

- Presinusoidal: within the portal tract.
- Sinusoidal: within sinusoid or space of Disse.
- Postsinusoidal: hepatic venular outflow tract causing a sinusoidal occlusion or Budd Chiari syndrome.
- Consequences—development of multiple acquired portosystemic shunts (APSS), abdominal effusion due to increased lymph formation, and predisposition to HE.
- APSS—collaterals connect the extrahepatic portal system to the caudal vena cava allowing hepatofugal flow in the valveless portal vein; develop within 1–2 months of acquired portal hypertension (PH).

Effusion Protein Content

- Hepatic causes—pure transudate reflects concurrent PH and hypoalbuminemia (protein < 1.5 g/dL).
- Posthepatic causes—modified transudate (protein > 2.5 g/dL).
- Prehepatic causes—often short-lived, pure or modified transudate, low cellularity reflects splanchnic lymph.

SYSTEMS AFFECTED

- Hepatobiliary disorders—obstructed blood flow in any zone or diffusely across sinusoids causes intrahepatic PH, splanchnic PH, ± passive splenic congestion (splenomegaly).
- Posthepatic disorders—hepatic passive congestion, hepatomegaly, and variable PH; APSS usually absent because of a lack of pressure differential between splanchnic portal vein and vena cava.
- Prehepatic disorders—cause splanchnic PH, splenic congestion (splenomegaly) and APSS; portal venous thrombi, stenosis, stricture, entrapment within porta hepatis (e.g., pancreatitis, neoplasia), mass compression (pancreatic inflammation; neoplasia).
- Nervous—HE due to APSS.

- Cardiovascular—APSS and ascites may develop with vena caval/hepatic vein obstruction (at the level of the diaphragm), but not with congestive heart failure or pericardial tamponade as these dually increase hydrostatic pressure in both hepatic and vena caval systems.
- Portal thrombi—caused by gastrointestinal inflammation/necrosis and splanchnic vasculitis, neoplasia, DIC, loss of anticoagulants, accelerated thrombosis.
- Gastrointestinal—splanchnic hypertension can provoke enteric edema, increased gut wall permeability provoking transmural bacterial translocation (endotoxemia, bacteremia), hypertensive enteric vasculopathy (enteric bleeding, ulceration), diapedesis blood loss, and protein malassimilation.

GENETICS

- Vascular malformations causing portal atresia (intrahepatic, prehepatic) are congenital and represent a severe phenotype of polygenic portal venous malformations in small-breed dogs (see Portosystemic Vascular Anomaly, Congenital).
- Ductal plate malformation (DPM): congenital hepatic fibrosis (CHF) phenotype causes APSS; these represent dysfunction of primary cilia; occur in numerous dog breeds and Persian related cats; increased frequency in Boxers; genetic cause and heritability not specifically studied in dogs; feline polycystin-1 precursor mutation has 15% occurrence.
- Non-cirrhotic PH: adult-onset diminution of tertiary portal branches, affects individual dogs of many breeds, described in Doberman pinschers (rare).
- Acquired sinusoidal PH due to necroinflammatory liver injury—immune-mediated chronic hepatitis (anecdotal in some breeds).
- Copper associated hepatopathy—Bedlington terrier *COMMD1* mutation, predisposition for copper associated hepatopathy in Labrador retrievers, Dalmatian, Doberman pinscher, and numerous other dogs may reflect pharmacogenetic breed differences in copper transporters (see Copper Associated Hepatopathy).

SIGNALMENT

Species

Dog > cat

Breed Predilections

Familial hepatic vascular disorders—Doberman pinschers (non-cirrhotic PH); Saint Bernard (AV malformation); Cocker spaniel hepatopathy; copper associated hepatopathy: Bedlington terriers, Doberman pinschers, Labrador retriever, others; ductal plate malformation (DPM)—congenital hepatic fibrosis (CHF) phenotype: Boxers predisposed, any large or small dog breed, and cats.

Mean Age and Range

- Juveniles—herited or congenital disorders; vena caval and cardiac malformations.
- Young dogs and cats < 1.5 years of age—

congenital hepatic vascular malformations with portal venous atresia: lack of microscopic portal vein tributaries or splanchnic portal vascular atresia, if PSVA are intolerant to surgical ligation and develop APSS; may be more common in Yorkshire terriers, Maltese, pugs, and cats.

- Juvenile and young adult dogs and cats—DPM with CHF phenotype.
- Young dogs and cats—hepatic AV malformations (rare), onset of signs < 1.5 years of age.
- Middle-aged and older animals—acquired hepatobiliary disorders and portal thrombi.

Predominant Sex

N/A

SIGNS

General Comments

- Depends on site, degree, and rate of onset of PH and causal factors.
- Acquired disorders—slowly progressive and chronic in onset.

Historical Findings

- Portal thromboembolism may acutely appear but remain unnoticed until APSS form; vague GI signs at occurrence including bloody diarrhea, ileus, abdominal pain, lethargy, and inappetence.
- Abdominal distention: ascites.
- HE—secondary to APSS.
- Cardiac disorders or pericardial restriction—cough; exercise intolerance; dyspnea, jugular pulse, weak femoral pulses or pulsus alternans, reduced heart sounds on auscultation.

Physical Examination Findings

- Abdominal effusion
- Hepatomegaly—posthepatic causes only
- Splenomegaly—reflects splanchnic congestion or venous thrombi, inconsistent
- Jugular vein distention—posthepatic cardiac or pericardial causes
- Muffled heart sounds—pericardial or pleural effusion
- Cardiac arrhythmias or murmur—cardiac disease
- Pulmonary “crackles” (edema)—cardiac or pericardial causes
- Confusion, stupor, coma, blindness, other neurobehavioral abnormalities—HE
- Jaundice—hepatic causes
- Hepatic bruit (hepatic AV malformation) (see Arteriovenous Malformation of Liver)
- Signs consequent to surgical ligation of PSVA (see Portosystemic Vascular Anomaly, Congenital)

CAUSES

Prehepatic

- Portal vein thrombosis, stenosis, or neoplasia
- Portal vein compression—large lymph nodes; neoplasia, granuloma; abscess; pancreatitis, entrapment in diaphragmatic hernia
- Postoperative complication of PSVA ligation, especially with ameroid constrictor
- Congenital portal vein atresia

Intrahepatic

- Hepatic fibrosis/cirrhosis
- Chronic inflammatory liver disease
- Chronic EHBDO > 6 weeks
- DPM: CHF phenotype
- Hepatic neoplasia—porta hepatis location
- Liver entrapment—in diaphragmatic hernia

(CONTINUED)

- Sinusoidal occlusion syndrome
- Veno-occlusive disease (zone 3 lesion), Budd-Chiari syndrome
- Non-cirrhotic portal hypertension
- Portal vein atresia (intra- or extrahepatic)
- Hepatic AV malformation

Posthepatic

- Right-sided congestive heart failure
- Heartworm disease
- Pericardial tamponade
- Pericarditis—restrictive or constrictive
- Cardiac neoplasia
- Cor triatriatum dexter
- Pulmonary TE
- Disorders affecting the supradiaphragmatic caudal vena cava—thrombosis; congenital kink or web; heartworm vena cava syndrome; occlusion by neoplasia; entrapment in diaphragmatic hernia

RISK FACTORS

Depend on underlying cause

**DIAGNOSIS****DIFFERENTIAL DIAGNOSIS**

- Physicochemical analysis of abdominal effusion—helps narrow diagnoses
- Pure transudate—hypoalbuminemia secondary to PLE, PLN, liver failure
- Modified transudate with normal or low albumin—PLE, PLN, liver failure (chronic effusion), neoplasia, splanchnic TE, liver (visceral) entrapment in diaphragmatic hernia
- Modified transudate with large liver and jugular distention—cardiac or pericardial abnormalities; heartworm; right atrial tumor
- Modified transudate with large liver without jugular distention, muffled heart, or pulmonary edema—kinked vena cava; Budd-Chiari-like or sinusoidal occlusion syndrome
- HE—liver fibrosis; cirrhosis; CHF; hepatic AV malformation; any cause of APSS
- Jaundice—chronic hepatitis, cholangitis; EHBD0; infiltrative hepatic neoplasm
- Bloody diarrhea, abdominal pain, ileus, signs of endotoxemia—acute splanchnic portal TE

CBC/BIOCHEMISTRY/URINALYSIS

- CBC—schistocytes with TE; RBC microcytosis with PSVA or APSS; icteric plasma with liver disease or microangiopathic shearing anemia (also show schistocytes).
- Biochemistry—liver disease associated with variable liver enzymes, low BUN, creatinine, cholesterol, and/or glucose concentrations, hyperbilirubinemia, and coagulation abnormalities; Posthepatic disorders associated with high liver enzymes, \pm azotemia, and normal plasma color.
- Urinalysis—ammonium biurate crystalluria with APSS; may note granular casts with TE affecting renal perfusion; may note proteinuria with heartworm disease.

OTHER LABORATORY TESTS

- TSBA—variable fasting and high 2-h postprandial concentrations with APSS or hepatobiliary disease; shunting pattern

(normal fasting and markedly high postprandial values) common.

- Blood ammonia—hyperammonemia with APSS or inferred by finding ammonium biurate crystalluria; ammonia tolerance testing and ammonia measurement less convenient and reliable compared to TSBA.

- Physicochemical characterization of abdominal effusion—high serum:effusion albumin ratio (> 1.1) consistent with PH.

IMAGING**Radiography**

- Thoracic radiography—may reveal cause of posthepatic PH (e.g., kinked vena cava, pericardial effusion, pulmonary disease, pleural effusion, diaphragmatic hernia).
- Abdominal radiography—may reveal effusion, splenomegaly, hepatomegaly (e.g., congestion, infiltrative neoplasia, or hepatic AV malformation); microhepatia in most hepatic disorders causing APSS and hepatic portal malformation associated with APSS (portal atresia).

Abdominal Ultrasonography

- Identify abnormalities involving the abdominal or extrahepatic portal vein: atresia, stricture, thrombi, occlusive lesions in porta hepatis.
- Identify lobe(s) containing AV malformations.
- Inspect splanchnic circulation using Doppler color flow; document hepatofugal circulation, identify portal thrombi (filling defects, abrupt flow termination), APSS (caudal to left kidney), or PSVA (interrogate vena cava for turbulent flow).
- Evaluate echogenicity of nonhepatic viscera; identify lymphadenomegaly, mass lesions (neoplasia), adhesions.
- Estimate hepatic venous distention—extrahepatic and supradiaphragmatic segments; may identify posthepatic causes of PH and sinusoidal occlusion syndrome.

Echocardiography

Detects congenital and acquired cardiac and pericardial disorders, neoplasia, thrombi, heartworms, pleural effusion, malformed or thrombosed vena cava, diaphragmatic hernia.

Angiography and Nuclear Imaging

- Colorectal or splenoportal scintigraphy—confirms PSS but not anatomic details.
- Radiographic angiography—celiac trunk and hepatic artery contrast studies confirm hepatic AV malformation; nonselective or selective studies—congenital cardiac disease, TE, hepatic vein disorders, AV malformation.
- Portovenography—confirm APSS.
- Multisector CT—high-quality characterization of regional vasculature; non-invasive; displays arterial and venous phases.

ADDITIONAL DIAGNOSTICS

- Electrocardiography and central venous pressure—with cardiac disease, cranial mediastinal obstructions.
- Liver biopsy—required for diagnosis of hepatobiliary

HYPERTENSION, PORTAL

disorders.

- Portal pressure—although may be measured during laparotomy is not recommended; unreliable in deducing underlying causes; PH blunted by APSS PH adequately confirmed with imaging studies and on gross inspection.

**TREATMENT****APPROPRIATE HEALTH CARE**

Inpatient—for severe HE, amelioration of tense ascites by therapeutic abdominocentesis, supportive care for acute TE.

NURSING CARE

- Fluid therapy—with all causes, restrict sodium concentration (avoid 0.9% NaCl); high likelihood of total-body sodium loading. Avoid iatrogenic pulmonary edema during fluid therapy (**caution:** if hypoalbuminemia).
- Monitor body weight and condition, girth circumference, plasma proteins, and PCV—assess hydration status, volume of abdominal effusion, and IV fluid tolerance.
- Low oncotic pressure—may require plasma or colloid administration (plasma preferred for liver patient); Voloven or VetStarch (6%; 130 MW/0.4 molar substitution) 10–20 mL/kg/day IV CRI) may be necessary for acute adjustments; avoid Hetastarch as can reduce platelet function.
- Glucose supplementation—with hepatic dysfunction and hypoglycemia; 2.5–5.0% dextrose with half-strength polyionic fluids initially; titrate dextrose concentration to achieve euglycemia (avoid hyperglycemia).

MOBILIZATION OF ASCITES

- *Abdominal effusion*—sequentially assess: body weight, girth, and body condition score; initially exercise restrict (improves renal perfusion, sodium and water elimination); enforce dietary sodium restriction.
- *Conventional diuretics*: combine furosemide and spironolactone; furosemide (0.5–2 mg/kg PO q12–24h) and spironolactone (0.5–2 mg/kg PO q12h, use a single doubled dose for loading one time): dose titrations based on response q4 days; adjust using incremental 25–50% dose increase. Spironolactone: potassium sparing; less potent than furosemide. Furosemide: potassium wasting, diuresis induces RAAS response. Serum:effusion albumin ratio (> 1.1) may predict response to diuretics.
- *Vasopressin V₂ antagonists* (aquaretics) may assist with management of diuretic resistant ascites. Tolvaptan successful in dogs with experimentally induced (rapid pacing) congestive heart failure. Human dose in cirrhosis is 7.5 mg/day; Tolvaptan is metabolized exclusively in the liver primarily by cytochrome P450; dose undetermined in dogs with liver disease.
- *Telmisartan*: angiotensin receptor blocker (ARB), nephro-protective in diabetes and renal injury

H

HYPERTENSION, PORTAL

(CONTINUED)

H in humans, also prevents effects of drug-induced hepatotoxicity and hepatic fibrosis) is an alternative diuretic worthy of consideration. ARBs selectively antagonize angiotensin-1 receptor bypassing intermediary activation steps within the RAAS cascade. Telmisartan administration PO in at 1.0 mg/kg/day significantly increased urine volume and sodium excretion in healthy dogs. • Taper diuretic dose after initial positive response; individualize chronic treatment to response; diuretics may be used intermittently to mobilize recurring ascites • Avoid dehydration as this can lead to HE. • Avoid hypokalemia as this can provoke HE. • If cardiac disease is the cause of ascites: treatment involves sodium restriction, enalapril, furosemide, newer diuretics described above. *Diuretic-resistant ascites*—large volume (therapeutic) abdominocentesis if ascites resistant to medical intervention or compromises food intake, ventilation, or sleep: requires aseptic technique, fluid removal over 45–90 minutes, concurrent polyionic fluid and/or colloids reduces risk for post-centesis hypotension and acute renal failure (ARF). Repeated large-volume fluid removal may result in: hypovolemia, hypoproteinemia, electrolyte depletion; iatrogenic infection; *postcentesis hypovolemia/hyperperfusion syndrome and ARF* (rapid redistribution of fluid into abdominal cavity). Use aseptic technique and concurrently provide polyionic fluids in moderation with colloids. General rule in humans: provide 4–8 g of albumin per L of ascites removed (consider colloids, discussed above). • If ascites fails to mobilize, consider measuring urine sodium output vs. sodium intake (dietary) to determine whether intake requires restriction or diuretics upward titration. Urine output should be measured over a minimum of 12 hours.

ACTIVITY

Depends on cause, restrict activity if ascites

DIET

• Ascites—restrict dietary sodium < 100 mg/100 kcal. • If HE—restrict dietary protein (see Hepatic Encephalopathy); **caution:** only restrict protein if nitrogen intolerance suspected.

CLIENT EDUCATION

Inform client that definitive diagnosis requires logical diagnostic strategies and no prediction for cure or chronic amelioration until definitive diagnosis is ascertained.

SURGICAL CONSIDERATIONS

• Ligation of APSS or vena caval banding strongly contraindicated. • If acute symptomatic PH after surgical ligation of PSVA—ligature removal imperative (see Portosystemic Vascular Anomaly,

Congenital). • Embolectomy of thrombi not recommended; emboli may recanalize with supportive care; clot dissolution (streptokinase, TPA) complicated, expensive, requires ICU hospitalization and monitoring, and warrants a grave prognosis. • LMW heparin (see Coagulopathy of Liver Disease). • Correction of chronic diaphragmatic hernia—release of entrapped viscera may provoke perioperative/postoperative endotoxemia, hypotension, shock, ARF. • Surgical correction and cure of cor triatriatum and kinked vena cava are possible. • Pericardectomy—pericardial restriction or tamponade; thoracoscopic procedure least invasive, with lowest mortality and best outcome. • Removal of tumor or fibrous adhesions causing hepatic vein occlusion may be difficult. • Removal (lobectomy) or embolization (acrylamide) of hepatic AV malformation may not be curative as microscopic intrahepatic AV shunting usually continues PH and APSS.

MEDICATIONS

DRUG(S) OF CHOICE

Treatment of abdominal effusion—sodium restriction (see above, “Diet”); combined diuretic therapy (spironolactone and furosemide), consider tolvaptan or telmisartan (see above), use large-volume paracentesis sparingly.

DIURETICS

(see above; mobilization of ascites)

CONTRAINDICATIONS

N/A

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

• Avoid drugs relying on first-pass hepatic extraction, biotransformation, or hepatic elimination; if not possible, adjust dosage based on available information. • Reduce dose of highly protein-bound drugs if patient hypoalbuminemic. • Avoid NSAIDs: these are metabolized in the P450 cytochrome-rich centrilobular regions where toxic adducts may provoke cell injury augmented by hypoxia, poor perfusion, sinusoidal occlusion, copper accumulation; NSAIDs may provoke ARF, sodium retention, and enteric bleeding that may augment HE.

ALTERNATIVE DRUG(S)

N/A

FOLLOW-UP

PATIENT MONITORING

- Sequentially monitor body weight, condition, and abdominal girth.

- Sequentially assess hydration, electrolytes, acid-base, and blood pressure as necessary.
- Monitor: albumin and glucose—with liver disease or APSS. • Monitor lung sounds, pulse oximetry, and ventilatory effort—in cardiovascular disorders.

POSSIBLE COMPLICATIONS

- Thrombosis • Endotoxemia • Hypotension
- Hepatic encephalopathy • Acute renal failure

EXPECTED COURSE AND PROGNOSIS

Depends on cause

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Chronic liver disease • Numerous disorders may cause prehepatic or posthepatic portal hypertension.

PREGNANCY/FERTILITY/BREEDING

Affects uterine perfusion and likely leads to abortion or stillbirths.

SEE ALSO

- Ascites • Cirrhosis and Fibrosis of the Liver
- Congestive Heart Failure, Right-Sided
- Hepatic Encephalopathy • Pericarditis
- Portosystemic Shunt, Acquired
- Portosystemic Vascular Anomaly, Congenital

ABBREVIATIONS

- ARF = acute renal failure • APSS = acquired portosystemic shunt(s) • ARB = angiotensin receptor blocker • AV = arteriovenous • CRI = constant rate infusion
- EHBDO = extrahepatic bile duct obstruction • HE = hepatic encephalopathy
- PH = portal hypertension • PLE = protein-losing enteropathy • PLN = protein-losing nephropathy • PSS = portosystemic shunting • PSVA = portosystemic venous anomaly • TE = thromboembolism • TPA = tissue plasminogen activator • TSBA = total serum bile acids

Author Sharon A. Center

Consulting Editor Sharon A. Center

HYPERTENSION, PULMONARY

BASICS

DEFINITION

Peak systolic pulmonary artery (PA) pressure > 30 mmHg and/or peak diastolic PA pressure > 15 mmHg

PATOPHYSIOLOGY

- Causes of elevated PA pressure:
 - (1) pulmonary arterial vasoconstriction,
 - (2) pulmonary arterial obstruction, (3) high left atrial pressure with resultant pulmonary venous and arterial hypertension, (4) excessive pulmonary blood flow.
 • As a result of pulmonary hypertension (PHTN) right heart pressures increase to maintain pulmonary blood flow. May result in right ventricular dysfunction and decreased pulmonary blood flow. Decreased pulmonary blood flow interferes with filling of the left heart which can lead to decreased cardiac output. High right heart pressures can cause venous congestion, tricuspid regurgitation, and R-CHF.

SYSTEMS AFFECTED

- Cardiovascular—see Pathophysiology
- Hepatobiliary—R-CHF may cause hepatic congestion and dysfunction
- Respiratory—Associated pulmonary disease; R-CHF may cause pleural effusion.

GENETICS

- No specific genetic basis found.
- Causes of primary disease (congenital heart disease—CHD, left heart disease, pulmonary disease) may have a genetic basis.

GEOGRAPHIC DISTRIBUTION

Unknown; likely higher prevalence in heartworm-endemic areas and at high altitudes.

SIGNALMENT

Species

Dogs and cats

Breed Predilections

- Possibly based on underlying cause of PHTN
- Increased incidence in the terrier breeds has been suggested.

Predominant Sex

Increased incidence in female is reported

SIGNS

General Comments

Signs due to hypoxia and cardiac dysfunction

Historical Findings

- Exercise intolerance
- Dyspnea/tachypnea
- Coughing/hemoptysis
- Syncope
- Abdominal distention
- Weight loss
- Lethargy
- Sudden death

Physical Examination Findings

- Dyspnea/tachypnea
- Coughing
- Hemoptysis
- Loud and/or split-second heart sound
- Pulmonary crackles and/or harsh bronchovesicular sounds
- Cyanosis

- Heart murmur
- Abdominal distention
- Jugular distention
- Subcutaneous edema
- Weight loss

CAUSES

Primary/Idiopathic/Familial PHTN

Etiology

- Primary congenital disorders of the pulmonary vasculature identified in humans.
- Abnormalities in endothelial derived vasodilatory/vasoconstrictor substances result in vascular obstruction and vasoconstriction.
- Not reported in companion animals.

Pulmonary Parenchymal Disease

Etiology

- *Vascular obstruction*—resulting from pulmonary lesions (e.g. fibrosis, neoplasia), vascular hypertrophy/inflammation
- *Vasoconstriction*—reactive vascular constriction secondary to hypoxia and acidemia
- *Causes:*
 - Pneumonia (bacterial, viral, fungal, parasitic)
 - Chronic bronchitis
 - Pulmonary fibrosis
 - Eosinophilic bronchitis
 - Pulmonary neoplasia
 - Acute respiratory distress syndrome

Pulmonary Thromboembolism (PTE)

Etiology

- *Vascular obstruction*—secondary to thrombus
- *Vasoconstriction*—secondary to hypoxia and vasoconstrictive substances released from the thrombus
- *Causes:*
 - Hyperadrenocorticism
 - Protein-losing nephropathy/enteropathy
 - Sepsis
 - Immune-mediated hemolytic anemia
 - Neoplasia
 - Pancreatitis
 - Endocarditis
 - Disseminated intravascular coagulation
 - Primary cardiac disease (typically right heart disease)

Heartworm Disease (HWD)

Etiology

- *Vascular obstruction*—vascular hypertrophy, inflammation, thromboembolism, and presence of heartworms
- *Vasoconstriction*—secondary to hypoxia/thrombi

Congenital Heart Disease (CHD) with Left-to-Right Shunting

Etiology

- *Excessive pulmonary blood flow* due to left-to-right shunting results in damage to pulmonary vasculature
- *Vasoconstriction/vascular obstruction*—result of vascular damage and vascular hypertrophy
- *Causes:*
 - Patent ductus arteriosus
 - Ventricular septal defect
 - Atrial septal defect

Left Heart Disease

Etiology

- *High left atrial pressure*—results in pulmonary venous and arterial hypertension
- *Vasoconstriction/vascular obstruction*—result of elevated pressure and vascular hypertrophy
- *Causes:*
 - Mitral regurgitation
 - Cardiomyopathy (dilated, hypertrophic, restrictive, unclassified)
 - Mitral stenosis
 - Congenital pulmonary venous obstruction (e.g., cor triatriatum sinister)
 - Left atrial tumors

Extrapulmonary Causes of Chronic Hypoxia

Etiology

- *Vasoconstriction*—some environmental/extrapulmonary factors result in hypoxia and acidemia leading to pulmonary vasoconstriction and secondary vascular hypertrophy
- *Causes:*
 - Hypoventilation (Pickwickian syndrome, neuromuscular disorders)
 - High altitude disease

RISK FACTORS

- Cardiac and pulmonary disease
- Heartworm disease
- Diseases causing hypercoagulability
- Obesity
- High altitude

DIAGNOSIS

H

DIFFERENTIAL DIAGNOSIS

- Left-sided congestive heart failure (L-CHF)*
- Collapsing trachea
- R-CHF*
- Primary pulmonary disease*
- HWD*
- Pneumothorax
- Pleural effusion (pyothorax, chylothorax, hemothorax, hydrothorax)
- Laryngeal paralysis/disease *without concurrent PHTN

CBC/BIOCHEMISTRY/URINALYSIS

- Polycythemia can be seen due to hypoxemia
- Leukocytosis seen with infectious lung disease
- Possible evidence of hypercoagulability

OTHER LABORATORY TESTS

- Arterial blood gases (hypoxemia)
- Occult heartworm test
- Workup for causes of PTE (urine protein:creatinine ratio, antithrombin III level, D-dimer, coagulation profile, urine cortisol:creatinine ratio, ACTH stimulation test, dexamethasone suppression test)
- Cytology of effusions

IMAGING

Radiography

- Dilated pulmonary artery and/or tortuous pulmonary vessels
- Right ventricle and atrial enlargement
- Dilated caudal vena cava
- Pleural effusion
- Hepatomegaly
- Ascites
- Evidence of primary pulmonary disease, PTE, or HWD

Echocardiography

- RV concentric/eccentric hypertrophy
- Flattening of the interventricular septum and/or paradoxical septal motion
- RA dilation
- PA dilation
- Pleural/pericardial effusion
- Evidence of left heart disease, HWD, CHD, or PTE
- Asymmetric and notched pulmonary outflow envelope/tracing

Echocardiographic Assessment of PHTN Severity

- Tricuspid valve regurgitation (TR): if present without pulmonic stenosis or pulmonary artery stenosis, the TR gradient estimates systolic PHTN severity.
- *Systolic pressure gradient* between the RV and RA: estimated with spectral Doppler using the

HYPERTENSION, PULMONARY

(CONTINUED)

modified Bernoulli equation: $4 \times (\text{peak TR velocity})^2$. • Pressure gradient > 35 mmHg (TR velocity $\geq 3.0 \text{ m/s}$) suggestive of PHTN. • Gradient determines severity: mild: 35–50 mmHg, moderate: 51–80 mmHg, severe > 80 mmHg. • Pulmonary valve insufficiency (PI): if PI is present without pulmonary artery stenosis the PI gradient estimates diastolic PHTN severity. • *Diastolic pressure gradient* between the pulmonary artery and the RV: estimated with spectral Doppler using the modified Bernoulli equation: $4 \times (\text{peak PI velocity})^2$. • Pressure gradient > 15 mmHg (PI velocity > 2.0 m/s) suggestive of PHTN.

CT Scan/MRI

May be of diagnostic value if pulmonary neoplasia or other infiltrative diseases

DIAGNOSTIC PROCEDURES

Transtracheal wash, bronchoscopy/bronchoalveolar lavage, or lung aspirate/biopsy may be of value if evidence of primary pulmonary disease

Electrocardiography

- Right mean electrical axis deviation
- Deep S waves leads I, II, III, and aVF
- Widening of QRS complex
- P-pulmonale
- ST segment depression/elevation
- Hypoxia-induced arrhythmias (VPCs)

Cardiac Catheterization and Pulmonary Angiography

- The gold standard of diagnosis
- Uncommonly performed due to risk and usefulness of echocardiography
- Indicated if necessary to confirm diagnosis or cause

PATHOLOGIC FINDINGS

- Dependent on underlying disease and severity:
 - Primary pulmonary lesions
 - PTE
 - Dilated PA/RV/RA/vena cava
 - Heartworms
 - Pleural/pericardial/abdominal effusions
 - Medial hypertrophy, intimal proliferation, and sclerosis of pulmonary vasculature
 - Necrotizing arteritis

TREATMENT

APPROPRIATE HEALTH CARE

- Hospitalize patients in severe respiratory distress
- Medical therapy as described below
- Perform diagnostics based on patient stability

NURSING CARE

- Judicious fluid therapy may be of benefit to improve pulmonary bloodflow
- Risk of CHF must be considered
- Maintain low-stress environment

CLIENT EDUCATION

- Prognosis varies with reversibility of the underlying disease, but generally very guarded
- Avoid environments that may predispose to respiratory distress—heat/humidity extremes, second-hand smoke, high altitudes

SURGICAL CONSIDERATIONS

Surgical heartworm extraction is a consideration in patients with severe infestation

MEDICATIONS

DRUG(S) OF CHOICE

- Treat the primary underlying disease process whenever possible
- The ideal therapeutic agent for PHTN causes pulmonary vasodilation without causing significant systemic hypotension

Oxygen

- Treatment of choice, but long-term administration not feasible
- Useful in acute setting to correct hypoxia and cause vasodilation

Phosphodiesterase Type V Inhibitor (PDE5 inhibitor)

- Inhibit the breakdown of cGMP causing increased nitric oxide and pulmonary vasodilation
- Avoid other drugs with similar effects (nitrates)
- Sildenafil—drug of choice for most causes of PHTN in dogs
- Tadalafil—one published study suggests benefit in dogs
- Vardenafil—not evaluated in companion animals

Other Vasodilators

- Limited benefit due to concurrent systemic vasodilation and hypotension
- Important in management of PHTN resulting from left heart disease
- ACE inhibitors, hydralazine, and calcium channel blockers

Phosphodiesterase Type III Inhibitor (PDE3 inhibitor)

- Pimobendan
- Causes pulmonary and systemic vasodilation
- Indicated if PHTN secondary to left heart disease
- Unclear if useful with other causes of PHTN

Bronchodilators

- May benefit patients with pulmonary disease
- Sympathomimetics (e.g., terbutaline) and methylxanthines (e.g., theophylline)
- Methylxanthines may also cause mild pulmonary arterial vasodilation

Anticoagulant Therapy

- In humans, common therapy for all causes of PHTN due to primary and/or secondary thromboembolism
- Use in companion animals unclear except in patients with PTE

Thrombolytic Therapy

- Streptokinase and t-PA indications and effectiveness debated in companion animals
- Likely only indicated if acute PTE with significant cardiac compromise

Anti-inflammatory and Antibiotic Therapy

- Steroids may be of benefit if cause of the PHTN has an inflammatory component (e.g., heartworm disease, some cases of primary pulmonary disease)
- Antibiotics indicated if suspect bacterial component

CONTRAINDICATIONS

- Respiratory depressants
- Cardiac myocardial depressants (e.g., beta-blockers)
- Bronchoconstrictors (e.g., nonspecific beta-blockers)
- Vasoconstrictors

PRECAUTIONS

- Vasodilators can cause systemic hypotension
- Bronchodilators can cause tachycardia and hyperexcitability
- Hypovolemia may result in depressed pulmonary blood flow

FOLLOW-UP

PATIENT MONITORING

- Serial echocardiography to assess improvement/progression
- Repeat thoracic radiographs, ECG, laboratory work, blood pressure as needed

POSSIBLE COMPLICATIONS

- Right-sided heart failure
- Syncope
- Arrhythmias
- Sudden death

EXPECTED COURSE AND PROGNOSIS

- Based on ability to reverse underlying disease
- In general, very guarded prognosis

MISCELLANEOUS

ABBREVIATIONS

- ACE = angiotensin-converting enzyme
- ACTH = adrenocorticotrophic hormone
- CHD = congenital heart disease
- CT = computed tomography
- ECG = electrocardiogram
- HWD = heartworm disease
- L-CHF = left-sided congestive heart failure
- MRI = magnetic resonance imaging
- PA = pulmonary artery
- PHTN = pulmonary hypertension
- PI = pulmonary valve insufficiency
- PTE = pulmonary thromboembolism
- RA = right atrium
- R-CHF = right-sided congestive heart failure
- RV = right ventricle
- TR = tricuspid valve regurgitation

BASICS

DEFINITION

Sustained elevation in systolic or diastolic (or both) arterial blood pressure. In dogs and cats, systolic BP > 160 mmHg or diastolic BP > 120 mmHg obtained by any method is considered abnormal. BP elevation may be transient and related to measurement artifact (stress-induced or white-coat effect), or sustained and pathologic. In veterinary patients, HT is usually due to another disease process and is termed secondary hypertension. If an underlying disease is not present or cannot be determined, the terms primary, essential or idiopathic HT are used.

PATHOPHYSIOLOGY

- Arterial BP is the product of cardiac output and systemic vascular resistance; cardiac output is determined by HR and stroke volume.
- BP regulation depends on integration of complex mechanisms within the central and peripheral nervous systems, renal and cardiac tissues, and humoral factors, which synergistically affect cardiac output and vascular resistance.
- Baroreceptors in the carotid sinus and aortic arch respond to changes in BP; a fall in BP increases sympathetic discharge, causing vasoconstriction and increased cardiac contractility and HR.
- Humoral substances that modulate BP include catecholamines, vasopressin, kinins, renin, angiotensin, aldosterone, prostaglandins, and atrial natriuretic peptide.
- Primary HT is not fully understood in veterinary patients, but some cases have a hereditary component.
- Secondary HT is most commonly associated with chronic kidney disease and endocrinopathies in dogs and cats.
- HT may also occur secondary to fluid therapy, vasoconstricting drugs, steroid administration, or erythropoietin therapy.
- Persistent elevation of BP causes tissue injury and is termed target organ damage (TOD).

SYSTEMS AFFECTED

- Cardiovascular
- Nervous
- Ophthalmic
- Renal/Urologic

GENETICS

Colonies of hypertensive dogs have been produced by mating dogs with essential HT; mode of inheritance not known.

INCIDENCE/PREVALENCE

- Varies with criteria for HT and method of measurement.
- Dogs: prevalence of HT in chronic kidney disease (9–93%; most studies support a rate of 25%), hyperadrenocorticism (73–80%), diabetes mellitus (24–46%).
- Cats: prevalence of HT in chronic kidney disease (19–65%), hyperthyroidism (9–23%).

SIGNALMENT

Species

Dog and cat

Breed Predilections

None

Mean Age and Range

- Usually older dogs and cats.
- Younger animals may be affected if renal disease due to infection (e.g., leptospirosis) or heritable disease (e.g., polycystic renal disease, dysplasia).

CLINICAL SIGNS AND FINDINGS

- Ocular: acute blindness, intraocular hemorrhage, dilated pupils, exudative retinal detachment, retinal vessel tortuosity, retinal perivasculär edema, papilledema, retinal degeneration (late).
- Neurologic: depression, head tilt, seizures, nystagmus, paresis, ataxia, circling, disorientation.
- Renal: polyuria/polydipsia associated with progression of chronic renal disease, hematuria, proteinuria.
- Cardiovascular: murmur, gallop rhythm, cardiomegaly, rarely CHF, epistaxis.

CAUSES

Primary or Essential

Not known; familial in some dogs

Secondary

- Accounts for most cases in dogs and cats
- Renal disease—tubulointerstitial or glomerular disease, amyloidosis, polycystic kidney disease, dysplasia
- Hyperadrenocorticism
- Hyperthyroidism
- Diabetes mellitus—less common
- Pheochromocytoma—less common
- Hyperaldosteronism—less common
- Central nervous system disease—less common

RISK FACTORS

Underlying renal disease or endocrinopathy

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cardiovascular—hypertrophic cardiomyopathy, thyrotoxic heart disease, aortic stenosis, arterial thromboembolic disease.
- Ophthalmic—ocular trauma, systemic infections (bacterial, fungal, viral), coagulopathies, vasculopathy.
- Neurologic—primary brain, spinal cord, or peripheral nerve disease.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC: usually normal; decreased PCV with severe chronic renal disease; increased PCV with hyperadrenocorticism.
- Biochemistry profile: azotemia, hyperphosphatemia, hypokalemia (renal insufficiency); hyperglycemia (diabetes mellitus); high ALP (hyperadrenocorticism); increased ALT (hyperthyroidism); hypokalemia (hyperaldosteronism).
- Urinalysis: proteinuria (glomerulonephritis, amyloidosis, hyperadrenocorticism); hematuria; poor urine concentrating ability (renal insufficiency,

hyperadrenocorticism); glucosuria (diabetes mellitus).

OTHER LABORATORY TESTS

- Glomerulonephropathy—increased urine protein:urine creatinine ratio (> 0.5 in dogs, > 0.4 in cats), decreased creatinine clearance.
- Renal dysfunction—decreased creatinine clearance.
- Hyperadrenocorticism—exaggerated ACTH response test, failure to suppress with dexamethasone, increased urine cortisol:creatinine ratio.
- Hyperthyroidism (cats)—increased T₄, inadequate suppression with a T₃ suppression test.
- Hypothyroidism (dogs)—decreased T₃, T₄, free T₃, free T₄; possibly increased T₃ and T₄ auto-antibodies, increased endogenous TSH.
- Pheochromocytoma—increased urinary catecholamine metabolites.
- Hyperaldosteronism—increased plasma aldosterone.

IMAGING

- Echocardiography to evaluate hypertensive heart disease (findings include left ventricular free wall and/or interventricular septal hypertrophy, diastolic dysfunction, or normal structure and function).
- Thoracic radiography to evaluate secondary cardiac changes (typically mild cardiomegaly without CHF).
- Abdominal radiography to evaluate liver, adrenals, and kidneys.
- Abdominal ultrasonography to evaluate kidneys, liver, adrenal glands, and bladder.
- CT or MRI scan if brain tumor, hemorrhage, hyperadrenocorticism suspected.
- Thyroid scintigraphy to evaluate hyperthyroidism.

DIAGNOSTIC PROCEDURES

Definitive diagnosis of HT requires documentation of high arterial BP via direct or indirect methods in the population at risk. There is no evidence that BP should be measured in all animals. Although correlation with direct BP measurements may vary, indirect measurements in the appropriate clinical population are invaluable in the treatment of HT and prevention of TOD.

Direct (Invasive)

Considered the gold standard, but seldom performed on an outpatient basis in awake animals; reserved for intraoperative monitoring or emergency management of severe HT.

Indirect (Non-invasive)

- Indirect BP measurement is easily performed in a clinical setting, and are most commonly obtained with oscillometric or Doppler techniques, depending on the size of the animal.
- An inflatable cuff is wrapped around an extremity; the width of the cuff should be approximately 30–40% (cats) or 40% (dogs) of the circumference of the limb or tail at the site of placement. The cuff should be at or near the level of heart when

HYPERTENSION, SYSTEMIC

(CONTINUED)

measuring BP. • A cuff that is too small will result in a falsely high BP measurement, while too large a cuff will result in a falsely low measurement. • An average of 5–7 measurements should be obtained for the BP session; discard the first measurement. • A permanent record of the BP measurement session should include: technique used, cuff size, limb used, time of day, time of medication, animal's disposition, and operator name. • Consistent techniques yield more reliable results. Interpret results in light of the animal's excitement level during the procedure and repeat if results are questionable.

Oscillometric Technique

- Oscillometric technique (Cardell, Memoprint, PetMap) detects pulse pressure oscillations beneath the cuff bladder that result from changes in arterial diameter.
- Place the animal in lateral or sternal recumbency in a calm environment. Place the artery arrow marker on the cuff on the caudomedial aspect of forearm (or proximal to the carpus with arrow pointed medially), over the dorsomedial metatarsal region (or distal to the tarsus) or on the ventral aspect of the tail in a snug position. The machine can inflate the cuff automatically with display of systolic, diastolic, and mean BP and the heart rate.
- The oscillometric technique is not as reliable as the Doppler method for animals with fast heart rates, very small arteries, or muscle tremors. However, a recent study showed that high definition oscillometry is accurate in cats. In both cats and dogs, the oscillometric devices tend to underestimate BP by increasing amounts as pressure increases.

Doppler Technique

- Doppler flow meters (Parks, Vet-Dop, Jorgensen) detect blood flow as a change in the frequency of reflected sound (Doppler shift) due to the motion of underlying red blood cells. For measurements taken from the front limb, a pneumatic cuff is wrapped snugly around the forearm above the carpus. An aneroid manometer connects to the occluding cuff. The Doppler transducer is placed over the median artery on the ventral aspect of the forepaw, between the metacarpal and carpal pads (distal to the cuff). The hair between the pads should be moistened to remove air pockets prior to applying the transducer with gel. Shaving the area is not necessary. • After inflating the cuff to 30–40 mmHg higher than the expected systolic pressure, the cuff is deflated at approximately 3–4 mmHg/sec. An audible blood flow signal is heard by the operator and denotes systolic BP. • The major limitation of the Doppler technique is the imprecise discrimination of the sounds designating the diastolic, and therefore mean, pressures. • The Doppler technique is the preferred method of BP measurement in cats.

PATHOLOGIC FINDINGS

- Arteriolar hypertrophy, tunica media vasorum hyperplasia, and destruction of the internal elastic lamina layer; vascular damage in the eye, kidney, cardiovascular and nervous system tissues leads to hemorrhage, thrombosis, edema, and necrosis.
- Ventricular hypertrophy develops in response to an increased workload.

TREATMENT

Treatment Guidelines for Dogs and Cats

- In order to reduce the risk of TOD, BP should ideally be reduced to a systolic BP < 150 mmHg and a diastolic BP < 100 mmHg. • The ACVIM Hypertension Consensus Panel and International Renal Interest Society have recommended that treatment for high BP be based on classifications of the patient which depends upon both reliable BP measurements and knowledge of TOD. • Antihypertensive treatment is indicated in any dog or cat with a sustained systolic BP > 200 mmHg or a diastolic BP > 120 mmHg, regardless of other clinical findings. • In both species, any animal with clear evidence of ongoing TOD generally should be considered a candidate for antihypertensive therapy. • Animals with no clinical signs and mildly elevated BP should not be treated.

APPROPRIATE HEALTH CARE

Usually managed on an outpatient basis. Inpatient care may be necessary depending upon the underlying condition (e.g., fluid therapy with renal failure) or serious complications related to HT (e.g., neurologic signs or acute retinal hemorrhage).

ACTIVITY

No restrictions unless acute blindness present

DIET

- Influenced by underlying cause; sodium restriction is controversial since it will activate the renin-angiotensin aldosterone axis. Sodium restriction alone is unlikely to lower BP. • Avoid high salt intake.

CLIENT EDUCATION

- Unless underlying cause is curable (e.g., hyperthyroidism) or controllable (e.g., hyperadrenocorticism), the patient is likely to be on antihypertensive medication for life.
- Alert owners to TOD of uncontrolled HT (e.g., retinal hemorrhage, retinal detachment, progressive renal impairment, cardiac disease, neurologic signs).

SURGICAL CONSIDERATIONS

May be indicated for hyperthyroidism, pheochromocytoma, hyperaldosteronism, and some forms of hyperadrenocorticism.

MEDICATIONS

DRUG(S) OF CHOICE

- Treat underlying cause if possible, although HT may persist even if underlying disease is well controlled.
- Cats—amlodipine is first-line oral drug, with an ACE inhibitor added if proteinuria (UPC > 0.4) is present.
- Dogs—ACE inhibitor (e.g., enalapril, benazepril) is first-line drug due to frequency of underlying proteinuria (UPC > 0.5), with amlodipine added as second drug if necessary.
- Spironolactone and hydralazine may be added to the antihypertensive regime if ACE inhibitors and amlodipine are ineffective in lowering BP to < 150 mmHg.
- In a hypertensive emergency, parenteral hydralazine, sodium nitroprusside, or labetolol can be used. Continuous direct BP monitoring is necessary.

Dihydropyridine Calcium Channel Blockers

- Lower peripheral vascular resistance by vasodilation.
- T_{1/2} of amlodipine is 30 hours in dogs, so this is a drug for chronic, not acute, management of HT.
- Amlodipine—dogs, 0.1–0.5 mg/kg PO q24h; cats, 0.625–1.25 mg/cat PO q24h.

ACE Inhibitors

- Lower peripheral vascular resistance and stroke volume by blocking the conversion of angiotensin I to angiotensin II; renoprotection; decrease vascular remodeling.
- Enalapril—dogs, 0.5 mg/kg PO q12h; cats, 0.25–0.5 mg/kg PO q12h.
- Benazepril—dogs and cats, 0.5 mg/kg PO q12h.

Angiotensin Receptor Blockers (ARBs)

- Blocks the activation of angiotensin II AT₁ receptors and directly causes vasodilation, reduces secretion of vasopressin, and reduces production and secretion of aldosterone.
- Telmisartan—dogs, 1.0 mg/kg PO q24h.

Direct-Acting Vasodilators

- Lower peripheral vascular resistance.
- Hydralazine—dogs, 0.5 mg/kg PO q12h, with a stepwise increase to 3 mg/kg PO q12h if needed. Caution if high-dose amlodipine also used.

Alpha-Receptor Antagonists

- Most commonly used with beta-receptor antagonists in cases of pheochromocytoma.
- Phenoxybenzamine—dogs, 0.25 mg/kg PO q12h; cats, 2.5 mg/cat PO q12h.

Diuretics

- Spironolactone—dogs and cats, 1–2 mg/kg PO q12h; primarily used for antialdosterone effects to limit fibrosis; weak diuretic.
- Furosemide—dogs, 2–4 mg/kg PO q12h; cats, 1–2 mg/kg PO q12h; not routinely used in antihypertensive therapy.

(CONTINUED)

Beta-Receptor Antagonists

- Lower HR and cardiac output and suppress renin secretion.
- Blocks the effects of excess thyroid hormone, although additional drugs are needed to control BP.
- Rarely used in dogs unless pheochromocytoma present.
- Propranolol—dogs, 0.2–1 mg/kg PO q8h; cats, 2.5–5 mg/cat PO q8–12h.
- Atenolol—dogs, 0.25–1 mg/kg PO q12h; cats, 6.25–12.5 mg/cat PO q12h.

CONTRAINDICATIONS

Taper or discontinue steroids, vasoconstricting drugs (e.g., phenylpropanolamine).

PRECAUTIONS

- Arterial vasodilators can cause reflex tachycardia; rapidly acting drugs and multiple vasodilators used together increase the risk of hypotension and acute renal failure.
- Beta blockers may worsen bronchiolar disease, CHF, conduction disturbances (e.g., second- and third-degree AV block).
- High volume IV fluid therapy increases BP.

POSSIBLE INTERACTIONS

- Combinations of drugs increase risk of hypotension.
- Hyperkalemia may result from ACE inhibitors and spironolactone, especially with underlying renal disease.

ALTERNATIVE DRUG(S)

In a hypertensive emergency, hydralazine (0.2 mg/kg SC or IM), sodium nitroprusside (1–5 µg/kg/min up to 10 µg/kg/min CRI), or labetolol (0.25 µg/kg q10min; 20–30 µg/kg/min CRI) can be used. Continuous direct BP monitoring is necessary.

**FOLLOW-UP****PATIENT MONITORING**

- BP measurements of < 150/100 are the treatment goal, although systolic BP < 160 mmHg is reasonable and will minimize risk of TOD.
- BP and hypertensive complications (especially retinopathy) should be checked weekly until BP is controlled.

- Laboratory tests to measure side effects of medications and clinical disease response (e.g., proteinuria, hematuria, anemia, thrombocytopenia, potassium balance, sodium balance, azotemia, albumin).

POSSIBLE COMPLICATIONS

- CHF (rare).
- Glomerulonephropathy (proteinuria, hematuria).
- Renal failure.
- Retinopathy (hemorrhage, detached retina).
- Cerebral vascular accident (various central nervous system signs).
- Gingival hyperplasia may develop with amlodipine treatment in dogs.

EXPECTED COURSE AND PROGNOSIS

- Dictated by underlying cause of HT.
- BP can be controlled with appropriate/combined therapy in most patients, but antihypertensive therapy does not necessarily improve survival time.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Chronic renal disease, endocrinopathies

ZOONOTIC POTENTIAL

None, unless Leptosirosis determined to cause renal disease and HT

PREGNANCY/FERTILITY/BREEDING

Pregnancy is a high volume state, and would be expected to make HT more severe.

AGE-RELATED FACTORS

Chronic renal disease, hyperthyroidism, and hyperadrenocorticism—more common in older animals.

H

HYPERTHYROIDISM

BASICS

DEFINITION

A pathologic, sustained, high overall metabolism caused by high circulating concentrations of thyroid hormones.

PATHOPHYSIOLOGY

- Hyperthyroidism in cats is most often caused by autonomously hyperfunctioning nodules of the thyroid gland that secrete T_4 and T_3 , uncontrolled by normal physiologic influences (e.g., TSH secretion); one or both lobes of the thyroid gland can be affected.
- Rare cases of feline hyperthyroidism (1–2%) are caused by hyperfunctioning thyroid carcinoma. • Extremely uncommon in dogs, it has been seen in some dogs with thyroid carcinoma (most dogs with thyroid gland neoplasia are euthyroid) and in dogs with oversupplementation of exogenous thyroid hormone.

SYSTEMS AFFECTED

- Behavioral. • Cardiovascular—myocardial hypertrophy and hypertension.
- Gastrointestinal—chronic cellular malnutrition, decreased gastrointestinal transit time, malabsorption, and hepatocellular damage. • Musculoskeletal—cachexia.
- Nervous. • Renal/Urologic—high GFR may mask underlying chronic renal failure, possible hyperfiltration injury, and decreased urine-concentrating ability.

GENETICS

No known genetic predisposition

INCIDENCE/PREVALENCE

- Most common endocrine disease of cats; one of the most common diseases in late middle-aged and old cats; true incidence is unknown, but diagnosis of the disease is increasing. In the United Kingdom, overall prevalence is 2–3%, with 9% prevalence in cats over 10 years old. • Rare in dogs.

SIGNALMENT

Species

Cat and (rarely) dog

Mean Age and Range

Mean age in cats, approximately 13 years; range 4–22 years. Uncommon in cats less than 6 years old.

SIGNS

General Comments

- Multisystemic; reflect the increase in metabolism. • Less than 10% of patients are referred to as “apathetic”; these cats exhibit atypical signs (e.g., poor appetite, anorexia, depression, and weakness).

Historical Findings

- Weight loss • Polyphagia • Vomiting
- Diarrhea • Polydipsia • Tachypnea
- Hyperactivity • Dyspnea • Aggression

Physical Examination Findings

- Large thyroid gland—70% of patients are affected bilaterally
- Poor body condition
- Heart murmur • Tachycardia • Gallop rhythm
- Unkempt appearance • Thickened nails

CAUSES

- Cats—autonomously hyperfunctioning nodules; rarely, thyroid carcinoma.
- Dogs— T_4 or T_3 secretion by a thyroid carcinoma or iatrogenic due to oversupplementation of thyroxine.

RISK FACTORS

- Some reports have linked feline hyperthyroidism to canned food diets.
- Recent studies have implicated endocrine disruptor toxins (e.g., PBDEs) as possible causes of feline hyperthyroidism, but this has not been proven. • Advancing age increases risk. • Risk may be decreased in purebred cats.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

The clinical signs of feline hyperthyroidism can overlap with those of chronic renal failure, chronic liver disease, and neoplasia (especially intestinal lymphoma); they can be excluded based on routine laboratory findings and thyroid function tests.

CBC/BIOCHEMISTRY/URINALYSIS

- Erythrocytosis (mild) and, less commonly, leukocytosis, lymphopenia, and eosinopenia—stress response associated with high T_3 and T_4 . • High ALT activity—common. • High ALP, LDH, AST, BUN, creatinine, glucose, phosphorus, and bilirubin—less common; caused by more severe complications of hyperthyroidism.

OTHER LABORATORY TESTS

- Serum total T_4 concentration (TT_4)—measures protein-bound and free (unbound) T_4 ; high resting concentration confirms the diagnosis of hyperthyroidism. • Serum total T_3 concentration—not reliable. • Free T_4 (FT_4) by equilibrium dialysis—sometimes useful to diagnose mild or early hyperthyroidism in cats with normal resting serum TT_4 concentrations. • In theory, FT_4 more accurately reflects true thyroid gland secretory status, but some cats with non-thyroidal illness exhibit unexplained elevations in FT_4 ; do not use FT_4 alone as a screening test. • T_3 suppression test—useful to diagnose mild hyperthyroidism (see Appendix II for protocol and interpretation).
- TRH stimulation test—useful to diagnose mild hyperthyroidism (see Appendix II for protocol and interpretation).

IMAGING

- Thoracic radiography and echocardiography may be useful in assessing the severity of

myocardial disease. • Dogs—thoracic radiography to detect pulmonary metastasis. • Cats—abdominal ultrasound may be useful to explore underlying renal disease. • Thyroid gland scintigraphy can be used to diagnose hyperthyroidism (thyroid-to-salivary gland ratio is increased in most cases) and to determine the location of abnormal thyroid tissue (mediastinal or sublingual ectopic disease is found in nearly 4% of cases).

DIAGNOSTIC PROCEDURES

- Treatment of hyperthyroidism can significantly decrease renal function; pursue any abnormal value revealed by CBC, serum biochemical testing, or urinalysis by bacterial culture of the urine, abdominal radiography, and ultrasonography of the urinary tract.
- Can measure GFR by plasma disappearance of iohexol or ^{99m}Tc -DTPA in cats with suspected underlying renal disease. Contrary to some reports, concentrated urine (specific gravity > 1.035) does not decrease the risk of post-treatment renal insufficiency. • Indirect blood pressure measurement may be useful in pretreatment assessment and monitoring of therapy.

PATHOLOGIC FINDINGS

- Adenomatous hyperplasia of one or both lobes of the thyroid gland • Carcinoma in dogs and 1–2% of cats

TREATMENT

APPROPRIATE HEALTH CARE

- Outpatient management usually suffices for cats, if antithyroid drugs are used.
- Radioiodine treatment and surgical thyroidectomy require inpatient treatment and monitoring. • Rare cases of overt congestive heart failure require emergency inpatient intensive care.

ACTIVITY

No alterations recommended

DIET

- Resolution of thyrotoxicosis obviates the need for modifications. • Poor absorption of many nutrients and high metabolism suggest the need for a highly digestible diet with high bioavailability of protein in untreated hyperthyroidism. • A commercial iodine-deficient diet (Hill's y/d) has been advocated for treatment of hyperthyroidism, but studies of disease control and long-term outcomes are lacking.

CLIENT EDUCATION

- Inform clients of adverse effects of antithyroid drugs (see below) and surgical complications. • Clients should be aware of possible (rare) recurrence after treatment.

SURGICAL CONSIDERATIONS

- Surgical thyroidectomy is one recommended treatment for hyperthyroidism

(CONTINUED)

in cats. • Surgical treatment of thyroid carcinoma (dogs and cats) is usually not curative, but can be palliative.

MEDICATIONS

DRUG(S) OF CHOICE

• Radioiodine therapy is arguably the safest and most effective treatment. • Methimazole (Tapazole) is most often recommended (5–15 mg/day divided q8–12h). • Methimazole can be given transdermally (compounded in PLO gel). Resolution of thyrotoxicosis takes longer with transdermal than with oral methimazole. • β -adrenergic blocking drugs—sometimes used to treat some of the cardiovascular and neurologic effects of excess thyroid hormone; can be used in combination with methimazole; mainly used to prepare the patient for surgical thyroidectomy or radioiodine therapy. Atenolol is useful for controlling tachycardia.

PRECAUTIONS

- Antithyroid drugs have several side effects.
- Anorexia and vomiting are common side effects of methimazole; rare side effects include self-induced excoriation of the face, thrombocytopenia, bleeding diathesis, agranulocytosis, serum antinuclear antibodies, and hepatopathy. • Side effects usually develop within the first 3 months of treatment and may or may not necessitate drug cessation and alternative treatment (depending on severity). • Bleeding, jaundice, and agranulocytosis necessitate immediate withdrawal of the drug. • With the exception of vomiting, side effects can occur with transdermal methimazole as well.

ALTERNATIVE DRUG(S)

- Carbimazole—another useful antithyroid drug; not available in the United States.
- Propylthiouracil—can be useful if methimazole is unavailable; adverse effects may be more common and more severe than with methimazole. • Iopodate—a radiographic contrast agent; can be used at 15 mg/kg PO q12h to treat some cases of mild hyperthyroidism, but not effective in most hyperthyroid patients; long-term effectiveness has not been established.

FOLLOW-UP

PATIENT MONITORING

- Methimazole (and other antithyroid drugs)—physical examination, CBC (with platelet count), serum biochemical analysis, and serum T_4 determination every 2–3 weeks for the initial 3 months of treatment; adjust the dosage to maintain serum T_4 concentration in the low-normal range.

- Surgical thyroidectomy—watch for development of hypocalcemia and/or laryngeal paralysis during the initial postoperative period; measure serum T_4 concentrations in the first week of surgery and every 3–6 months thereafter to check for recurrence. • Radioiodine—measure serum T_4 concentrations 2 weeks after treatment and every 3–6 months subsequently. • Renal function—GFR declines following treatment in most patients; therefore, perform a physical examination, serum biochemistry, and urinalysis 1 month after treatment and then as indicated by the clinical history.

POSSIBLE COMPLICATIONS

- Untreated disease can lead to congestive heart failure, intractable diarrhea, renal damage, retinal detachment (as a result of hypertension), and death. • Complications of surgical treatment include hypoparathyroidism, hypothyroidism, and laryngeal paralysis.
- Hypothyroidism can occur following radioiodine therapy and during treatment with antithyroid drugs. Evidence suggests that iatrogenic hypothyroidism is associated with decreased renal function and decreased survival.

EXPECTED COURSE AND PROGNOSIS

- Uncomplicated disease—prognosis is excellent; recurrence is possible and is most commonly associated with poor owner compliance with medical management; regrowth of hyperthyroid tissue is possible but uncommon after surgical thyroidectomy or radioiodine treatment. • Reported mean survival time in cats treated with radioiodine is 4 years; mean survival time with methimazole is 2 years; mean survival time of cats treated with radioiodine and methimazole is 5.3 years. • Cats with pre-existing renal disease have a poorer prognosis. Renal failure is the most common cause of death in hyperthyroid cats. • Dogs or cats with thyroid carcinoma—prognosis is poor; treatment with radioiodine, surgery, or both is usually followed by recurrence of disease; adjuvant chemotherapy is of questionable benefit.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- In cats with underlying renal disease (either secondary to chronic hypertension or unrelated to thyroid disease), the prognosis is less favorable. • Renal insufficiency may not become apparent until euthyroidism has been established; for this reason, a reversible form of treatment (i.e., antithyroid drugs) is recommended if renal disease is suspected in a cat with hyperthyroidism. Recent studies show the most significant post-treatment decline in GFR occurs during the first month post-treatment, so 30 days should be sufficient

HYPERTHYROIDISM

time for a trial with antithyroid drugs prior to use of a more permanent treatment for hyperthyroidism. • In some patients, hyperthyroidism might be best left untreated.

SYNOMYNS

HYPERTROPHIC OSTEODYSTROPHY

BASICS

DEFINITION

An inflammatory disease of bone that affects rapidly growing giant- and largebreed puppies.

PATHOPHYSIOLOGY

- Characterized by non-septic, suppurative inflammation within metaphyseal trabeculae of long bones.
- Rapidly growing bones more severely affected (distal radius, ulna, and tibia).
- Metaphyses—widened owing to perimetaphyseal swelling and bone deposition.
- Trabecular microfracture and metaphyseal separation—occur adjacent and parallel to the physis.
- Bone formation defective.
- Ossifying periostitis—may be extensive.
- Etiology unknown.

SYSTEMS AFFECTED

- Gastrointestinal—diarrhea.
- Musculoskeletal—symmetrical distribution; distal forelimbs most severely affected; may note soft tissue mineralization in other organs; widened costochondral junctions.
- Respiratory—interstitial pneumonia.

GENETICS

Suspect hyperreactivity to immune stimulation (vaccination)

INCIDENCE/PREVALENCE

Low

GEOGRAPHIC DISTRIBUTION

Northeastern United States—highest in fall; lowest in winter

SIGNALMENT

Species

Dog

Breed Predilections

- Large- and giant- breeds.
- Great Danes; Weimaraners—most common.
- Reported—Irish wolfhounds; Saint Bernards; Kuvaszes; Irish setters; Doberman pinschers; German shepherds; Labrador retrievers; boxers; Chesapeake Bay retriever; golden retriever; Irish setter; others.

Mean Age and Range

- Affects puppies 3–6 months old
- Range of onset—2–8 months of age

Predominant Sex

Males 2.3 times more than females

SIGNS

General Comments

Lameness—may be episodic; degree varies from mild to non-weight-bearing; initial episode may resolve with or without relapse.

Historical Findings

- Depend on severity of the episode.
- Owners often describe a depressed puppy that is reluctant to move.
- Inappetence—common.
- Painful.
- Shifting leg lameness.

Physical Examination Findings

- Lameness—symmetrical, more severe in forelimbs
- Metaphyses—painful; warm; swollen distal metaphyses of radius, ulna, and tibia
- Pyrexia—as high as 41.1°C (106°F)
- Inappetence
- Depression
- Weight loss
- Dehydration
- Diarrhea
- Cachexia
- Debilitation
- Manifestations of systemic illness—respiratory or gastrointestinal
- Foot pad hyperkeratosis
- Anemia

CAUSES

Unknown; the following hypotheses have been proposed.

Metabolic

- Hypovitaminosis C—discounted; may be seen as a result of overuse of available vitamin C in hyperactive bone formation.
- Hypocuprosis—in rats but not in dogs.

Nutritional

- Overnutrition and oversupplementation—association inconsistent.
- Incomplete occurrence in litters.
- Correcting diet does not always alter the course of the disease or eliminate relapses.

Infectious

- Bacterial or fungal organisms—may be secondary when found.
- Not transmissible.
- Temporal association with canine distemper virus vaccination.
- Secondary development may depend on the timing of the neonate's exposure.

RISK FACTORS

Vaccination against canine distemper virus may precipitate an uncontrolled inflammatory reaction in the osteogenic centers.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Panosteitis—no metaphyseal swelling; cottony intramedullary densities in long bones on radiographs.
- Septic metaphysitis/epiphysitis—radiographs of the extremities not typical of hypertrophic osteodystrophy; asymmetrical; may note septic suppurative inflammation on needle aspiration of metaphyseal/epiphyseal

lesions; hematologic findings implicate bacterial infection (neutrophilia plus left shift).

- Elbow dysplasia—no metaphyseal swelling; no fever; pain localized to the elbow(s); typical radiographic signs.
- Osteochondritis dissecans—no metaphyseal swelling or fever; pain localized to shoulder or elbow; subchondral defects on radiographs.
- Septic polyarthritis—septic suppurative inflammation on arthrocentesis; culture.
- Non-septic polyarthritis—non-septic suppurative inflammation on arthrocentesis.

CBC/BIOCHEMISTRY/URINALYSIS

- Do not positively contribute to diagnosis
- Stress leukogram
- Normal serum parameters
- Hypocalcemia uncommon

OTHER LABORATORY TESTS

N/A

IMAGING

- Distal extremity radiographs—irregular radiolucent zones within metaphyses, parallel and adjacent to physes; flared metaphyses; extraperiosteal new bone extending up the diaphyses; mineralization of peri-metaphyseal soft tissues; asynchronous growth in paired bones; cranial bowing; valgus deformity; usually bilaterally symmetric.
- Vertebrae, metacarpal bones, metatarsal bones, ribs, scapula, humerus, and mandible—rarely affected.
- Thoracic radiographs—may reveal interstitial infiltrates.

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Distal metaphyses of the radius and ulna—most severe changes; similar abnormalities in all long bones.
- Gross—wide metaphyses; peripheral mineralization; soft tissue swelling.

Histologic

- Non-septic suppurative inflammation of the metaphysis (osteochondritis), especially adjacent to growth plates.
- Necrosis and probable secondary failure of osseous tissue deposition onto the calcified cartilage lattice of the primary spongiosa.
- Trabecular microfractures and impaction.
- Mineralization of peri-metaphyseal soft tissues and soft tissues in other regions of the body.
- Interstitial pneumonia.

TREATMENT

APPROPRIATE HEALTH CARE

- None specific.
- Supportive—from none to intensive care for severely affected puppies.

(CONTINUED)

- Depends on the severity of the episode, pyrexia, and the patient's ability to maintain normal hydration and willingness to eat.

NURSING CARE

- Some patients will not stand or move—prone to develop pressure sores; turn every 2–4 hours to prevent sores and hypostatic congestion of the dependent lung.
- Intravenous fluid therapy—for dehydration; maintenance fluid thereafter.

ACTIVITY

- Restricted—running and jumping may exacerbate metaphyseal injury and result in further inflammation.
- Confine to a small well-padded area—recommended.
- Leash-walking only.

DIET

- Normal commercial puppy ration
- Avoid supplements

CLIENT EDUCATION

- Warn the client of the disease's relapsing nature.
- Inform client that bony deformities will remodel to some degree with time but that bowing and valgus deformations are permanent.
- Warn client that the more severe the disease, the more severe the bowing deformity.

SURGICAL CONSIDERATIONS

- None specific.
- May implement surgical methods of alimentation (pharyngostomy tube, esophagostomy tube, gastrostomy tube)—in debilitated puppies that will not eat or drink and have frequently relapsing episodes of acute clinical signs.
- Corrective osteotomy if growth deformity develops from physeal disruption.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Anti-inflammatory drugs—for pain and antipyretic effects; may try:
 - Aspirin (10 mg/kg PO q12h)
 - Carprofen (2.2 mg/kg IM or PO q12h)
 - Firocoxib (5 mg/kg PO q24h)
 - Etodolac (10–15 mg/kg PO q24h)
 - Deracoxib (1–2 mg/kg PO q24h)
(3–4 mg/kg PO q24h, 7-day limit)
 - Meloxicam (dogs, load 0.2 mg/kg PO, then 0.1 mg/kg PO q24h; cats, 0.1 mg/kg PO q24h—liquid)
 - Tepoxalin (load 20 mg/kg, then 10 mg/kg PO q24h).
- Analgesics—can be used in conjunction with anti-inflammatory medication.

- Tramadol (1–4 mg/kg PO q8–12h)
- Prednisone 0.5–1 mg/kg PO q24h); may cause physeal growth disturbances.
- Opiates may be needed in severe cases.

CONTRAINdications

Vitamin C—may be contraindicated; may accelerate dystrophic calcification and decrease bone remodeling.

PRECAUTIONS

- Avoid immunosuppressive drugs if secondary infection is present.
- NSAIDs—may cause gastric ulceration; watch for hematemesis or melena; NEVER use in conjunction with other NSAIDs or steroids.

POSSIBLE INTERACTIONS

None

ALTERNATIVE DRUG(S)

None

**FOLLOW-UP****PATIENT MONITORING**

Signs of improvement—less metaphyseal sensitivity; patient gets up; appetite improves; pyrexia resolves.

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

- Cachexia
- Permanent bowing deformities
- Secondary bacterial infection
- Pressure sores
- Muscle fasciculations, seizure—with hypocalcemia
- May see secondary septicemia
- Recurrence
- Death

EXPECTED COURSE AND PROGNOSIS

- Course—days to weeks.
- Most patients—one or two episodes and recover.
- Some patients—seem to have intractable relapsing episodes of pain and pyrexia; rarely die or are euthanized.
- Prognosis—usually good; guarded with multiple relapses or complicating secondary problems.
- Persistent bowing deformity—eliminates many purebred puppies from the show ring.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

None proven

AGE-RELATED FACTORS

Vaccination (canine distemper virus)

ZOONOTIC POTENTIAL

None

PREGNANCY/FERTILITY/BREEDING

Occurs only in juveniles

SYNOMYS

- Metaphyseal osteopathy
- Vitamin C deficiency
- Scurvy
- Moller Barlow's disease
- Osteodystrophy II

SEE ALSO

- Elbow Dysplasia
- Osteochondrosis
- Panosteitis

ABBREVIATION

NSAID = nonsteroidal anti-inflammatory drug

H

HYPERTROPHIC OSTEOPATHY

BASICS

OVERVIEW

- Disease of the distal extremities resulting from peripheral blood flow changes which stimulate an overgrowth of vascular connective tissue and subsequent periosteal proliferation.
- Pathogenesis—speculative; Increased blood circulation in the limb due to neural or humoral mechanisms are likely secondary to an underlying disease process—most notably intra-thoracic or intra-abdominal neoplasia. Predominately affects the diaphyseal region of long bones and distal extremities (distal phalanges, metacarpals, and metatarsals).
- A primary form occurs in humans (Marie's disease).

H

SIGNALMENT

- More common in dog than cat.
- Age of highest frequency—8 years; coincides with the peak incidence of neoplasia.
- Mean age—5.6 years; dogs with non-neoplastic lung lesions.

SIGNS

Historical Findings

- Chronically or acutely lame and painful in one or more limbs.
- Reluctance to move.
- Enlargement of the distal portion of the extremities.
- Respiratory clinical signs if intrathoracic disease present (rare).

Physical Examination Findings

- Lame, sore, and pain noted in distal extremities.
- Distal extremities—enlarged, firm, taut, thickened; not edematous.
- Firm swelling may extend proximally with progression of disease.

CAUSES & RISK FACTORS

- Primary and metastatic neoplasia: lung tumors, esophageal sarcoma, rhabdomyosarcoma, adenocarcinoma of the adrenal gland, liver or prostate, nephroblastoma, renal cell carcinoma, thoracic and abdominal mesotheliomas.
- Non-neoplastic conditions: pneumonia, lung abscess/granulomas, dirofilariasis; congenital or acquired heart disease, bronchial foreign bodies; *Spirocercus lupi* infestation of the esophagus; focal lung atelectasis.
- Obscure toxins, hypertension, hyperestrogenism, congenital idiopathic megaesophagus.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Osteomyelitis—asymmetrical; generally edematous; lytic bone lesions; history of penetrating trauma or systemic infection.
- Metastatic neoplasia—asymmetrical.
- Hypervitaminosis A (feline)—asymmetrical; generally involves joint surface.

- Hypertrophic osteodystrophy—metaphyseal abnormality, young dogs.
- Multiple cartilaginous exostosis—metaphyseal abnormality, young dogs.
- Degenerative joint disease.

CBC/BIOCHEMISTRY/URINALYSIS

- Depends on the underlying cause.
- Serum ALP—nonspecific elevation

OTHER LABORATORY TESTS

- Fecal examination—rule out gastrointestinal and respiratory parasitism.
- Ultrasound—helps identify and differentiate primary lesions.

IMAGING

- Radiographs of affected long bones—bilaterally symmetric extensive, aggressive or nonaggressive periosteal new bone formation on diaphyseal regions; periosteal reaction project outward from the cortex and perpendicular to the long axis (palisade-like); periosteal new bone forms around the entire circumference of the bone; joints not affected.
- Radiographs of the thoracic and abdominal cavities—identify underlying cause.
- Abdominal ultrasound—identify underlying cause.

DIAGNOSTIC PROCEDURES

Bone biopsy and culture (bacterial and fungal)—necessary only in atypical cases to rule out neoplasia and osteomyelitis.

TREATMENT

- Directed at underlying primary cause—may involve surgical resection of mass or treatment of underlying primary condition.
- Options in selected cases—unilateral vagotomy on the side of a lung lesion or bilateral cervical vagotomy; incising through parietal pleura; subperiosteal rib resection.

MEDICATIONS

DRUG(S)

- Depends on underlying cause.
- Analgesics—as needed.

FOLLOW-UP

PATIENT MONITORING

Condition indicates other disease processes—important to identify the primary cause.

EXPECTED COURSE AND PROGNOSIS

- Clinical signs may resolve with treatment of underlying disease.
- Bony changes may take several months to regress.

- Prognosis—guarded to poor due to the common occurrence of neoplastic causes.
- Tumor recurrence or metastasis may occur and osteopathy may return.
- No relationship between size, site, or histologic type of primary lesion and the development of or recurrence of hypertrophic osteopathy postoperatively.

MISCELLANEOUS

SYNOMYMS

- Hypertrophic pulmonary osteopathy/osteoarthropathy (HPO/HPOA)
- Hypertrophic osteoarthropathy (HOA)

ABBREVIATION

- ALP = alkaline phosphatase

HYPERTROPHIC PYLORIC GASTROPATHY, CHRONIC

BASICS

DEFINITION

Pyloric stenosis or chronic hypertrophic pyloric gastropathy is an obstructive narrowing of the pyloric canal resulting from varying degrees of muscular hypertrophy or mucosal hyperplasia.

PATHOPHYSIOLOGY

- Can result from a congenital lesion composed primarily of hypertrophy of the smooth muscle or be one of three types of acquired form—primarily circular muscle hypertrophy (type 1), a combination of muscular hypertrophy and mucosal hyperplasia (type 2), or primarily mucosal hyperplasia (type 3).
- The cause is unknown; proposed factors include increased gastrin concentrations (which have a trophic effect on the muscle and mucosa) or changes in the myenteric plexus that lead to chronic antral distension and its associated effects.

SYSTEMS AFFECTED

- Gastrointestinal—chronic intermittent vomiting; regurgitation has also been reported.
- Musculoskeletal—weight loss.
- Respiratory—possible aspiration pneumonia.

GENETICS

Inheritance pattern unknown

INCIDENCE/PREVALENCE

Uncommon

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

- More common in dog
- Rare in cat

Breed Predilections

- Congenital—brachycephalic breeds (boxer, Boston terrier, bulldog); Siamese cats
- Acquired—Lhasa apso, Shih Tzu, Pekingese, poodle

Mean Age and Range

- Congenital—shortly after weaning (introduction of solid food) and up to 1 year of age.
- Acquired—9.8 years of age.

Predominant Sex

Twice as many males as females

SIGNS

General Comments

- Clinical signs are related to the degree of pyloric narrowing.
- Projectile vomiting is generally not a presenting complaint. Animals are generally in good body condition.

Historical Findings

- Chronic intermittent vomiting of undigested or partially digested food (rarely containing bile) often several hours after eating.
- Congenital lesions associated with clinical signs shortly after weaning.
- Frequency of vomiting increases with time.
- Lack of response to antiemetic agents or motility modifying agents.
- Occasional anorexia with weight loss.
- Regurgitation.

Physical Examination Findings

Most dogs are generally in good physical condition.

CAUSES

- Congenital or acquired
- May be influenced by infiltrative mural diseases
- Chronic elevations in gastrin concentrations
- Neuroendocrine factors may play a role

RISK FACTORS

Chronic stress, inflammatory disorders, chronic gastritis, gastric ulcers, and genetic predispositions influence the disease process in humans and may play a role in small animals.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Gastric neoplasia
- Gastric foreign body
- Granulomatous fungal disease (e.g., pythiosis)
- Eosinophilic granuloma
- Motility disorders
- Cranial abdominal mass—pancreatic or duodenal

CBC/BIOCHEMISTRY/URINALYSIS

- Findings vary, depending on the degree and chronicity of obstruction.
- Hypochloremic metabolic alkalosis (characteristic of pyloric outflow obstruction) or metabolic acidosis (or mixed acid-base imbalance).
- Hypokalemia.
- Anemia—if concurrent GI ulceration.
- Prerenal azotemia—if dehydration present.

OTHER LABORATORY TESTS

N/A

IMAGING

Abdominal Radiographs

Normal to markedly distended stomach.

Upper GI Barium Contrast Study

- May display a “beak” sign created by pyloric narrowing, allowing minimal barium to pass into the pyloric antrum.
- Retention of most of the barium in the stomach after 6 hours indicates delayed gastric emptying.

- Intraluminal filling defects or pyloric wall thickening.

Fluoroscopy

- Normal gastric contractility.
- Delayed passage of barium through the pylorus.

Abdominal Ultrasound

Measurable thickening of the wall of the pylorus and antrum.

DIAGNOSTIC PROCEDURES

Endoscopy—allows evaluation of the mucosa for ulceration, hyperplasia, and mass lesions; specimens can be obtained for histopathologic evaluation.

PATHOLOGIC FINDINGS

- Include focal to multifocal mucosal polyps, diffuse mucosal thickening, and pyloric wall thickening, with variable degree of pyloric narrowing.
- Changes range from hypertrophy of the circular smooth muscle to hyperplasia of the mucosa and associated glandular structures; a wide spectrum of inflammatory cell infiltration exists.

H

TREATMENT

APPROPRIATE HEALTH CARE

- Depends on severity of clinical signs.
- Patients should be evaluated and surgery scheduled at the earliest convenience.

NURSING CARE

- Appropriate parenteral fluids to correct any electrolyte imbalances and metabolic alkalosis or acidosis.
- Isotonic saline (with potassium supplementation) is the fluid of choice for hypochloremic metabolic alkalosis.
- Consideration of postoperative nutritional support is important.
- In severe cases treated with gastroduodenostomy or gastrojejunostomy, surgical placement of a jejunostomy tube for enteral nutrition may be advantageous.

ACTIVITY

Restrict

DIET

Highly digestible, low-fat—until surgical intervention is feasible.

CLIENT EDUCATION

- Surgical treatment is highly successful.
- If clinical signs recur postoperatively, more aggressive surgical procedures may be indicated.

SURGICAL CONSIDERATIONS

- Surgical intervention is the treatment of choice.
- Goals involve establishing a diagnosis with histopathologic samples, excising abnormal tissue, and restoring GI function with the least-invasive procedure.

HYPERTROPHIC PYLORIC GASTROPATHY, CHRONIC

(CONTINUED)

- Surgical procedures depend on the extent of obstruction—pyloromyotomy (Freder-Ramstedt), pyloroplasty (Heineke-Mikulicz or antral advancement flap), gastroduodenostomy (Billroth 1), gastrojejunostomy (Billroth 2).

**MEDICATIONS****DRUG(S) OF CHOICE**

- Antiemetics and motility modifiers are generally ineffective.
- H_2 -antagonists and proton pump inhibitors may provide symptomatic relief.

H**CONTRAINDICATIONS**

- Evidence of complete pyloric obstruction precludes the use of promotility drugs.
- Avoid anticholinergic agents because of their inhibitory effects on GI motility.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

N/A

**FOLLOW-UP****PATIENT MONITORING**

Postoperatively for recurrence of clinical signs because of poor choice of surgical procedure.

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

Postoperative surgical complications include recurrence of clinical signs, gastric ulceration, pancreatitis, bile duct obstruction, and incisional dehiscence with peritonitis.

EXPECTED COURSE AND PROGNOSIS

- 85% of dogs show good-to-excellent results with resolution of clinical signs upon proper surgical intervention.
- Poor prognosis if gastric neoplasia (especially adenocarcinoma) is an underlying cause.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Gastric ulceration

AGE-RELATED FACTORS

Intermittent vomiting in young brachycephalic breeds upon weaning is suggestive of congenital stenosis.

ZOONOTIC POTENTIAL

None

PREGNANCY/FERTILITY/BREEDING

High gastrin concentrations in pregnant females may predispose to development of the syndrome.

SYNONYMS

- Chronic hypertrophic antral gastropathy
- Hypertrophic gastritis
- Acquired antral pyloric hypertrophy
- Congenital pyloric stenosis

ABBREVIATION

GI = gastrointestinal

HYPERVISCOSITY SYNDROME

BASICS

OVERVIEW

- An assortment of clinical signs caused by high blood viscosity.
- Typically results from markedly high concentration of plasma proteins, although can result (rarely) from extremely high erythrocyte (polycythemia) or white blood cell count (leukemia).
- Most frequently seen as a paraneoplastic syndrome, often associated with multiple myeloma and other lymphoid tumors or leukemia.
- Total plasma protein may exceed 10 g/dL, with serum protein electrophoresis showing monoclonal gammopathy.
- Clinical signs caused by reduced blood flow through smaller vessels, high plasma volume, and associated coagulopathy.
- Systems affected include hemic/lymphatic/immune, ophthalmic, and nervous. In rare cases, pulmonary thromboembolism may occur.

SIGNALMENT

- Dogs more frequently affected than cats.
- No sex or breed predilections.
- More common in older animals due to increased incidence of malignancy.

SIGNS

Historical Findings

- No consistent signs
- Anorexia
- Lethargy
- Depression
- Polyuria and polydipsia
- Blindness, ataxia, and seizures
- Bleeding tendencies
- Respiratory distress

Physical Examination Findings

- Neurologic deficits, including seizures and disorientation.
- Tachycardia and tachypnea if congestive heart failure present owing to volume overload or pulmonary thromboembolism.
- Epistaxis or other mucosal bleeding.
- Hepatomegaly/splenomegaly/lymphadenopathy.
- Visual deficits associated with engorged retinal vessels, retinal hemorrhage or detachment, and papilledema.

CAUSES & RISK FACTORS

- Multiple myeloma and plasma cell tumors ($\text{IgM} > \text{IgA} > \text{IgG}$).
- Lymphocytic leukemia or lymphoma.
- Marked polycythemia ($\text{HCT} > 65\%$).

- Chronic atypical inflammation with monoclonal gammopathy (e.g., ehrlichiosis in dogs).
- Chronic autoimmune disease (e.g., systemic lupus erythematosus and rheumatoid arthritis)—very rare.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other unexplained neurologic disease or bleeding disorders.
- Hyperviscosity is a syndrome, not a final diagnosis.

CBC/BIOCHEMISTRY/URINALYSIS

- Nonregenerative anemia (in patients without polycythemia as a cause of hyperviscosity), thrombocytopenia, or leukopenia.
- Hyperproteinemia (total plasma protein $> 9 \text{ g/dL}$) and hyperglobulinemia ($> 5 \text{ g/dL}$).
- Azotemia and hypercalcemia if hyperviscosity caused by a paraneoplastic syndrome.
- Isosthenuria and marked proteinuria.

OTHER LABORATORY TESTS

- High concentration of IgG, IgA, or IgM, as detected by radial immunodiffusion.
- High plasma or serum viscosity (> 3 relative to water).
- Prolonged prothrombin time or activated partial thromboplastin time.
- Other testing as indicated by primary disease; polycythemia may be relative or absolute, and if absolute, due to hypoxemia (e.g., right to left cardiac shunt) or primary (polycythemia vera).

IMAGING

Hepatosplenomegaly, cardiomegaly, and osteolytic lesions (in association with multiple myeloma) are possible.

DIAGNOSTIC PROCEDURES

- Plasma cell or lymphoid infiltrate revealed by bone marrow biopsy.
- Bence-Jones proteinuria in patients with multiple myeloma.

TREATMENT

APPROPRIATE HEALTH CARE

- Generally treat as inpatient
- Treat underlying disease
- Phlebotomy (15–20 mL/kg) with crystalloid fluid volume replacement
- Plasmapheresis, either manual or automated

NURSING CARE

As dictated by underlying disease

MEDICATIONS

DRUG(S)

- Provide treatment for underlying neoplastic or inflammatory condition.
- See other chapters for drug therapy for the underlying cause (e.g., plasma cell tumor, lymphocytic leukemia, lymphoma, ehrlichiosis, and polycythemia).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Avoid use of medications that might increase vascular volume, including synthetic colloids (e.g., hetastarch); do not try to correct compensatory low albumin.
- Avoid medications that alter platelet function (e.g., NSAIDs).

H

FOLLOW-UP

- Monitor serum or plasma proteins frequently as a marker of treatment efficacy.
- CBC, biochemistry panel, and urinalysis to monitor other laboratory abnormalities.

MISCELLANEOUS

SEE ALSO

- Ehrlichiosis (Anaplasma)
- Leukemia, Chronic Lymphocytic
- Lymphoma—Cats
- Lymphoma—Dogs
- Multiple Myeloma

HYPHEMA

BASICS

DEFINITION

Blood inside the anterior chamber in the form of a blood clot, settled blood in the ventral anterior chamber, or red blood cells suspended throughout the aqueous, giving a "cherry Kool-Aid" appearance to the aqueous.

PATHOPHYSIOLOGY

- Breakdown of the blood-aqueous barrier and/or direct injury to the iris and ciliary body blood vessels. Causes include direct tissue trauma to the cornea or anterior uvea (iris and ciliary body); prostaglandin release from tissue trauma or inflammatory mediators such as infectious agents; and direct damage to blood vessel walls, as with systemic hypertension, antigen-antibody complexes, or circulating infectious organisms or neoplastic cells.
- Abnormal hemostasis due to a clotting deficiency or thrombocytopenia.
- Bleeding from abnormal vessels within the eye. This is most commonly due to pre-iridal fibrovascular membranes (PIFMs), which form in response to chronic intraocular disease (uveitis, retinal detachment, glaucoma, neoplasia). Rarely, abnormal congenital blood vessels in the eye such as persistent pupillary membranes, tunica vasculosa lentis, or hyaloid artery may bleed, causing hyphema.

SYSTEMS AFFECTED

Ophthalmic

INCIDENCE/PREVALENCE

Not an uncommon ophthalmic finding and one that is important to recognize, as it may be the presenting clinical sign for a serious underlying systemic disease.

SIGNALMENT

Species

Dog and cat

Breed Predilections

Collies with collie eye anomaly

SIGNS

Historical Findings—Primary Ophthalmic Causes

- Usually a unilateral presentation in an otherwise systemically normal patient.
- Blunt globe trauma will often have a history of hit by a car, periocular dog bite, or exposure to cattle or horses.
- Corneal perforation may have a history of a corneal ulcer with subsequent perforation; or preceding encounter with a cat resulting in a cat claw laceration, especially in puppies.

Historical Findings—Systemic Causes

- Unilateral or bilateral presentation; bilateral presentation is strongly supportive of a systemic etiology.
- Weight loss, anorexia, lethargy, and decreased vision or loss of vision may accompany some systemic causes.
- Ocular pain usually accompanies infectious and neoplastic causes due to the accompanying uveitis.

Physical Examination Findings—Primary Ophthalmic Causes

- Except in cases of generalized trauma (hit by car), the physical exam will be unremarkable with abnormalities restricted to the globe and periorbital soft tissues.
- Blunt trauma will have painful periorbital soft tissue swelling and uncommonly orbital rim fractures; there is often total hyphema obscuring other intraocular structures.
- Perforating trauma is associated with severe pain, a bloody or clear (aqueous) ocular discharge, varying degrees of hyphema, miosis, and anterior synechia, and a shallow anterior chamber; corneal edema will surround the perforation site and an iris prolapse may be present through the perforation.
- Hyphema due to PIFMs, retinal detachment, neoplasia, or congenital vasculature are usually non-painful with very

little intraocular inflammation (aqueous flare, miosis).

- Hypermature cataract supports the development of either PIFM or retinal detachment as a cause of the hyphema.

Physical Examination

Findings—Systemic Disease Causes

- When an underlying systemic disease is suspected, a thorough physical exam is warranted; depending on the systemic disease the physical exam may be unremarkable or have significant findings such as lymphadenopathy.
- Ophthalmic examination findings will vary depending on the etiology of the hyphema.
- Non-inflammatory etiologies such as hypertension, thrombocytopenia, and clotting disorders will usually have minimal discomfort and uveitis (trace or no aqueous flare, no miosis, no conjunctival hyperemia). Hypertension is almost always associated with retinal involvement such as retinal hemorrhages and/or retinal detachment.
- Clotting deficiencies may have bleeding elsewhere, including the subconjunctival tissue and retrobulbar space; thrombocytopenia may have petechia on the palpebral or nictitans conjunctiva. Infectious and neoplastic etiologies will often have significant pain, anterior uveitis (miosis, aqueous flare, fibrin, iridal hyperemia and swelling), chorioretinitis with retinal detachment, and possible secondary glaucoma.

CAUSES

See Table 1.

RISK FACTORS

- Ophthalmic: hypermature cataract, retinal detachment, chronic anterior uveitis.
- Systemic: any disease, disorder, or geographic location predisposing to the systemic diseases known to cause uveitis or direct vascular damage (e.g., chronic renal disease or hyperthyroidism predisposing to systemic hypertension).

Table 1

Causes of hyphema.	
Primary Ophthalmic Etiologies	Systemic Disease Etiologies
Trauma (blunt or perforating)	Hypertension
Extraocular vascular compression (choking, chest compression)	Hyperviscosity syndrome
Preiridal fibrovascular membrane	Thrombocytopenia
Retinal detachment	Clotting disorder
Primary intraocular neoplasia (iris melanoma, ciliary body adenoma/adenocarcinoma)	Metastatic neoplasia (especially lymphoma)
Golden retriever pigmentary uveitis	Rickettsial disease
Patent anomalous congenital blood vessels (persistent pupillary membranes, tunica vasculosa lentis, hyaloid artery)	FIP
	Fungal disease
	Prototheca
	Parasitic (aberrant intraocular larval migration)

(CONTINUED)

HYPHEMA**DIAGNOSIS****DIFFERENTIAL DIAGNOSIS**

Deep corneal vascularization, along the ventral limbus, can be mistaken for hyphema.

CBC/BIOCHEMISTRY/URINALYSIS

Abnormal findings may help support a systemic disease.

OTHER LABORATORY TESTS

Based on history and physical examination findings, clotting profile and serology (rickettsial, fungal) may be indicated if systemic disease is suspected.

IMAGING

- Ocular ultrasound is indicated to evaluate for retinal detachment or uveal tumors when not visible on the ophthalmic examination.
- Based on history and physical examination findings, thoracic radiographs, abdominal radiographs, and abdominal ultrasound may be indicated if systemic disease is suspected.

DIAGNOSTIC PROCEDURES

- Doppler blood pressure measurement if hypertension is suspected.
- Lymph node aspirates if lymphadenopathy is present or if neoplasia or fungal disease is suspected.

PATHOLOGIC FINDINGS

Gross hemorrhage in the anterior chamber.

**TREATMENT****APPROPRIATE HEALTH CARE**

Outpatient medical care is appropriate unless an underlying systemic disease is identified that requires hospitalization.

ACTIVITY

No restricted activity is required unless the patient is blind (restrict environment to fenced yards, no in-ground pools, leash walks, etc.) or the hyphema is due to thrombocytopenia or clotting disorder (avoid rough play, unrestricted running, etc.).

CLIENT EDUCATION

- Hyphema itself, although it appears dramatic, is not painful.
- It is very important to identify the underlying cause of the hyphema, as some etiologies pose a serious health threat.

- Ophthalmic treatment is important to initiate immediately to try to prevent painful and sometimes irreversible and blinding sequela like glaucoma.

SURGICAL CONSIDERATIONS

- Hyphema secondary to a perforating corneal laceration or ulceration should be surgically repaired by direct suturing of the cornea (laceration) or corneal graft (perforated ulcer) when a visual outcome is expected. For a severe perforation with extensive iris prolapse and loss of the pupil, enucleation is recommended.
- Permanently blind and painful eyes should be enucleated (with histopathology) for permanent comfort.
- Surgical irrigation/removal of the hyphema is not successful, as the trauma of the surgery results in exacerbation of the hyphema and intraocular inflammation.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Topical prednisolone acetate 1% or dexamethasone 0.1% q4–8h to help stabilize the blood-aqueous barrier; *do not use if a corneal ulcer or perforation is present*.
- Atropine 1% q6–24h to help prevent posterior synechia; *atropine is contraindicated if secondary glaucoma is present*.
- Systemic NSAID (carprofen, meloxicam, deracoxib) with perforating trauma for analgesia and to help stabilize the blood-aqueous barrier.
- Systemic prednisone/prednisolone with known or suspected choroidal/retinal involvement, *depending on the underlying cause*; anti-inflammatory dose (0.5–1.0 mg/kg PO q24h) can be used for blunt trauma, FIP, and rickettsial and fungal disease with proper antimicrobial therapy.
- Topical carbonic anhydrase inhibitors (dorzolamide 2%, brinzolamide 1%) q8h, beta-blocker (timolol 0.5%) q8–12h, and/or sympathomimetic (dipivefrin 0.1%) q8–12h can be used if secondary glaucoma is present.

CONTRAINDICATIONS

- Topical NSAIDs (e.g., flurbiprofen, diclofenac, ketorolac,) are generally considered contraindicated with hyphema.
- Topical prostaglandin analogues (latanoprost, travoprost, bimatoprost) are contraindicated in secondary glaucomas.

**FOLLOW-UP****PATIENT MONITORING**

- Tonometry should be used to monitor for secondary glaucoma, which lowers the prognosis for a visual outcome.
- Perform tonometry every 1–2 days if the IOP is high normal or greater, or if risk factors such as fibrin and/or posterior synechia are present.
- Perform tonometry weekly if the IOP is low, or if the hyphema and anterior uveitis are mild-moderate in severity.
- Tonometry is contraindicated with a corneal perforation.*

POSSIBLE COMPLICATIONS

Secondary glaucoma, posterior synechia/dyscoria, cataract formation, loss of vision, possible loss of the eye if the eye becomes permanently blind and painful.

EXPECTED COURSE AND PROGNOSIS

- If the underlying cause of the hyphema can be successfully treated, such as repair of a corneal laceration or control of hypertension, and intraocular damage is not extensive, the prognosis is good for complete resolution of the hyphema.
- If trauma to the eye is severe or if the underlying disease is not controlled, the hyphema will persist and blindness can result; no improvement in hyphema after 2 weeks following blunt trauma has a poor prognosis for return of vision.
- Hyphema caused by bleeding from PIFMs usually does not resolve or will resolve and recur.
- If the eye is painful due to a perforated globe or secondary glaucoma, with no reasonable hope of regaining vision, enucleation is recommended.

**MISCELLANEOUS****ABBREVIATIONS**

- CEA = collie eye anomaly
 - FIP = feline infectious peritonitis
 - IOP = intraocular pressure
 - NSAID = nonsteroidal anti-inflammatory drug
 - PIFM = pre-iridal fibrovascular membrane
- Author** Margi A. Gilmour
Consulting Editor Paul E. Miller

H

HYPOADRENOCORTICISM (ADDISON'S DISEASE)

BASICS

DEFINITION

- Hypoadrenocorticism is an endocrine disorder resulting from deficient production of glucocorticoids and/or mineralocorticoids.
- Primary hypoadrenocorticism is due to destruction of the adrenal cortices, typically resulting in glucocorticoid and mineralocorticoid deficiency.
- Addison's disease refers to a deficiency of both glucocorticoids and mineralocorticoids resulting from idiopathic (immune-mediated) primary hypoadrenocorticism.
- The term atypical hypoadrenocorticism has been applied to the subset of dogs with primary hypoadrenocorticism that present with normal electrolytes. Recent work, however, has demonstrated that most of these dogs are mineralocorticoid deficient and thereby may not be so atypical.
- Secondary hypoadrenocorticism results from pituitary ACTH insufficiency, resulting in inadequate glucocorticoid production by the adrenal cortices.

PATOPHYSIOLOGY

- Mineralocorticoid (aldosterone) deficiency results in a diminished ability to excrete potassium and retain sodium, disrupting sodium and potassium balance in the body.
- Sodium deficiency leads to diminished effective circulating volume. This then contributes to pathophysiologic changes and clinical abnormalities including prerenal azotemia, hypotension, dehydration, weakness, and depression.
- Hyperkalemia can contribute to clinical abnormalities including weakness, lethargy and anorexia. In combination with other electrolyte and metabolic derangements, it may result in myocardial toxicity as evidenced by bradycardia and various arrhythmias.
- Glucocorticoid (cortisol) deficiency contributes to the occurrence of anorexia, vomiting, diarrhea, melena, lethargy, and weight loss. Due to its role in glucose homeostasis hypocortisolemia predisposes to hypoglycemia. In addition, free water excretion is impaired.

SYSTEMS AFFECTED

- Gastrointestinal
- Musculoskeletal
- Cardiovascular
- Renal/Urologic
- Skin

GENETICS

A genetic basis has been determined in standard poodles, bearded collies and Leonbergers.

INCIDENCE/PREVALENCE

No exact figures available; considered uncommon to rare in dogs and very rare in cats.

SIGNALMENT

Species

Dog and cat

Breed Predilections

- Great Danes, rottweilers, Portuguese water dogs, standard poodles, bearded collies, Leonbergers, West Highland white terriers, Nova Scotia duck tolling retrievers and Wheaten terriers have increased relative risk. Golden retrievers and Chihuahuas have decreased relative risk.
- No predilection in cats.

Mean Age and Range

- Dogs—range, < 1 to > 12 years; median, 4 years; most are young to middle-aged
- Cats—range, 1–9 years; most are middle-aged

Predominant Sex

Female dogs are at an increased relative risk; no predilection in cats.

SIGNS

General Comments

Signs vary from mild and few in some patients with chronic hypoadrenocorticism to severe and life-threatening in an acute Addisonian crisis. Multiple organ systems may be involved; type and extent of involvement varies from case to case.

Historical Findings

- Dogs—lethargy, anorexia, vomiting, weakness, weight loss, diarrhea, waxing/waning course, previous response to therapy, shaking, PU/PD, melena
- Cats—lethargy, anorexia, weight loss, vomiting, waxing/waning course, previous response to therapy, PU/PD

Physical Examination Findings

- Dogs—depression, weakness, dehydration, collapse, hypothermia, slow CRT, melena, weak pulse, bradycardia, painful abdomen, hair loss
- Cats—dehydration, weakness, hypothermia, slow CRT, depression, weak pulse, bradycardia, colapse

CAUSES

- Primary hypoadrenocorticism—idiopathic (immune-mediated), mitotane overdose, trilostane overdose, granulomatous disease, metastatic tumors, fungal disease, coagulopathy
- Secondary hypoadrenocorticism—iatrogenic following withdrawal of long-term glucocorticoid administration, isolated ACTH deficiency, panhypopituitarism, pituitary or hypothalamic lesions

RISK FACTORS

N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Signs are nonspecific and are seen in other, more common medical disorders, particularly gastrointestinal and renal diseases.
- Although no signs are pathognomonic, a waxing and waning course and previous response to nonspecific medical intervention ("fluids and steroids") should alert the clinician to consider the diagnosis.

CBC/BIOCHEMISTRY/URINALYSIS

- Hematologic abnormalities may include anemia, eosinophilia, and lymphocytosis.
- The absence of a stress (glucocorticoid influence) leukogram in a patient that has been ill for a few days should prompt consideration of hypoadrenocorticism.
- Serum biochemical findings may include hyperkalemia, azotemia, hyponatremia, hypochloremia, decreased total CO₂, hyperphosphatemia, hypercalcemia, increased ALT, increased serum alkaline phosphatase, and hypoglycemia.
- Urinalysis often reveals impaired urine-concentrating ability and in some cases isothenuria. Some patients with isothenuria are also azotemic, potentially causing confusion with primary renal disease.
- Some patients with hypoadrenocorticism exhibit normal electrolyte levels (so-called atypical hypoadrenocorticism).

OTHER LABORATORY TESTS

- Definitive diagnosis is by demonstration of undetectable-to-low baseline serum cortisol concentrations that fail to increase appropriately following ACTH administration. We prefer to determine cortisol concentrations before and 1 hour after administration of synthetic ACTH IV (5 µg/kg in dogs, 0.125 mg in cats). Alternatively, ACTH gel can be given IM (2 U/kg in dogs, 10 U in cats). ACTH gel (usually 40 U/mL) is available from several compounding pharmacies. Based on a recent study performed in normal dogs, it was recommended determine serum cortisol concentrations at both 1 and 2 hours post-ACTH administration when using a compounded ACTH gel.
- In hypovolemic dehydrated animals, use synthetic ACTH IV or delay testing until after initial fluid administration is completed and tissue perfusion restored.
- If IV synthetic ACTH is used, the ACTH stimulation test can be performed during initial stabilization and treatment if dexamethasone is used since it does not cross-react with the cortisol assay.
- If prednisone, prednisolone, or hydrocortisone have been administered, these treatments must be discontinued, and the

(CONTINUED)

HYPOADRENOCORTICISM (ADDISON'S DISEASE)

ACTH stimulation test performed at least 24 hours after changing the glucocorticoid to dexamethasone.

- A recent study demonstrated that a resting cortisol concentration above 2 µg/dL would make hypoadrenocorticism very unlikely in a dog that had not recently received glucocorticoids. Please note that this cutoff is a guideline and may vary a little based on methodology of the cortisol assay used, as well as from laboratory to laboratory using the same methodology. Also, a low resting cortisol does not confirm hypoadrenocorticism; an ACTH stimulation test is required. Determine the plasma ACTH concentration in patients with normal electrolyte levels to differentiate primary from secondary hypoadrenocorticism; must collect sample before initiating therapy, especially glucocorticoids. Carefully follow sample handling instructions from the laboratory being used. Plasma ACTH concentrations are high with primary hypoadrenocorticism and undetectable-to-low with secondary hypoadrenocorticism.

IMAGING

Radiographs may reveal microcardia, narrowed vena cava or descending aorta, hypoperfused lung fields, less commonly microhepatica, and very rarely megaesophagus. Abdominal ultrasound may reveal small adrenal glands.

PATHOLOGIC FINDINGS

- Gross examination—atrophy of the adrenal glands.
- Microscopically—lymphocytic-plasmacytic adrenalitis and/or adrenocortical atrophy. Other abnormalities may be present depending on etiology (neoplasia, fungal disease, etc.).

**TREATMENT****APPROPRIATE HEALTH CARE**

- An acute Addisonian crisis is a medical emergency requiring intensive therapy and 24 hour observation and care. The diagnostic workup is performed while initial treatment and stabilization are ongoing. Cats often respond more slowly than dogs.
- The intensity of treatment for patients with chronic hypoadrenocorticism depends on the severity of clinical signs; usually initial stabilization and therapy are conducted on an inpatient basis.

NURSING CARE

- Treat acute Addisonian crisis with rapid correction of hypovolemia and restoration of volume status using isotonic fluids (preferably 0.9% NaCl).
- Monitor hydration status, blood pressure, urine output, temperature and heart rate and rhythm.

ACTIVITY

Avoid unnecessary stress and exertion during an Addisonian crisis.

DIET

No need to alter

CLIENT EDUCATION

- Life-long glucocorticoid and/or mineralocorticoid replacement therapy is required.
- Increased dosages of glucocorticoid (above maintenance requirements) are required during periods of stress such as travel, boarding, hospitalization, and surgery.

**MEDICATIONS****DRUG(S) OF CHOICE**

- Chronic primary hypoadrenocorticism—most patients will need daily glucocorticoid replacement (prednisone, 0.1–0.2 mg/kg/day), as well as mineralocorticoid replacement (DOCP, Percorten, 2.2 mg/kg IM or SC typically given monthly, and adjusted as needed on the basis of serial electrolyte determinations). The initial monthly DOCP dose for an average size cat is 12.5 mg. Though not preferred, an alternative means of administering glucocorticoid replacement to cats is Depo-Medrol (10 mg IM monthly).
- Alternatively an oral mineralocorticoid replacement can be used (fludrocortisone acetate, Florinef, 5–10 µg/kg q12h, adjusted by 0.05- to 0.1-mg increments on the basis of serial electrolyte determinations). Fludrocortisone acetate has some glucocorticoid activity and the maintenance dose of prednisone for patients receiving fludrocortisone may be lower than for dogs receiving DOCP. A few dogs develop PU/PD and/or polyphagia on fludrocortisone acetate.
- In an Addisonian crisis, parenteral administration of a rapidly acting glucocorticoid such as dexamethasone sodium phosphate or prednisolone sodium succinate is indicated; dexamethasone sodium phosphate is preferred because prednisolone cross-reacts with cortisol assays. Dexamethasone sodium phosphate is given at a dose of 2–4 mg/kg IV; this dose can be repeated in 2–6 hours if necessary. Glucocorticoid is gradually tapered as the condition improves. If prednisone, prednisolone, or hydrocortisone have been given, ACTH stimulation testing will need to be delayed until the glucocorticoid has been switched to dexamethasone for at least 24 hours.
- Fluid therapy with 0.9% NaCl as needed based on the patient's hydration, volume status and blood pressure. In an Addisonian crisis, fluids are typically initiated at a rate of 60–80 mL/kg/h for the first 1–2 hours, then tapered based on the clinical status and

discontinued when appropriate. If severe hyponatremia is noted on preliminary lab work, correct no quicker than 10–12 mEq/L per day over the first 48 hours of therapy.

- If necessary a colloid also can be given to help treat hypotension and hypovolemia.
- Treat hypoglycemia if present with IV dextrose.
- Sodium bicarbonate therapy is rarely needed; reserve for severe acidosis.
- Treat hyperkalemic myocardial toxicity with an intravenous insulin and glucose protocol. Alternatively use intravenous calcium chloride or calcium gluconate (cardioprotective only).
- Patients with confirmed secondary hypoadrenocorticism require only glucocorticoid supplementation (prednisone, 0.1–0.2 mg/kg/day).

PRECAUTIONS

N/A

ALTERNATIVE DRUG(S)

- See Hyperkalemia chapter for specific recommendations for emergency management of severe hyperkalemia.
- See Hyponatremia chapter for specific recommendations for emergency management of severe hyponatremia.

**FOLLOW-UP****PATIENT MONITORING**

- Depending on their clinical presentation, patients hospitalized for treatment of hypoadrenocorticism may require intensive monitoring and frequent laboratory evaluations. Monitor clinical status, urine output, CBC, blood chemistry, and ECG as needed. Blood glucose and electrolytes may need to be evaluated several times daily during initial therapy. Determine blood gas status when necessary.
- After the first 2 injections of DOCP, ideally measure electrolyte levels at 2, 3, and 4 weeks to determine the duration of effect; thereafter, check electrolyte levels at the time of injection for the next 3–6 months (and adjust the dosage of DOCP if necessary) and then every 6 months.
- DOCP is usually required at monthly intervals; rare patients need injections as often as every 2 or 3 weeks. On the other hand, an occasional dog will require DOCP as infrequently as every 6 weeks. Less than 5% of dogs require a dose of DOCP higher than 2.2 mg/kg per injection.
- The large majority of dogs with hypoadrenocorticism will be well controlled on a maintenance DOCP dose of 2.2 mg/kg/injection every month. If necessary, the DOCP dosage can be sequentially decreased based on electrolyte determinations as some dogs can be controlled on a monthly dosage that is significantly less

HYPOADRENOCORTICISM (ADDISON'S DISEASE)

(CONTINUED)

than 2.2 mg/kg. Alternatively, the interval between injections can be increased while monitoring electrolyte concentrations.

- Adjust the daily dose of fludrocortisone by 0.05- to 0.1-mg increments as needed, based on serial electrolyte determinations; following initiation of therapy, check electrolyte levels weekly until they stabilize in the normal range; thereafter, check electrolyte concentrations monthly for the first 3–6 months and then every 3–12 months.
- In many dogs given fludrocortisone, the daily dose required to control the disorder increases incrementally, usually during the first 6–24 months of therapy; in most dogs, the final fludrocortisone dosage needed is 20–30 µg/kg/day; very few can be controlled on 10 µg/kg/day or less.
- In patients that were initially azotemic, monitor creatinine concentrations as needed following discharge from the hospital.

PREVENTION/AVOIDANCE

- Continue hormonal replacement therapy for the lifetime of the patient.
- Increase the dosage of replacement glucocorticoid during periods of stress such as travel, boarding, hospitalization, and surgery.

POSSIBLE COMPLICATIONS

- PU/PD may occur from prednisone administration, necessitating decreasing or discontinuing the drug or trying an alternative glucocorticoid.
- PU/PD may occur from fludrocortisone administration, necessitating a change to DOCP therapy.

- Side effects from DOCP are very uncommon; rarely weight gain is seen and very rarely PU/PD.

EXPECTED COURSE AND PROGNOSIS
